PERMUTATIONS

Let n be a positive integer and let $N = \{1, \ldots, n\}$. A permutation on N is a one-one function from N onto N. In what follows, all permutations will be on N.

Suppose P and Q are permutations. We define a new permutation $R = Q \cdot P$ by $R(j) = (Q \cdot P)(j) = Q(P(j))$ for $j \in N$. Note that in general $P \cdot Q \neq Q \cdot P$, although $\cdot$ is associative. The operation $\cdot$ is ordinary function composition. The identity permutation is the identity function I on N, defined by $I(j) = j$ for $j \in N$. An inverse of a permutation P is a permutation P^{-1} with the property that $P \cdot P^{-1} = P^{-1} \cdot P = I$. It is easily proved that every permutation has a unique inverse; indeed, if P is a permutation, its inverse P^{-1} is given by $P^{-1}(j) = s$ where s is such that $P(s) = j$, $j \in N$. Note also that if P and Q are permutations, $(Q \cdot P)^{-1} = P^{-1} \cdot Q^{-1}$. The conjugate of Q by P is the permutation $P \cdot Q \cdot P^{-1}$.

A transposition is a permutation that moves at most two elements of N; that is, T is a transposition if and only if integers i and j exist such that $T(k) = k$ for $k \neq i, j$. It may easily be proved that every permutation can be written as a product $T_1 \cdot T_2 \cdot \ldots \cdot T_n$ of transpositions where for $i = 1, \ldots, n$ there exists $k_i \in N$ such that:

$$T_i(j) = \begin{cases} k_i & \text{if } j = i \\ i & \text{if } j = k_i \\ j & \text{if } j \neq i, k_i \end{cases}$$

Every transposition is its own inverse.

If P is a permutation, we will identify P and the symbol

$$\begin{pmatrix} 1 & 2 & \ldots & n \\ p_1 & p_2 & \cdots & p_n \end{pmatrix}$$

where

$$p_i = P(i) \text{ for } i = 1, \ldots, n.$$

At times we will also identify the permutation P and the vector $(p_1, \ldots, p_n)$. Whenever this is the case we will write "... permutation $P = (p_1, \ldots, p_n)$ ...", or "permutation vector $P = (p_1, \ldots, p_n)$".

Similarly, if T is the transposition given by:

$$T(j) = \begin{cases} j & \text{if } j \neq i, k \\ i & \text{if } j = k \\ k & \text{if } j = i \end{cases}$$

then we identify T and the symbol (i, k). (This leads to no difficulty if $n = 2$, since in this case all permutations are also transpositions.)

We note above that any permutation P can be written as a product $T_1 \cdot \ldots \cdot T_n$ of transpositions of a certain form. In the new notation we have $P = (1, t_1) \cdot \ldots \cdot (n, t_n)$, $t_i \in N$, $i = 1, \ldots, n$. The t_i are generally not distinct. At times we will identify the product $(1, t_1) \cdot \ldots \cdot (n, t_n)$ and the vector $(t_1, \ldots, t_n)$. Whenever this identification is meant we will write "... transposition vector $P = (t_1, \ldots, t_n)$".

Permutations can be used to induce rearrangements of ordered collections of objects. The convention that we will use is illustrated by the following example. Suppose that A is an m by n matrix and C_i is the i^{th} column of A for $i = 1, \ldots, n$. If the permutation $P = (p_1, \ldots, p_n)$ is applied to the columns of A, there results the m by n matrix A' whose p_i^{th} column, C_{p_i}, is C_i for $i = 1, \ldots, n$.

Examples

Suppose $n = 5$, and let P and Q be the permutations given by:

$P(1) = 3$ $P(2) = 1$ $P(3) = 5$ $P(4) = 2$ $P(5) = 4$

and

$Q(1) = 1$ $Q(2) = 3$ $Q(3) = 5$ $Q(4) = 2$ $Q(5) = 4$

Then P and Q may also be written as:

$$P = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 1 & 5 & 2 & 4 \end{pmatrix} \quad \text{and} \quad Q = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 1 & 3 & 5 & 2 & 4 \end{pmatrix}$$

or as the permutation vectors:

$$P = (3, 1, 5, 2, 4) \quad \text{and} \quad Q = (1, 3, 5, 2, 4)$$

Now:

$$Q \cdot P = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 1 & 3 & 5 & 2 & 4 \end{pmatrix} \cdot \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 1 & 5 & 2 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 5 & 1 & 4 & 3 & 2 \end{pmatrix}$$

while:

$$P \cdot Q = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 1 & 5 & 2 & 4 \end{pmatrix} \cdot \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 1 & 3 & 5 & 2 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 3 & 5 & 4 & 1 & 2 \end{pmatrix}$$

P^{-1} is the permutation given by

$$P^{-1}(1)=2 \quad P^{-1}(2)=4 \quad P^{-1}(3)=1 \quad P^{-1}(4)=5$$

$$P^{-1}(5)=3$$

or

$$P^{-1}=\begin{pmatrix}1&2&3&4&5\\2&4&1&5&3\end{pmatrix}$$

or the permutation vector P = (2,4,1,5,3).

We now write P as a product of transpositions in the standard form defined above. We have:

$$P=\begin{pmatrix}1&2&3&4&5\\3&1&5&2&4\end{pmatrix}=(1,3)\cdot\begin{pmatrix}1&2&3&4&5\\1&3&5&2&4\end{pmatrix}$$

$$=(1,3)\cdot\left[(2,3)\cdot\begin{pmatrix}1&2&3&4&5\\1&2&5&3&4\end{pmatrix}\right]$$

$$=(1,3)\cdot(2,3)\cdot$$

$$\left[(3,5)\cdot\begin{pmatrix}1&2&3&4&5\\1&2&3&5&4\end{pmatrix}\right]$$

$$=(1,3)\cdot(2,3)\cdot(3,5)\cdot$$

$$\left[(4,5)\cdot\begin{pmatrix}1&2&3&4&5\\1&2&3&4&5\end{pmatrix}\right]$$

$$=(1,3)\cdot(2,3)\cdot(3,5)\cdot(4,5)\cdot(5,5).$$

Hence P is equivalent to the transposition vector (3,3,5,5,5).

Subroutine PPRCN

Subroutine PPRCN computes the permutation vector that is the composition of two given permutation vectors, and the permutation vector that is the conjugate of a given permutation vector by another permutation vector. (See the general discussion for definitions and notation.)

1. Mathematical background

Suppose that IP1 = $(p_1,\ldots,p_n)$ and IP2 = $(q_1,\ldots,q_n)$ are permutation vectors on $N=\{1,\ldots,n\}$.

a. The composition IP3 = IP2•IP1 of IP1 and IP2 is given by IP3 = $(r_1,\ldots,r_n)$ where $r_i = q_{p_i}$ for $i = 1,\ldots,n$.

b. The conjugate IP3 = IP1•IP2•$IP1^{-1}$ of IP2 by IP1 is given by IP3 = $(r_1,\ldots,r_n)$ where $r_{p_i} = p_{q_i}$ for $i=1,\ldots,n$.

2. Programming considerations

Depending on whether the input parameter IPAR is nonnegative or negative, subroutine PPRCN computes either the composition of IP1 and IP2 or the conjugate of IP2 by IP1.

Subroutine PERM is used to check that n is positive and that IP1 and IP2 are permutation vectors on N. If n is not positive or if IP1 and IP2 are not both permutation vectors on N, computation is terminated as soon as the error is detected, and the error parameter IER is set to -1 or 1, respectively. If there is no error, IER is set to zero.

The computation of the resulting vector IP3 proceeds as follows.

a. If IPAR is nonnegative, for each i, i = 1,..., n, IP3(i) is set to IP2(IP1(i)).

b. If IPAR is negative, initially subroutine PERM is used to compute $IP1^{-1}$, which is stored in IP3. Then, for i = 1,...,n, IP3(i) is set to IP1 (IP2 (IP3(i))).

IP3 cannot have the same storage allocation as IP1 or IP2. IP1 and IP2 are returned unchanged.

```

Subroutine PERM

Subroutine PERM computes the permutation vector that is the inverse of a given permutation vector, the permutation vector that is equivalent to a given transposition vector, and a transposition vector that is equivalent to a given permutation vector. (See the general discussion for definitions and notation.)

1. Mathematical background

Let $N = \{1, \ldots, n\}$.

a. If $IP1 = (p_1, \ldots, p_n)$ is a permutation vector on N, its inverse, IP2, is given by $IP2 = (r_1, \ldots, r_n)$ where $r_{p_i} = i$ for $i = 1, \ldots, n$.

b. Let $IP1 = (t_1, \ldots, t_n)$ be a transposition vector on N. The computation of the permutation vector that is equivalent to IP1 is based on the identity:

$$\begin{pmatrix} 1 & \ldots & n \\ s_1 & \ldots & s_n \end{pmatrix} \cdot (i, v_i) = \begin{pmatrix} 1 & \ldots & i & \ldots & v_i & \ldots & n \\ s_1 & \ldots & s_{v_i} & \ldots & s_i & \ldots & s_n \end{pmatrix} \tag{1}$$

Applying (1) for $i = 1, \ldots, n$ to the right-hand side of the identity

$$(1, t_1) \cdot \ldots \cdot (n, t_n) = \begin{pmatrix} 1 & \ldots & n \\ 1 & \ldots & n \end{pmatrix} \cdot (1, t_1) \cdot \ldots \cdot (n, t_n)$$

there results

$$(1, t_1) \cdot \ldots \cdot (n, t_n) = \begin{pmatrix} 1 & \ldots & n \\ q_1 & \ldots & q_n \end{pmatrix}$$

The desired permutation vector, IP2, is $IP2 = (q_1, \ldots, q_n)$.

c. Let $IP1 = (p_1, \ldots, p_n)$ be a permutation vector on N. The computation of a transposition vector that is equivalent to IP1 is based on the identity:

$$\begin{pmatrix} 1 & \ldots & n \\ & & \\ s_1 & \ldots & s_n \end{pmatrix} = (i, s_i) \cdot \begin{pmatrix} 1 & \ldots & i & \ldots & k & \ldots & n \\ & & & & & & \\ s_1 & \ldots & i & \ldots & s_i & \ldots & s_n \end{pmatrix} \tag{2}$$

for $i = 1, \ldots, n$ where for each i, k is such that $p_k = i$. Using (2) with i successively $1, \ldots, n$ we may write:

$$\begin{pmatrix} 1 & \ldots & n \\ & & \\ p_1 & \ldots & p_n \end{pmatrix} = (1, t_1) \cdot \ldots \cdot (n, t_n) \cdot \begin{pmatrix} 1 & \ldots & n \\ & & \\ 1 & \ldots & n \end{pmatrix}$$

$$= (1, t_1) \cdot \ldots \cdot (n, t_n)$$

for some $t_i \in N$. The desired transposition vector is IP2=($t_1, \ldots, t_n$).

2. Programming considerations

Depending on whether the input parameter IPAR is negative, zero, or positive, subroutine PERM performs the computation described above in 1a, 1b, or 1c, respectively.

If n is not positive, there is no computation and the error parameter IER is set to -1. If IPAR is not zero and IP1 is not a permutation vector on N, or if IPAR is zero and IP1 is not a transposition vector on N, computation is terminated as soon as the error is detected and IER is set to 1. If there is no error, IER is set to zero.

The computation of the resulting vector IP2 proceeds as follows.

a. If IPAR is negative, for each i, i=1,...,n, IP2(IP1(i)) is set to i.

b. If IPAR is zero, initially IP2(i) is set to i for i=1,...,n, and then for i=1,...,n in that order, IP2(i) and IP2(IP1(i)) are interchanged.

c. If IPAR is positive, initially IP1 is moved to IP2, and then the following two steps are repeated for i successively 1,...,n:

(1) Find the smallest j ≥ i such that IP2(j)=i.

(2) Set IP2(j) to IP2(i).

IP2 cannot have the same storage allocation as IP1. IP1 is returned unchanged.

Subroutines TEAS and DTEAS

The problem is to assign a scalar value S to a given sequence $x_1, x_2, x_3, \ldots$. In case of convergence of the sequence, S should be the limit. The Epsilon algorithm possibly increases the speed of convergence and determines an approximate value FIN of S in terms of the given members of the finite sequence $x_1, x_2, x_3, \ldots, x_N$.

1. Theoretical background

The value FIN is calculated by means of the Epsilon algorithm (see Figure 16).

The first column (with superscript 1) is identical to the given sequence:

$$x_i^{(1)} = x_i \qquad (i = 1, 2, 3, \ldots)$$

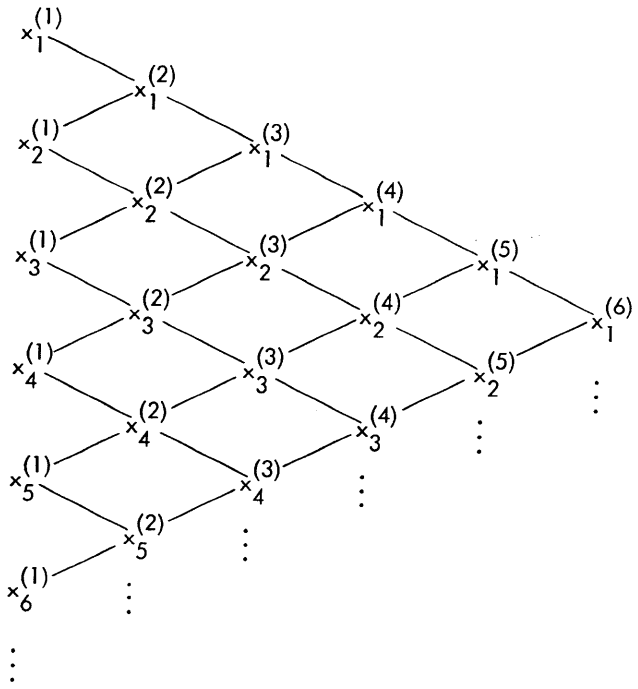

Figure 16. The complete Epsilon array

The values in the third column (with superscript 3) are derived from three consecutive members of the sequence; for example, $x_2^{(3)}$ is derived from $x_2^{(1)}$, $x_3^{(1)}$ and $x_4^{(1)}$. Generally, the column with superscript $2k + 1$ ($k = 1, 2, 3, \ldots$) contains quantities derived from $2k + 1$ consecutive members of the sequence. The intermediate values with even superscripts are auxiliary quantities.

The Epsilon algorithm is based on the following relationship:

$$x_i^{(k)} = x_{i+1}^{(k-2)} + \frac{1}{x_{i+1}^{(k-1)} - x_i^{(k-1)}} \qquad \begin{matrix}(k = 2, 3, 4, \ldots) \\ (i = 1, 2, 3, \ldots)\end{matrix} \qquad (1)$$

$$x_i^{(o)} = 0$$

With this fundamental relationship the complete Epsilon array shown in Figure 16 is built up from left to right.

2. Programming considerations

Subroutines TEAS and DTEAS generate only the first five columns of the complete Epsilon array; this E-2 transformation is used in an iterative way. Within one iteration the quantities in the upward diagonals are computed in a DO-loop by means of the algorithmic relationship (1). This process requires six auxiliary storage boxes (W1, W2, W3, W4, W5, W6).

The values in the fifth column $x_1^{(5)}, x_2^{(5)}, \ldots, x_{NEW-4}^{(5)}$ are successively stored in x(1), x(2), ..., x(NEW-4) as long as they are finite.

If a term $x_k^{(5)}$ in the fifth column becomes formally infinite, the values $x_1^{(5)}$ up to $x_k^{(5)}$ are cancelled and $x_{k+1}^{(5)}$ is stored in x(1), $x_{k+2}^{(5)}$ in x(2), and so on. Hence, after one iteration no component of the transformed vector x becomes infinite except possibly the last.

Consecutive equal terms in the column with superscript k(k=1, 2, 3) are reproduced in the column with superscript k+2. The basic mesh of the E-2 transformation is shown in Figure 17.

As a nonlinear algorithm the E-2 transformation is sensitive to roundoff errors; therefore special procedures are incorporated to avoid undue loss of accuracy:

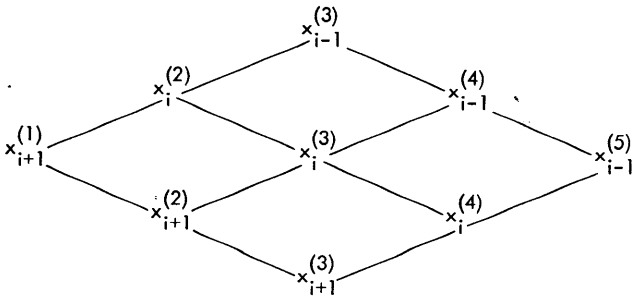

Figure 17. Basic mesh of the E-2 transformation

a. If there is an intolerable loss of significance in the calculation of a term in the third or fifth column, TEAS or DTEAS transfers out of the diagonal loop and uses for further calculation only those components of vector x, which have already been transformed.

b. If two consecutive quantities in the second column $x_i^{(2)}$ and $x_{i+1}^{(2)}$ (see Figure 17) are nearly equal, $x_i^{(3)}$ is large and ill-determined. Therefore, if:

$$\left| x_{i+1}^{(2)} - x_i^{(2)} \right| \leqq 10^{-4} \cdot \left| x_{i+1}^{(2)} \right| \quad \text{in single precision or}$$

$$\left| x_{i+1}^{(2)} - x_i^{(2)} \right| \leqq 10^{-12} \cdot \left| x_{i+1}^{(2)} \right| \quad \text{in double precision} \qquad (2)$$

subroutine TEAS or DTEAS calculates the iterated member of the sequence $x_{i-1}^{(5)}$ with a singular rule:

$$x_{i-1}^{(5)} = \frac{x_i^{(3)} \cdot W7}{1 + W7} \qquad (3)$$

where $$W7 = \frac{x_{i+1}^{(3)}}{x_i^{(3)} - x_{i+1}^{(3)}} + \frac{x_{i-1}^{(3)}}{x_i^{(3)} - x_{i-1}^{(3)}} - \frac{x_{i+1}^{(1)}}{x_i^{(3)} - x_{i+1}^{(1)}}$$

This requires two more auxiliary storage locations W7 and T.

c. If $x_i^{(2)}$ and $x_{i+1}^{(2)}$ are exactly equal, $x_i^{(3)}$ becomes infinite, and the singular rule for the Epsilon algorithm is simply:

$$x_{i-1}^{(5)} = x_{i+1}^{(3)} + x_{i-1}^{(3)} - x_{i+1}^{(1)} \qquad (4)$$

d. If three or more consecutive terms in the second column are equal, singular rule (4) cannot be applied; the corresponding iterated members of the sequence in the fifth column become formally infinite.

Iteration is terminated if one of the following conditions holds true:

a. Three times in succession the relative difference between neighboring transformed terms $X(I) = x_i$ is not greater than EPS; that is,

$$\left| x_i - x_{i+1} \right| \leqq EPS \cdot \left| x_{i+1} \right| \qquad (i = k, k+1, k+2) \qquad (5)$$

In case $\left| x_{i+1} \right| \leqq 1$, the relative difference (5) is replaced by the absolute

$$\left| x_i - x_{i+1} \right| \leqq EPS \qquad (i = k, k+1, k+2) \qquad (6)$$

b. The number of the transformed members of sequence (NEW-IMIN) is less than six.

In the first case x_{k+2} is returned as result value FIN, and IER = 0 as the error parameter. In the second case the values IER = 1 and FIN = x_1 are returned.

Some remarks are in order. First, the user must specify N--that is, the dimension of the input vector x--so that the character of the infinite sequence is recognizable. Second, subroutine TEAS or DTEAS works satisfactorily if the convergence of the given sequence is a geometric one; that is,

$$x_n - S = A \cdot \lambda^n + O(\lambda^n), \qquad |\lambda| < 1 \qquad (7)$$

Subroutines TEUL and DTEUL

These subroutines calculate the sum value of the series $\sum_{k=1}^{\infty} F_k$ by means of a refined Euler transformation.

The following abbreviations are used:

$$\Delta^0 F_i = F_i$$

$$\Delta^1 F_i = \frac{1}{2}\left[F_i + F_{i+1}\right]$$

$$\Delta^2 F_i = \frac{1}{2}\left[\Delta F_i + \Delta F_{i+1}\right] = \frac{1}{4}\left[F_i + 2F_{i+1} + F_{i+2}\right]$$

$$\Delta^3 F_i = \frac{1}{2}\left[\Delta^2 F_i + \Delta^2 F_{i+1}\right] = \frac{1}{8}\left[F_i + 3F_{i+1} + 3F_{i+2} + F_{i+3}\right]$$

Generally:

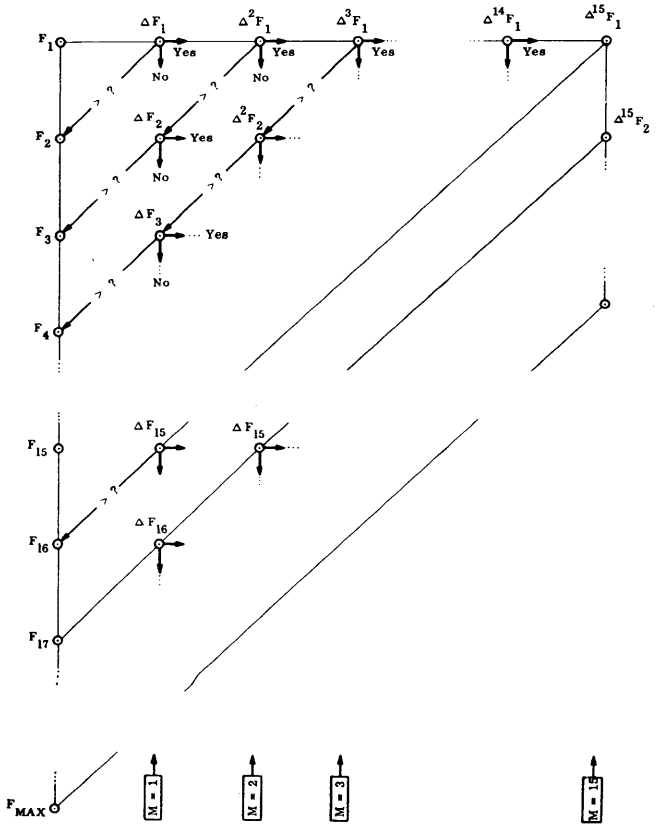
$$\Delta^m F_i = \frac{1}{2}\left[\Delta^{m-1} F_i + \Delta^{m-1} F_{i+1}\right] = \frac{1}{2^m}\left[F_i + \binom{m}{1} F_{i+1} + \binom{m}{2} F_{i+2} + \ldots + \binom{m}{m-1} F_{i+m-1} + \binom{m}{m} F_{i+m}\right]$$

Euler transformation means that the given infinite series will be transformed as follows:

$$\sum_{k=1}^{\infty} F_k = \frac{1}{2}\left[F_1 + \Delta F_1 + \Delta^2 F_1 + \Delta^3 F_1 + \Delta^4 F_1 + \ldots\right]$$

The transformed series will converge whenever the given series does, and to the same sum. It may even converge when the parent series does not; in this case the sum is called the Euler sum of the parent series.

A refined Euler transformation is explained by means of the following diagram.



The computation is done in this way. First the absolute value $|\Delta F_1|$ is compared with $|F_2|$ (see diagram). In case $|\Delta F_1| < |F_2|$, the value $\frac{1}{2}(\Delta F_1)$ is added to the initial value $\frac{1}{2}F_1$ (the beginning of the Euler transformation). Then $|\Delta^2 F_1|$ is compared with $|\Delta F_2|$ (see "YES" in diagram).

In case $|\Delta F_1| \geq |F_2|$, the value ΔF_1 is added to $\frac{1}{2}F_1$ and, as next $|\Delta F_2|$, is compared with $|F_3|$ (see "NO"). This means that F_1 is added unchanged, and the Euler transformation is delayed for one term, and so forth.

If in this sequence of comparisons $|\Delta^i F_k| < |\Delta^{i-1} F_{k+1}|$ is generally true, the value $\frac{1}{2}(\Delta^i F_k)$ is added to the current sum in the sense of the Euler transformation. If it is not true, the value $\Delta^i F_k$ is added and the Euler transformation is delayed for one term--that is, the terms F_1, F_2, ..., F_k are added unchanged, and the transformation actually starts with term F_{k+1}.

The highest term in the scheme of calculation may be $\Delta^{15} F_i$ ($i = 1, 2, 3, \ldots,$ MAX-15), in case MAX > 15. Hence a maximum of fourteen terms of the series may be transformed in succession by Euler. If the procedure is not terminated up to this point, the index of the transformed terms is raised by 1, and a further unchanged term is added.

The last term of the parent series which may be used by the computation is F_{MAX}.

The procedure is terminated if with five successive terms of the series the relative change of the sum value is less than EPS, or if MAX terms of the series were used for calculation.

Subroutines ALI and DALI

These subroutines perform an Aitken-Lagrange interpolation. Given the table x_i, y_i ($i = 1, 2, \ldots, n$) of argument and function values stored in the two one-dimensional storage arrays ARG and VAL, the problem is to interpolate function value Y at the given point X. It is assumed that the table represents a single-valued function $y = y(x)$ which is suitable for approximation by a polynomial+, and that $|x_i - X| \geq |x_j - X|$ for $i > j$.++

Then, using the following formulas:

$$y_{1,2} = \frac{1}{x_2 - x_1} \cdot \begin{vmatrix} y_1 & x_1 - X \\ y_2 & x_2 - X \end{vmatrix};$$

$$y_{1,3} = \frac{1}{x_3 - x_1} \cdot \begin{vmatrix} y_1 & x_1 - X \\ y_3 & x_3 - X \end{vmatrix},$$

$$y_{1,2,3} = \frac{1}{x_3 - x_2} \cdot \begin{vmatrix} y_{1,2} & x_2 - X \\ y_{1,3} & x_3 - X \end{vmatrix};$$

$$y_{1,4} = \frac{1}{x_4 - x_1} \cdot \begin{vmatrix} y_1 & x_1 - X \\ y_4 & x_4 - X \end{vmatrix},$$

$$y_{1,2,4} = \frac{1}{x_4 - x_2} \cdot \begin{vmatrix} y_{1,2} & x_2 - X \\ y_{1,4} & x_4 - X \end{vmatrix},$$

$$y_{1,2,3,4} = \frac{1}{x_4 - x_3} \cdot \begin{vmatrix} y_{1,2,3} & x_3 - X \\ y_{1,2,4} & x_4 - X \end{vmatrix};$$

.....,

it is possible to generate by row the triangular Aitken scheme shown in Figure 18.

x_1	y_1				
x_2	y_2	$y_{1,2}$			
x_3	y_3	$y_{1,3}$	$y_{1,2,3}$		
x_4	y_4	$y_{1,4}$	$y_{1,2,4}$	$y_{1,2,3,4}$	
⋮	⋮	⋮	⋮		
x_n	y_n	$y_{1,n}$	$y_{1,2,n}$	$y_{1,2,3,n}$	... $y_{1,2,3,\ldots,n}$

Figure 18. Aitken's scheme for Lagrange interpolation

All result values of row j can be stored in VAL(J). Thus, it is possible to generate the downward diagonal of Aitken's scheme in storage array VAL, using the machine-processable formula:

$$\text{VAL(J)} = \frac{\text{VAL(I)}*(\text{X-ARG(J)}) - \text{VAL(J)}*(\text{X-ARG(I)})}{\text{ARG(I)} - \text{ARG(J)}}$$

$$(\text{I} = 1, 2, \ldots, \text{J-1}) \qquad (1)$$

for J = 2, 3, ..., NDIM.

The procedure stops under the following conditions: if the difference of two successive values in the downward diagonal is absolutely less than a given tolerance ϵ (test starts at step J = 3), or if the absolute value of this difference stops diminishing, thus showing the influence of rounding errors (test starts at step J = 5, or for double-precision, J = 8), or if the procedure has worked through the whole triangular Aitken scheme, or if it discovers two table points with identical arguments.

Finally, Y is set equal to VAL(J) in case of monotonically decreasing absolute differences, or equal to VAL(J-1) if these differences start oscillating.

For reference see F. B. Hildebrand, Introduction to Numerical Analysis, McGraw-Hill, New York/Toronto/London, 1956, pp. 49-50.

+This order in table x_i, y_i, ($i = 1, 2, \ldots, n$) could be generated by subroutines ATSG, ATSM, ATSE, DATSG, DATSM, DATSE.

++This means y(x) should be closely approximated by a polynomial of low degree which has the table points with arguments next to x as nodes.

Subroutines AHI and DAHI

These subroutines perform an Aitken-Hermite interpolation. Given the table x_i, y_i, y'_i (i = 1, 2, ..., n) of argument, function and derivative values, stored in the two one-dimensional storage arrays ARG and VAL, the problem is to interpolate function value Y at the given point X. It is assumed that the table represents a single-valued function y = y(x) which is suitable for approximation by a polynomial[+], and that it is stored as shown in Figure 19 (first and second column) with $|x_i - X| \geq |x_j - X|$ for i > j.[++]

Before starting Aitken's iteration scheme, the components of vector VAL (that is, function and derivative values) are replaced by interpolation values z_i of first order (third column). This is done by the following machine-processable formulas:

$$VAL(I) = Y + VAL(I+1) * H_1$$

$$(I = 1,3,5,\ldots,2 * NDIM-1) \qquad (1)$$

$$VAL(I+1) = Y + (VAL(I+2)-Y)\,\frac{H_1}{H_1 - H_2}$$

$$(I = 1,3,5,\ldots,2 * NDIM-3) \qquad (2)$$

with

$$Y = VAL(I),\quad H_1 = X - ARG(J-1),\quad H_2 = X - ARG(J)$$

and

$$J = \frac{I+1}{2} + 1 .$$

Now it is possible to generate successively the upward diagonals of the triangular Aitken scheme, using the following formulas:

$$z_{1,2} = \frac{1}{x_2 - x_1} \cdot \begin{vmatrix} z_1 & x_1 - X \\ z_2 & x_2 - X \end{vmatrix} ;$$

$$z_{2,3} = \frac{1}{x_2 - x_1} \cdot \begin{vmatrix} z_2 & x_1 - X \\ z_3 & x_2 - X \end{vmatrix} ,$$

$$z_{1,2,3} = \frac{1}{x_2 - x_1} \cdot \begin{vmatrix} z_{1,2} & x_1 - X \\ z_{2,3} & x_2 - X \end{vmatrix} ;$$

$$z_{3,4} = \frac{1}{x_3 - x_2} \cdot \begin{vmatrix} z_3 & x_2 - X \\ z_4 & x_3 - X \end{vmatrix} ,$$

$$z_{2,3,4} = \frac{1}{x_3 - x_1} \cdot \begin{vmatrix} z_{2,3} & x_1 - X \\ z_{3,4} & x_3 - X \end{vmatrix} ;$$

$$z_{1,2,3,4} = \frac{1}{x_3 - x_1} \cdot \begin{vmatrix} z_{1,2,3} & x_1 - X \\ z_{2,3,4} & x_3 - X \end{vmatrix} ;$$

.....

All result values of an upward diagonal can be stored in positions of vector VAL with decreasing subscripts, using the machine-processable formula:

$$VAL(K) = \frac{VAL(K)*(X-H_1) - VAL(K+1)*(X-ARG(L))}{ARG(L) - H_1}$$

$$(J = 1,2,\ldots,I) \qquad (3)$$

with

$$K = I + 1 - J,\quad M = \left[\frac{I+3}{2}\right],\quad L = \left[\frac{K+1}{2}\right]$$

and

$$H_1 = ARG(M)$$

for I = 1,2,...,2 * NDIM-2.

The procedure stops under the following circumstances: if the difference between two successive interpolated values VAL(1) is absolutely less than a given tolerance ε or if the absolute value of this difference stops diminishing, thus showing the influence of rounding errors (test starts at step i = 5, or for double-precision, i = 8), or if the procedure has worked through the whole triangular Aitken scheme, or if it discovers two table points with identical arguments.

[+]This order in table x_i, y_i, y_i (i = 1, 2, ..., n) could be generated by subroutines ATSG, ATSM, ATSE, DATSG, DATSM, DATSE.

[++]This means y(x) should be closely approximated by a polynomial of low degree which has the table points with arguments next to x as nodes and which has the specified derivative values in these nodes.

ARG(1) = x_1	VAL(1) = y_1	VAL(1) = z_1	$z_{1,2}$	$z_{1,2,3}$	$z_{1,2,3,4}$
	VAL(2) = y'_1	VAL(2) = z_2	$z_{2,3}$	$z_{2,3,4}$	
ARG(2) = x_2	VAL(3) = y_2	VAL(3) = z_3	$z_{3,4}$		
	VAL(4) = y'_2	VAL(4) = z_4			
...	...	...	...	...	...
ARG(NDIM) = x_n	VAL(2*NDIM-1) = y_n	VAL(2*NDIM-1) = z_{2n-1}			
	VAL(2*NDIM) = y'_n				

Figure 19. Aitken's scheme for Hermite interpolation

Finally, Y is set equal to VAL(1) in case of monotonically decreasing absolute differences, or to VAL(1) of the step before if these differences start oscillating.

Subroutines ACFI and DACFI

These subroutines perform a continued fraction interpolation. Given the table x_i, y_i (i = 1, 2, ..., n) of argument and function values, stored in the two one-dimensional storage arrays ARG and VAL, the problem is to interpolate function value Y at the given point X. It is assumed that the table represents a single-valued function y = y(x) which is suitable for approximation by a rational function[+], and that $|x_i - X| \geq x_j - X|$ for $i > j$.[++]

Then, using the following formulas:

$$y_{1,2} = \frac{x_2 - x_1}{y_2 - y_1};$$

$$y_{1,3} = \frac{x_3 - x_1}{y_3 - y_1}; \quad y_{1,2,3} = \frac{x_3 - x_2}{y_{1,3} - y_{1,2}};$$

$$y_{1,4} = \frac{x_4 - x_1}{y_4 - y_1}; \quad y_{1,2,4} = \frac{x_4 - x_2}{y_{1,4} - y_{1,2}};$$

$$y_{1,2,3,4} = \frac{x_4 - x_3}{y_{1,2,4} - y_{1,2,3}};$$

the triangular scheme of inverted differences shown in Figure 20 can be generated by row for the given table x_i, y_i.

All result values of row i can be stored in VAL(I). Thus, it is possible to generate the downward diagonal of the inverted differences scheme in storage array VAL, using the machine-processable formula:

$$\text{VAL(I)} = \frac{\text{ARG(I)} - \text{ARG(J)}}{\text{VAL(I)} - \text{VAL(J)}} \quad (\text{J} = 1, 2, \ldots, \text{I-1}) \qquad (1)$$

for I = 2, 3, ..., NDIM.

[+]This order in table x_i, y_i (i = 1, 2, ..., n) could be generated by subroutines ATSG, ATSM, ATSE, DATSG, DATSM, DATSE.

[++]This means y(x) should be closely approximated by a rational function, with numerator and denominator of low degree, which has the table points with arguments next to x as nodes.

x_1	y_1					
x_2	y_2	$y_{1,2}$				
x_3	y_3	$y_{1,3}$	$y_{1,2,3}$			
x_4	y_4	$y_{1,4}$	$y_{1,2,4}$			
.	.	.	.	$y_{1,2,3,4}$		
.	.	.	.	.		
.	.	.	.	.	...	
x_n	y_n	$y_{1,n}$	$y_{1,2,n}$	$y_{1,2,3,n}$		$y_{1,2,3,\ldots,n}$

Figure 20. Triangular scheme for fraction interpolation

If for J = I-1, VAL(I) is equal to the infinity element, table point ARG(I), VAL(I) (that is, x_i, y_i) gets interchanged with a table point ahead.

Now, after computation of each new component VAL(I), continued fraction interpolation generates the following set of parameters:

$$P_3 = VAL(I) * P_2 + (X - ARG(I-1)) * P_1 \qquad (2)$$

$$Q_3 = VAL(I) * Q_2 + (X - ARG(I-1)) * Q_1 \qquad (3)$$

and

$$Y = P_3/Q_3 \qquad (4)$$

starting with $P_1 = 1$, $P_2 = VAL(1)$, $Q_1 = 0$, $Q_2 = 1$. After having done this, it sets $P_1 = P_2$, $P_2 = P_3$, $Q_1 = Q_2$, $Q_2 = Q_3$ after each step.

The procedure stops under the following conditions: if the difference between two successive values of Y is absolutely less than a given tolerance ε, or if the absolute value of this difference starts oscillating (test of oscillating differences starts at step I = 8, or for double-precision, I = 10), or if I has become NDIM, or if the procedure discovers two table points with identical argument values.

These subroutines perform a table selection out of a given general table.

Given a search argument x and a general table z_i, f_i (i = 1, 2, ..., irow) stored in two vectors Z and F (in case icol = 1), or z_i, f_i, f_i' (i = 1, 2, ..., irow) stored in vector Z and the two columns of matrix F (in case icol = 2); the problem is to select those n ($\leq$ irow) points z_{i_j}, f_{i_j} or z_{i_j}, f_{i_j}, f'_{i_j} (j = 1, 2, ..., n), respectively, which are next to x and to store their coordinates in two vectors ARG and VAL so that the distances $|x - z_{i_j}|$ increase with increasing subscript j. This problem may arise when using interpolation subroutines ALI, AHI, ACFI, DALI, DAHI, DACFI. The table for the case icol = 1 is shown in Figure 21, and that for case icol = 2 in Figure 22.

Selection is done in two parts. In the first part, auxiliary vector WORK with components $z_i - x$ (i = 1, 2, ..., irow) is generated and its greatest component, $\max_i |z_i - x|$, is stored in an auxiliary storage location. In each of the n steps of the second part the subscript i_j of the smallest component of vector WORK is searched for. Afterwards this component is replaced by a number greater than $\max_i |z_i - x|$.

Then, z_{i_j} goes into the storage location ARG(J) and:

In case icol = 1 -- f_{i_j} into the storage location VAL(J)

In case icol = 2 -- f_{i_j} into the storage location VAL(2 * J - 1) and f'_{i_j} into the storage location VAL(2 * J)

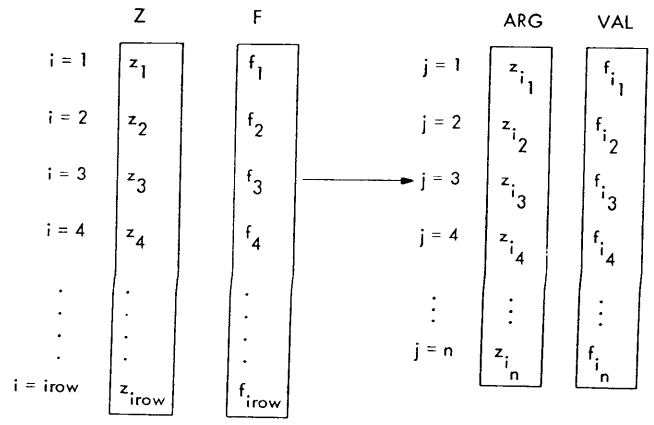

Figure 21. Table selection in case icol=1

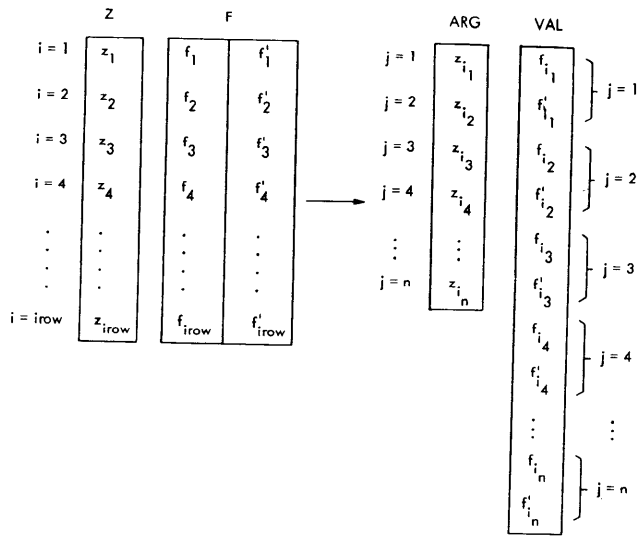

Figure 22. Table selection in case icol=2

If (by an error of the user) the dimension n of the table to be selected is greater than the dimension irow of the given table, the procedure selects only a maximum table of irow points. In order to avoid errors in further work with table (ARG, VAL), the user ought to check the correspondence between the selected table and its dimension by comparison of n and irow. This test may be done before or after calling subroutine ATSG or DATSG.

```

These subroutines perform a table selection out of a given monotonic table. They have the same function as subroutines ATSG and DATSG with the difference that the given table is stored with monotonically increasing or decreasing arguments z_i.

Selection is done in two parts. In the first part, argument z_i next to search argument x is searched for by "binary search". This procedure (in case irow = 10) is shown in Figure 23.

The second part starts at z_{i_1}. At each of the n steps, the procedure decides by comparison of distances if the next step has to go to the right or to the left. Care must be taken that none of the selected subscripts i_j becomes greater than irow or less than one. Thus, in case n = 5, the sequence of argument values becomes $z_{i_1} = z_6$, $z_{i_2} = z_7$, $z_{i_3} = z_5$, $z_{i_4} = z_8$, $z_{i_5} = z_9$. The selected table is stored in the same way as in subroutine ATSG or DATSG.

If (by an error of the user) the dimension n of the table to be selected is greater than the dimension irow of the given table, the procedure selects only a maximum table of irow points. In order to avoid errors in further work with table (ARG, VAL), the user ought to check the correspondence between the selected table and its dimension by comparison of n and irow. This test may be done before or after calling subroutine ATSM or DATSM.

(1) x lies between z_1 and z_{10}.

(2) x lies between z_5 and z_{10}.

(3) x lies between z_5 and z_7.

(4) x lies between z_6 and z_7.

(5) Comparison of the two distances $|z_6 - x|$ and $|z_7 - x|$ shows that z_6 is next to x.

Subroutines ATSE and DATSE

These subroutines perform a table selection out of a given equidistant table. They have the same function as subroutines ATSG and DATSG with the difference that the given table is stored with equidistant arguments. Instead of vector Z of argument values, subroutines ATSE and DATSE need only the starting argument z_s and the increment of arguments dz.

Selection is done in two parts. In the first part, the subscript i_1 of the argument next to search argument x is computed, using the formula

$$i_1 = \left[\frac{x - z_s}{dz} + 1.5 \right]$$

where [a] means "integer part of a".

The second part starts at z_{i_1} and goes one step to the left (right), one to the right (left), and so on until all n arguments are selected. Care must be taken that none of the selected subscripts i_j becomes greater than irow or less than one. In the example shown in Figure 24, the sequence (z_{i_j}) becomes

$z_{i_1} = z_6$, $z_{i_2} = z_5$, $z_{i_3} = z_7$, $z_{i_4} = z_4$, $z_{i_5} = z_8$, $z_{i_6} = z_3$, $z_{i_7} = z_2$.

The selected table is stored in the same way as in subroutine ATSG or DATSG.

If, by a user error, the dimension n of the table to be selected is greater than the dimension irow of the given table, the procedure selects only a maximum table of irow points. In order to avoid errors in further work with table (ARG, VAL), the user ought to check the correspondence between the selected table and its dimension by comparison of n and irow. This test may be done before or after calling subroutine ATSE or DATSE.

Subroutine SG13 and DSG13

These subroutines compute a vector $Z = (z_1, \ldots, z_n)$ of smoothed function values, given vectors $X = (x_1, \ldots, x_n)$ of argument values and $Y = (y_1, \ldots, y_n)$ of corresponding function values. Except at the endpoints x_1 and x_n, each smoothed value z_i is obtained by evaluating at x_i the least-squares polynomial of degree 1 relevant to the three successive points (x_{i-1}, y_{i-1}), (x_i, y_i), and (x_{i+1}, y_{i+1}).

1. Mathematical background

For $i = 3, \ldots, n$ we must find m_i and b_i such that

$$w_i(x) = m_i x + b_i \tag{1}$$

gives the least-squares fit to the points (x_{i-1}, y_{i-2}), (x_{i-1}, y_{i-1}), and (x_i, y_i). The problem, then, is to minimize

$$F(m_i, b_i) = \sum_{k=0}^{2} \left[w_i(x_{i-k}) - y_{i-k} \right]^2$$

This minimum will occur when

$$\frac{\partial F}{\partial b_i} = 0 \text{ and } \frac{\partial F}{\partial m_i} = 0 \tag{2}$$

Now

$$\left.\begin{aligned} \frac{\partial F}{\partial b_i} &= 2 \sum_{k=0}^{2} \left[w_i(x_{i-k}) - y_{i-k} \right] \\ \text{and} \\ \frac{\partial F}{\partial m_i} &= 2 \sum_{k=0}^{2} x_{i-k} \left[w_i(x_{i-k}) - y_{i-k} \right] \end{aligned}\right\} \tag{3}$$

Solving equations (2) and (3) yields:

$$m_i = \frac{\sum_{k=0}^{2} x_{i-k}\, y_{i-k} - 1/3 \left(\sum_{k=0}^{2} x_{i-k} \right) \left(\sum_{k=0}^{2} y_{i-k} \right)}{\sum_{k=0}^{2} x_{i-k}^2 - 1/3 \left(\sum_{k=0}^{2} x_{i-k} \right)^2} \tag{4}$$

and

$$b_i = \frac{i}{3} \sum_{k=0}^{2} \left(y_{i-k} - m_i x_{i-k} \right) \tag{5}$$

Letting:

$$\left.\begin{aligned} \bar{y}_i &= \frac{i}{3} \sum_{k=0}^{2} y_{i-k}, \quad \bar{x}_i = \frac{i}{3} \sum_{k=0}^{2} x_{i-k}, \\ t_{i,k} &= x_{i-k} - \bar{x}_i \quad \text{and} \quad v_{i,k} = y_{i-k} - \bar{y}_i \end{aligned}\right\} \tag{6}$$

we may rewrite (4) and (5) as:

$$m_i = \frac{\sum_{k=0}^{2} t_{i,k}\, v_{i,k}}{\sum_{k=0}^{2} t_{i,k}^2} \tag{7}$$

and

$$b_i = \bar{y}_i - m_i \bar{x}_i \tag{8}$$

Using (8) in (1) gives

$$w_i(x) = m_i(x - \bar{x}_i) + \bar{y}_i$$

where m_i is as in (7).

The desired smoothed values z_i are given by:

$$z_i = \begin{cases} w_3(x_1) = m_3 t_{3,2} + \bar{y}_3 & \text{if } i=1 \\ w_{i+1}(x_i) = m_{i+1} t_{i+1,1} + \bar{y}_{i+1} & \text{if } i=2, \ldots, n-1 \\ w_n(x_n) = m_n t_{n,0} + \bar{y}_n & \text{if } i=n \end{cases} \tag{9}$$

2. Programming considerations

The subroutines compute the z_i in serial order according to (9). If $n<3$, there is no computation, and the error parameter IER is set to -1. Otherwise IER is set to zero at the end of the computation. The output vector Z can have the same storage allocation as X or Y.

Subroutines SE13 and DSE13

These subroutines compute a vector $Z = (z_1, \ldots, z_n)$ of smoothed function values, given a vector $Y = (y_1, \ldots, y_n)$ of function values whose entries y_i correspond to n equidistantly spaced argument values x_i, with $x_i - x_{i-1} = h$ for $i = 2, \ldots, n$. Except at the endpoints x_1 and x_n, each smoothed value z_i is obtained by evaluating at x_i the least-squares polynomial of degree 1 relevant to the three successive points (x_{i+k}, y_{i+k}), $k = -1, 0, 1$.

1. Mathematical background

The procedure is exactly that described for subroutines SG13 and DSG13, but here we have the additional relation $x_i - x_{i-1} = h$, a constant, for $i = 2, \ldots, n$. This leads to the following expressions for the z_i:

$$z_i = \begin{cases} \frac{1}{6}(5y_1 + 2y_2 - y_3) & \text{if } i=1 \\ \frac{1}{3}(y_{i-1} + y_i + y_{i+1}) & \text{if } i=2,\ldots,n-1 \\ \frac{1}{6}(-y_{n-2} + 2y_{n-1} + 5y_n) & \text{if } i=n \end{cases} \quad (1)$$

2. Programming considerations

The subroutines compute the z_i in serial order according to (1). If $n < 3$, there is no computation, and the error parameter IER is set to -1. Otherwise IER is set to zero at the end of the computation. The output vector Z can have the same storage allocation as Y.

Subroutines SE15 and DSE15

These subroutines compute a vector $Z = (z_1, \ldots, z_n)$ of smoothed function values, given a vector $Y = (y_1, \ldots, y_n)$ of function values whose entries y_i correspond to n equidistantly spaced argument values x_i with $x_i - x_{i-1} = h$ for $i = 2, \ldots, n$. Except at the points x_1, x_2, x_{n-1}, and x_n, each smoothed value z_i is obtained by evaluating at x_i the least-squares polynomial of degree 1 relevant to the five successive points (x_{i+k}, y_{i+k}), $k = -2, -1, \ldots, 2$.

1. Mathematical background

For $i = 5, \ldots, n$ we find m_i and b_i such that

$$w_i(x) = m_i x + b_i \tag{1}$$

gives the least-squares fit to the points (x_{i-k}, y_{i-k}), $k=0, \ldots, 4$. The problem, then, is to minimize

$$F(m_i, b_i) = \sum_{k=0}^{4} \left[w_i(x_{i-k}) - y_{i-k} \right]^2$$

This minimum will occur when

$$\frac{\partial F}{\partial b_i} = 0 \quad \text{and} \quad \frac{\partial F}{\partial m_i} = 0 \tag{2}$$

Now

$$\frac{\partial F}{\partial b_i} = 2 \sum_{k=0}^{4} \left[w_i(x_{i-k}) - y_{i-k} \right]$$

and

$$\frac{\partial F}{\partial m_i} = 2 \sum_{k=0}^{4} x_{i-k} \left[w_i(x_{i-k}) - y_{i-k} \right] \tag{3}$$

Solving equations (2) and (3) yields:

$$m_i = \frac{\sum_{k=0}^{4} x_{i-k} y_{i-k} - \frac{1}{5} \left(\sum_{k=0}^{4} x_{i-k} \right) \left(\sum_{k=0}^{4} y_{i-k} \right)}{\sum_{k=0}^{4} x_{i-k}^2 - \frac{1}{5} \left(\sum_{k=0}^{4} x_{i-k} \right)^2} \tag{4}$$

and

$$b_i = \frac{1}{5} \sum_{k=0}^{4} \left[y_{i-k} - m_i x_{i-k} \right] \tag{5}$$

Using the fact that $x_j - x_{j-1} = h$, a constant, for $j = 2, \ldots, n$, (4) and (5) may be rewritten as

$$m_i = \frac{1}{10h} (2y_i + y_{i-1} - y_{i-3} - 2y_{i-4}) \tag{6}$$

and

$$b_i = \frac{1}{5} \sum_{k=0}^{4} y_{i-k} - m_i x_{i-2} \tag{7}$$

Using (7) in (1) yields

$$w_i(x) = m_i(x - x_{i-2}) + \frac{1}{5} (y_{i-4} + \ldots + y_i)$$

The desired smoothed function values z_i are given by:

$$z_i = \begin{cases} w_5(x_1) = \frac{1}{5} (3y_1 + 2y_2 + y_3 - y_5) & i=1 \\ w_5(x_2) = \frac{1}{10} (4y_1 + 3y_2 + 2y_3 + y_4) & i=2 \\ w_{i+2}(x_i) = \frac{1}{5} (y_{i-2} + y_{i-1} + y_i + y_{i+1} + y_{i+2}) & i=3, \ldots, n-2 \\ w_n(x_{n-1}) = \frac{1}{10} (y_{n-3} + 2y_{n-2} + 3y_{n-1} + 4y_n) & i=n-1 \\ w_n(x_n) = \frac{1}{5} (-y_{n-4} + y_{n-2} + 2y_{n-1} + 3y_n) & i=n \end{cases} \tag{8}$$

2. Programming considerations

The subroutines compute the z_i in serial order according to (8). If $n < 5$, there is no computation, and the error parameter IER is set to -1. Otherwise IER is set to zero at the end of the computation. The output vector Z can have the same storage allocation as Y.

Subroutine SE35 and DSE35

These subroutines compute a vector $Z = (z_1, \ldots, z_n)$ of smoothed function values, given a vector $Y = (y_1, \ldots, y_n)$ of function values whose entries y_i correspond to n equidistantly spaced argument values x_i, with $x_i - x_{i-1} = h$ for $i = 2, \ldots, n$. Except at the points x_1, x_2, x_{n-1}, and x_n, each smoothed value z_i is obtained by evaluating at x_i the least-squares polynomial of degree 3 relevant to the five successive points (x_{i+k}, y_{i+k}), $k = -2, -1, \ldots, 2$.

1. Mathematical background

For $i = 5, \ldots, n$ we must find a_i, b_i, c_i, and d_i such that

$$w_i(x) = a_i x^3 + b_i x^2 + c_i x + d_i \qquad (1)$$

gives the least-squares fit to the points (x_{i-k}, y_{i-k}), $k = 0, \ldots, 4$.

The problem, thus, is to minimize

$$F(a_i, b_i, c_i, d_i) = \sum_{k=0}^{4} \left[w_i(x_{i-k}) - y_{i-k} \right]^2 \qquad (2)$$

The minimum will occur when

$$\frac{\partial F}{\partial a_i} = \frac{\partial F}{\partial b_i} = \frac{\partial F}{\partial c_i} = \frac{\partial F}{\partial d_i} = 0$$

Now:

$$\left.\begin{aligned} \frac{\partial F}{\partial a_i} &= 2 \sum_{k=0}^{4} x_{i-k}^3 \left[w_i(x_{i-k}) - y_{i-k} \right] \\ \frac{\partial F}{\partial b_i} &= 2 \sum_{k=0}^{4} x_{i-k}^2 \left[w_i(x_{i-k}) - y_{i-k} \right] \\ \frac{\partial F}{\partial c_i} &= 2 \sum_{k=0}^{4} x_{i-k} \left[w_i(x_{i-k}) - y_{i-k} \right] \\ \frac{\partial F}{\partial d_i} &= 2 \sum_{k=0}^{4} \left[w_i(x_{i-k}) - y_{i-k} \right] \end{aligned}\right\} \qquad (3)$$

Solving (2) and (3) for a_i, b_i, c_i, and d_i, with $x_i - x_{i-1} = h$, we get:

$$a_i = A_i$$

$$b_i = -3 A_i x_{i-2} + B_i$$

$$c_i = 3 A_i x_{i-2}^2 - 2 B_i x_{i-2} + C_i$$

$$d_i = -A_i x_{i-2}^3 + B_i x_{i-2}^2 - C_i x_{i-2} + D_i + \bar{y}_i$$

where:

$$\bar{y}_i = \frac{1}{5} \sum_{k=0}^{4} y_{i-k}$$

$$A_i = -\frac{1}{12 h^3} (y_{i-4} - 2y_{i-3} + 2y_{i-1} - y_i)$$

$$B_i = \frac{1}{14 h^2} (4y_{i-4} + y_{i-3} + y_{i-1} + 4y_i - 10 \bar{y}_i)$$

$$C_i = \frac{1}{12h} (y_{i-4} - 8y_{i-3} + 8y_{i-1} - y_i)$$

$$D_i = -\frac{1}{7} (4y_{i-4} + y_{i-3} + y_{i-1} + 4y_i - 10 \bar{y}_i)$$

Finally, the desired smoothed values z_i are given by:

$$z_i = \left\{ \begin{array}{ll} w_5(x_1) = y_1 - \frac{1}{70} \delta^4 y_3 & \text{if } i=1 \\ w_5(x_2) = y_2 + \frac{2}{35} \delta^4 y_3 & \text{if } i=2 \\ w_{i+2}(x_i) = y_i - \frac{3}{35} \delta^4 y_i & \text{if } i=3, \ldots, n-2 \\ w_n(x_{n-1}) = y_{n-1} + \frac{2}{35} \delta^4 y_{n-2} & \text{if } i=n-1 \\ w_n(x_n) = y_n - \frac{1}{70} \delta^4 y_{n-2} & \text{if } i=n \end{array} \right\} \qquad (4)$$

where

$$\delta^4 y_i = y_{i-2} - 4 y_{i-1} + 6y_i - 4y_{i+1} + y_{i+2}$$

for $i=3, \ldots, n-2$

2. Programming considerations

These subroutines compute the z_i in serial order according to (4). If $n < 5$, there is no computation, and the error parameter IER is set to -1. Otherwise IER is set to zero at the end of the computation. The output vector Z can have the same storage allocation as Y.

Subroutine APFS and DAPFS

These subroutines compute the solution of the normal equations set up by subroutines APLL and DAPLL. This is the second step in the procedure for determining the least-squares fit of a given discrete function.

1. Mathematical background

Let $f(x)$, $g_i(x)$, $i=1, 2, \ldots, m$, and $w(x) > 0$ be functions defined for $x=x_1, x_2, \ldots, x_n$.

The problem is to determine the coefficients c_i of the linear combination

$$p(x) = \sum_{i=1}^{m} c_i g_i(x)$$

such that

$$e_m = \sum_{k=1}^{n} w(x_k) \left(f(x_k) - p(x_k)\right)^2 = \text{minimum} \qquad (1)$$

The necessary conditions

$$\frac{\partial e_m}{\partial c_i} = 0, \quad i=1, 2, \ldots, m \qquad (2)$$

form a system of m linear equations in m unknowns c_i.

To simplify the notation we introduce the following matrices:

$$X = \begin{bmatrix} x_1 \\ x_2 \\ . \\ . \\ . \\ x_n \end{bmatrix}, \quad F = \begin{bmatrix} f(x_1) \\ \\ . \\ . \\ . \\ f(x_n) \end{bmatrix}, \quad W = \begin{bmatrix} w(x_1) & & & & \\ & w(x_2) & & & \\ & & . & & \\ & & & . & \\ & & & & w(x_n) \end{bmatrix},$$

$$c = \begin{bmatrix} c_1 \\ . \\ . \\ . \\ c_m \end{bmatrix}, \quad G = \begin{bmatrix} g_1(x_1) & . & . & g_1(x_n) \\ . & & & . \\ . & & & . \\ g_m(x_1) & . & . & g_m(x_n) \end{bmatrix}$$

Then we have

$$e_m = (F^T - C^T G)\, W\, (F - G^T C)$$

or, with $e_o = F^T W F$,

$$e_m = e_o - 2C^T GWF + C^T GWG^T C \qquad (1')$$

Using (1'), equations (2) may be written as

$$GWG^T C = GWF \qquad (2')$$

Combining (1') and (2') gives

$$e_o - e_m = C^T GWG^T C \qquad (3)$$

The normal equations (2') for the unknown vector C may be solved using Cholesky's method, since the coefficient matrix $A = GWG^T$ is obviously symmetric and is positive definite if all the fundamental functions $g_i(x)$ are linearly independent for the arguments x_i; that is, if the rows of G are linearly independent. Let $R = GWF$. Using Cholesky's method, A and R are replaced without additional storage requirements by T and $(T^T)^{-1}R$, where $A = T^T T$, and T is upper triangular.

Using these facts, an easy calculation shows

$$e_o - e_m = \left\| (T^T)^{-1} R \right\|^2$$

Introducing additional fundamental functions in the linear combination p(x) will not affect the first m rows and columns of A or the first m elements of R. Therefore, Cholesky's method gives a decomposition of $e_o - e_m$ into the separate components corresponding to individual degrees of freedom.

2. Programming considerations

All least-squares fits of dimension 1, 2, ..., m may be computed from the reduced normal equations $TC = (T^T)^{-1} R$. If the solutions are generated in the storage locations of T, there is no additional storage requirement.

Using the decomposition of $e_o - e_m$, the factorization may be terminated with dimension k if $e_k < \eta e_o$, giving the least-squares fit of dimension k which satisfies the user-specified precision (relative tolerance η). Due to rounding errors this will work only if η is approximately between 1 and 10^{-6} in single precision, and between 1 and 10^{-15} in double precision. Nevertheless, the square sum of residuals corresponding to a least-squares fit calculated in single or double precision may be as small as $e_o\, 10^{-12}$ or $e_o\, 10^{-30}$, respectively.

Due to rounding errors the square root method may break down if very small or negative pivot elements indicate a loss of significance. Therefore, all pivot elements are tested against the absolute value of EPS multiplied by the first diagonal element of A. If the kth pivot element is not greater than this internal test value, the normal equations are treated as if they had dimension k-1 only.

Let N1, N2 denote the following numbers:

N1 = the largest number less than or equal to m for which there is no indication of loss of significance

N2 = the smallest number less than or equal to m for which

$$e_{N2} \leq \left| \eta \, e_o \right|$$

Depending on the input parameter IOP, which specifies the operations to be performed, the dimension IRES (that is, the dimension of the subsystem of the normal equations used for calculation) is set to N1 if IOP is positive or zero, and to the smaller of the two numbers N1, N2 if IOP is negative.

The operations performed by APFS are:

IOP = 0 Compute the triangular factorization $A = T^T T$, $TC = (T^T)^{-1}R$ and e_{IRES} only.

IOP = ±1 In addition to the above, the least-squares fit of dimension IRES is computed and stored in column IRES of the triangular array WORK.

IOP = ±2 In addition to IOP = 0 calculations, all least-square fits of dimension 1 up to IRES are computed and stored in columns 1 up to IRES of the array WORK.

a. Storage allocation

Initially the symmetric coefficient matrix A is stored columnwise in compressed form in the triangular array WORK. It is followed immediately by the right-hand side vector R and a single location containing e_o initially and e_{IRES} on return. This storage scheme is generated by subroutine APLL.

b. Errors

The error parameter IER is set to -1 if a non-positive dimension m has been specified.

If IOP is positive or zero, IER is set to 1 in case of an indication of a loss of significance.

If IOP is negative, IER is set to 1 if the specified accuracy could not be reached, even with a fit of dimension IRES.

Subroutine APCH and DAPCH

These subroutines set up the normal equations for a polynomial least-squares fit to a given discrete function. The solution of these equations is determined by subroutine APFS. The best fitting polynomial is computed in terms of its Chebyshev expansion.

1. Mathematical background

Let f(x) be a function defined for $x = x_1, x_2, \ldots x_n$.

The problem is to determine the coefficients of the polynomial

$$p(x) = \sum_{i=1}^{m} c_i x^{i-1}, \text{ such that}$$

$$\sum_{i=1}^{n} (f(x_i) - p(x_i))^2 = \text{minimum}$$

This problem leads to a system of linear equations AC = R where C is the vector of unknown coefficients, A is the m by m symmetric positive definite matrix with elements

$$a_{jk} = \sum_{i=1}^{n} x_i^{j-1} x_i^{k-1}$$

and R is the vector with elements

$$r_j = \sum_{i=1}^{n} f(x_i) x_i^{j-1}$$

If there is a weight w_i corresponding to each point $(x_i, f(x_i))$, the i^{th} term of the sums for the a_{jk} and r_j must be multiplied by w_i.

In practice the positive definite matrix A is badly ill-conditioned. Therefore, the straightforward method described above is feasible only for polynomials of low degree, about 3 or 4.

Use of Chebyshev polynomials instead of monomials results in a remarkable improvement of the condition of the normal equations, provided the arguments have a sensible distribution (for example, equidistant).

Let x_L and x_R denote the leftmost and rightmost arguments. By means of the linear transformation

$$t(x) = \frac{2x - (x_L + x_R)}{x_R - x_L} = x_D \cdot x + x_0$$

the argument range $x_L \le x \le x_R$ is reduced to the argument range $-1 \le t \le +1$.

The polynomial p(x) is calculated in the form of its Chebyshev expansion $p(x) = b_1 T_0(t) + b_2 T_1(t) + \ldots + b_m T_{m-1}(t)$, where $T_k(t)$ is the Chebyshev polynomial of degree k.

Then the vector B of the unknown coefficients b_i is a solution of the matrix equation AB = R, where A is an m by m symmetric positive definite matrix with elements

$$a_{jk} = \sum_{i=1}^{n} T_{j-1}(t(x_i)) T_{k-1}(t(x_i))$$

and R is a vector with elements

$$r_j = \sum_{i=1}^{n} T_{j-1}(t(x_i)) f(x_i)$$

The values of the Chebyshev polynomials for the argument t are calculated by means of the three-term recurrence equation:

$$T_k(t) = 2t \cdot T_{k-1}(t) - T_{k-2}(t); \quad k \ge 2$$

with starting values $T_0(t) = 1$, $T_1(t) = t$.

In setting up the matrix A, time is saved by using the identity $2T_j \cdot T_k = T_{j+k} + T_{j-k}$.

a. Remarks

The Chebyshev expansion of the polynomial p(x) gives a much better indication of the accuracy of the approximation than the coefficient vector of the polynomial itself. If the specified degree of the polynomial is too high, the last terms of the Chebyshev expansion will be uniformly small compared to the coefficients in front. The degree may be reduced by the number of small trailing coefficients without unduly enlarging the overall error.

An upper bound for the error introduced by neglecting the last terms of the Chebyshev expansion is given by the sum of the absolute values of these terms. Normally, transformation of the Chebyshev expansions in t(x) to ordinary polynomials in x results in severe loss of accuracy. Therefore, no attempt is made to return the polynomial expansions, which is no disadvantage since the Chebyshev expansion may be evaluated effectively for a specified argument x using subroutines CNPS and DCNPS with argument $t = x \cdot x_D + x_0$ and the calculated coefficient vector of the Chebyshev expansion.

The transformation of the calculated Chebyshev expansion to an ordinary polynomial may be accomplished using subroutines TCNP and DTCNP.

2. Programming considerations

Input arrays passed to subroutines APCH and DAPCH are DATI and WORK. DATI contains the given data set to be approximated, consisting of n argument values $x_1, \ldots, x_n$ followed by corresponding function values $f_1, \ldots, f_n$ and by corresponding weight values (if any). Constant weighting (value one) is implied if DATI (2n + 1) contains a nonpositive value.

Instead of arguments x_i, we use $t_i = x_i \cdot x_D + x_0$ for setting up the normal equations. The constants x_D and x_0 are returned as result values.

The normal equations are generated in the triangular array WORK. Only the upper triangular part of the symmetric coefficient matrix is generated and stored columnwise, followed immediately by the right-hand side and by the weighted square sum of function values.

This storage allocation scheme is required by subroutine APFS and DAPFS, which may be used for calculation of the solution of the normal equations. Exceptions are indicated by the error parameter IER, which is set to -1 if n and m are not both positive or if n is less than m, and to +1 if the arguments are coinciding; otherwise to zero, indicating successful operation.

Subroutines ARAT and DARAT

These subroutines compute the best rational approximation $P(x)/Q(x)$ to a discrete function, $f(x)$, in the least-squares sense. The argument range should be the interval $[-1, +1]$.

Subroutines FRAT and DFRAT are an integral part of the procedure and have no independent meaning.

1. Mathematical background

Given positive integers ip, iq, and n, arguments x_i, function values f_i, and positive weights w_i, i=1, 2,...,n, the problem is to determine the coefficients of the polynomials

$$P(x) = p_1 + p_2 x + \ldots + p_{ip} x^{ip-1}$$

$$Q(x) = q_1 + q_2 x + \ldots + q_{iq} x^{iq-1}$$

such that

$$F = \sum_{i=1}^{n} w_i \left[f_i - \frac{P(x_i)}{Q(x_i)} \right]^2 = \text{minimum} \qquad (1)$$

A direct approach to the problem (1) leads to a system of nonlinear equations. Therefore the problem is reformulated in the following way.

Let $P_o(x)$ and $Q_o(x)$ be an approximate solution to (1). The problem is then to determine increments $\Delta P_o(x)$ and $\Delta Q_o(x)$ such that

$$F = \sum_{i=1}^{n} w_i \left[f_i - \frac{P_o(x_i) + \Delta P_o(x_i)}{Q_o(x_i) + \Delta Q_o(x_i)} \right]^2 = \text{minimum} \qquad (1')$$

Without loss of generality it may be assumed that the constant term of Q_o remains unchanged, that is that the constant term of ΔQ_o is zero, since numerator and denominator of the rational approximation are determined only up to a common factor.

Linearizing $\dfrac{P_o + \Delta P_o}{Q_o + \Delta Q_o}$ with respect to ΔP_o and ΔQ_o,

$$\frac{P_o + \Delta P_o}{Q_o + \Delta Q_o} \approx \frac{P_o}{Q_o} \left[1 + \frac{\Delta P_o}{P_o} - \frac{\Delta Q_o}{Q_o} \right] \qquad (2)$$

and using (2) in (1') gives the approximation $F \approx F_o$ where

$$F_o = \sum_{i=1}^{n} \frac{w_i}{Q_o(x_i)^2} \left[f_i Q_o(x_i) - P_o(x_i) - \Delta P_o(x_i) + \frac{P_o(x_i)}{Q_o(x_i)} \Delta Q_o(x_i) \right]^2$$

Defining

$$f_i^* = f_i Q_o(x_i) - P_o(x_i)$$

$$w_i^* = w_i / Q_o(x_i)^2$$

and a set of functions

$$g_k(x) = -\frac{P_o(x)}{Q_o(x)} x^k \qquad k = 1, 2, \ldots, iq-1$$

$$g_k(x) = x^{k-iq} \qquad k = iq, iq+1, \ldots, iq+ip-1$$

we may write

$$F_o = \sum_{i=1}^{n} w_i^* \left[f_i^* - g(x_i) \right]^2$$

where

$$g(x) = \sum_{i=1}^{m} c_i g_i(x) \qquad m = iq+ip-1$$

and the c_i are the coefficients of $\Delta Q_o(x)$ and $\Delta P_o(x)$:

$$\Delta Q_o(x) = \sum_{i=1}^{iq-1} c_i x^i$$

$$\Delta P_o(x) = \sum_{i=iq}^{m} c_i x^{i-iq}$$

Now the coefficients c_i are determined so that F_o = minimum. This is a problem of the type discussed in APLL with function values f_i^*, weights w_i^* and fundamental functions $g_i(x)$, and leads to a system of linear equations

$$AC = R$$

with symmetric positive semi-definite coefficient matrix A (see APLL writeup for a desciption of A and R).

In subroutine ARAT, APLL is used to set up the normal equations AC = R, and APFS is used to solve the system for the coefficient vector C.

Given a solution ΔP_o and ΔQ_o to the problem F_o = minimum, a new approximation is formed using

$$P_1 = P_o + \Delta P_o$$

$$Q_1 = Q_o + \Delta Q_o$$

In general, given approximations P_k and Q_k, increments ΔP_k and ΔQ_k are determined as indicated above, and the next approximations are

$$P_{k+1} = P_k + \Delta P_k$$

$$Q_{k+1} = Q_k + \Delta Q_k \qquad (3)$$

This process is started with some initial approximation (usually with $P_o(x) \equiv 0$, $Q_o(x) \equiv 1$) and is stopped when there is indication of convergence (see below).

a. Refinement of the calculation procedure

The above approach has several defects:

(1) There is no guarantee for improvement of the rational fit obtained with successive iterations if the initial approximation is not close enough to a true solution.

(2) Zeros may come into the denominator, causing a complete breakdown of the procedure.

(3) The normal equations of the linearized problem are badly ill-conditioned if monomials are used as fundamental functions.

The first difficulty is resolved using an approach suggested by D. Braess in reference (1). Let

$$S_k = \sum_{i=1}^{n} w_i \left[f_i - \frac{P_k(x_i)}{Q_k(x_i)} \right]^2$$

Then instead of using the relations (3) we use

$$P_{k+1} = P_k + r \Delta P_k$$

$$Q_{k+1} = Q_k + r \Delta Q_k$$

where the relaxation factor r is chosen so that S_{k+1} is close to a minimum when regarded as a function of r, and $S_{k+1} \leq S_k$. If this cannot be done, the error parameter IER is set to IER = 1, and the process is stopped. Choosing r sufficiently small also prevents zeros from entering the denominator.

The condition of the normal equations is improved remarkably by using Chebyshev polynomials $T_k(x)$ instead of monomials x^k as fundamental functions; that is, the numerator and denominator are calculated in terms of their Chebyshev expansions. The argument range is assumed to be (-1, +1).

If it turns out that the normal equations are still ill-conditioned, the diagonal elements of the coefficient matrix are slightly increased. This modification was suggested by D. W. Marquardt in reference (2). In this case again the calculated increment is modified by a relaxation factor r; but now r may take on values even greater than 1 if this does not imply zeros coming into the denominator.

b. Convergence

Let T_k denote the sum of the absolute values of the coefficients of $P_k(x)$ and $Q_k(x)$. Then, assuming that the Marquardt modification was not needed, the process is stopped if either

$$\frac{S_k - S_{k+1}}{S_{k+1}} \leq r\,\epsilon$$

or

$$\frac{|T_k - T_{k+1}|}{T_{k+1}} \leq r\,\epsilon$$

or

$$S_{k+1} \leq \eta\, T_{k+1}$$

Here $\epsilon = 10^{-5}$ and $\eta = 10^{-11}$. If the diagonal terms of the coefficient matrix of the normal equations were increased, only the last test is applied. If none of these conditions is met, the process is repeated until the maximum number of iterations k = LIMIT is reached (LIMIT is set to 20 in ARAT).

c. Remarks

(1) The user must specify the dimension of the denominator and of the numerator of the rational approximation he wants to calculate. The calculation procedure is somewhat sensitive to getting adequate dimensions. If the specified dimensions are unrealistically high, the calculation procedure may break down due to a very poor convergence. In this case it is best to repeat the calculation with decreased dimensions.

(2) The initial approximation which the user has the option to specify must be such that the denominator is free of zeros over the range of approximation (-1, +1). The standard initial approximation is $P(x) \equiv 0$ and $Q(x) \equiv 1$.

(3) The arguments of the given discrete functions should be reduced to the interval (-1, +1). Arguments absolutely greater than 1 cause error propagation in the calculation of Chebyshev polynomials and may produce dubious results.

(4) Numerical experience has shown that the dimensions used in single precision should not exceed 5, and in double precision should not be above 10.

(5) Transformation of Chebyshev expansions to ordinary polynomials normally results in severe loss of accuracy. Therefore, no attempt is made to return the polynomial coefficients. This transformation may be easily accomplished through subroutines TCNP and DTCNP. The calculated Chebyshev expansions may be evaluated for a specified argument using subroutines CNPS and DCNPS.

2. Programming considerations

Arrays passed to subroutines ARAT and DARAT are DATI, WORK, and P. DATI contains the given data set to be approximated, consisting of n arguments $x_1, \ldots, x_n$ followed by the corresponding function values $f_1, \ldots, f_n$ and by weights $w_1, \ldots, w_n$. Constant weighting (value one) is implied if DATI (2n + 1) contains a nonpositive value.

WORK is used as working storage. On return it contains the values of the numerator in WORK (n + 1) up to WORK (2n) and the values of the denominator in WORK (2n + 1) up to WORK (3n). The storage positions WORK (1) up to WORK (n) and WORK (3n + 1) up to WORK (4n) are used to record the current nonmoderated values of change of numerator and denominator respectively. The remaining (ip + iq)(ip + iq + 1) + 1 storage locations of WORK are used to store the normal equations in compressed form twice, in a working area as well as in a save area. This is necessary to avoid recalculation of the normal equations in case of an ill-conditioned coefficient matrix.

P is a vector of dimension ip + iq containing the calculated rational approximation on return. The coefficients of the Chebyshev expansion of the denominator are stored first, immediately followed by the coefficients of the Chebyshev expansion of the numerator. Coefficients are ordered from low to

high. P may also be used as an input array containing the initial approximation in terms of its Chebyshev expansions (with same ordering) optionally.

The normal equations are generated internally by means of subroutines APLL and DAPLL in the storage allocation scheme which is required by subroutines APFS and DAPFS. Subroutines FRAT and DFRAT are simply the interface between subroutines ARAT, DARAT and APLL, DAPLL used for handling the given data set and the specified fundamental functions.

The error parameter IER gives an indication of success or failure of the procedure.

IER = 0 The process converged in the sense mentioned above.

IER = -1 Formal error occurred in specified dimensions or initial approximations such as violation of any of the restrictions $n > 0$, $ip > 0$, $iq > 0$, $n \geq ip + iq$ or $Q_0(x) \neq 0$ on $(-1, 1)$. The latter could occur only if an optional initial approximation was used.

IER = 1 The Marquardt modification was tried LIMIT times without success, or a suitable relaxation factor could not be found.

IER = 2 The process has not converged after LIMIT steps.

In all cases where IER $\geq$ 0 there is a calculated approximation available, but only in the case IER = 0 is there strong indication that this approximation is close to the best rational fit in the least-squares sense.

Subroutines APLL and DAPLL

These subroutines set up the normal equations for a linear least-squares fit to a given discrete function. APLL is a preparatory step for the calculation of the least-squares fit. Normally it is followed by subroutine APFS.

A user-coded external subroutine must be supplied to compute the values of the fundamental functions.

1. Mathematical background

Let $f(x)$, $g_i(x)$, $i = 1, 2, \ldots, m$, and $w(x) > 0$ be functions defined for $x = x_1, x_2, \ldots, x_n$ (the x_i may be vectors as well as scalars). The problem is to determine the coefficients c_i of the linear combination

$$p(x) = \sum_{i=1}^{m} c_i g_i(x)$$

such that

$$\sum_{k=1}^{n} w(x_k)\,(f(x_k) - p(x_k))^2 = \text{minimum}$$

This problem leads to a system of linear equations $AC = R$, where C is the vector of unknown coefficients, A is the m by m symmetric positive definite matrix with elements

$$a_{jk} = \sum_{i=1}^{n} w(x_i)\, g_j(x_i)\, g_k(x_i)$$

and R is an m-dimensional vector with elements

$$r_j = \sum_{i=1}^{n} w(x_i)\, f(x_i)\, g_j(x_i)$$

(See APFS for details.)

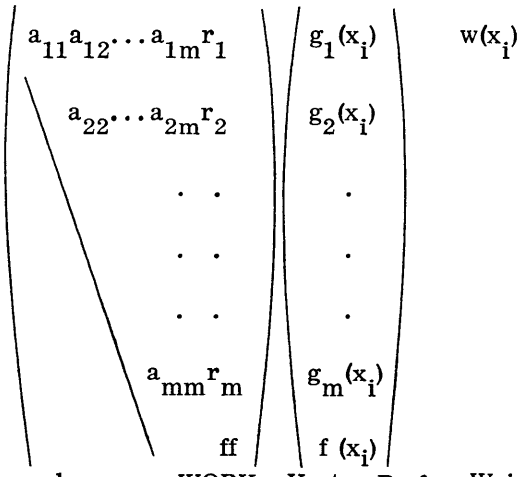
Some remarks regarding polynomial approximation are in order. Use of monomials $g_i(x) = x^{i-1}$ as fundamental functions results in a badly ill-conditioned coefficient matrix A. If Chebyshev or Legendre polynomials are used instead, the condition of the normal equations is improved remarkably, provided the arguments have a sensible distribution (for example, are equidistant in the interval -1 to +1).

2. Programming considerations

To allow for full flexibility in data handling, the user must provide an external subroutine that returns the values $g_1(x_i)$, $g_2(x_i)$,..., $g_m(x_i)$, $f(x_i)$ stored in a vector P together with the weight value $w(x_i)$. Input values to this subroutine are the current subscript value i, a number of points n, and -- for ease of communication between main line and external -- a dummy array named DATI.

Coefficient matrix A and right-hand side R are allocated adjacently. A is stored columnwise in compressed form, and R is augmented by one element ff in which the weighted square sum of function values is returned. The coefficient matrix A, right-hand side R, and square sum of function values ff are generated in a loop over i from 1 to n. Initially they are set to zero.

Storage allocation scheme:



Triangular array WORK of dimension m+1 by m+1 | Vector P of dimension m+1 | Weight WGT

For updating of the j^{th} column of the triangular array WORK, the j^{th} element of vector P is multiplied by the weight WGT, giving AUX and then P(i). AUX is added to the i^{th} element in the j^{th} column of WORK for i equal 1 up to j.

In this way the coefficient matrix A, the right-hand side R, and the square sum of function values are generated quite naturally by one and the same scheme.

a. External subroutine for data handling

The error parameter IER may be declared as scalar (that is, vector with one element) or vector in the user's main line. Within APLL it is treated as a vector with one element.

IER(1) is used for control purposes. If IER(1) is set to a nonzero value within the external subroutine, APLL returns to the calling program (main line), with an unchanged value of IER(1).

APLL sets the error parameter IER(1) to zero at the beginning. An error return with IER(1) = -1 is activated if n and m are not both positive or if n is less than m.

The user has full flexibility for handling of the data x_i, $f(x_i)$, $w(x_i)$, $g_1(x_i)$,..., $g_m(x_i)$.

(1) If he wishes to allocate x_i, $f(x_i)$, $w(x_i)$, $g_1(x_i)$,..., $g_m(x_i)$ in main storage, he may use an array the name of which replaces the dummy DATI.

Integer values needed for addressing may be inserted as additional components in the vector IER.

(2) Use of COMMON is another possibility for data exchange between the main line and the data handling external subroutine.

(3) Calculation of some or all of the required quantities as functions of the subscript or as functions of the argument x_i is another convenient choice.

(4) The needed data may be read in sequentially from one or more external devices, for example, x_i, $f(x_i)$, $w(x_i)$ from card unit, and/or $g_1(x_i)$,..., $g_m(x_i)$ from tape unit.

The four cases listed above may occur in any sensible combination.

Subroutine FORIF

This subroutine produces the Fourier coefficients for a given periodic function.

Given:

1. A function f(x) for values of x between 0 and 2π
2. N - the spacing desired such that the interval is $2\pi/(2N + 1)$
3. M - the desired order of the Fourier coefficients, $0 \leq M \leq N$

the coefficients of the Fourier series that approximate the given function are calculated as follows:

$$C_1 = \cos\left(\frac{2\pi}{2N+1}\right) \quad (1)$$

$$S_1 = \sin\left(\frac{2\pi}{2N+1}\right) \quad (2)$$

$$U_2 = 0$$

$$U_1 = 0$$

$$C = 1$$

$$S = 0$$

$$J = 1$$

The following recursive sequence is used to compute U_0, U_1, and U_2:

$$U_0 = f\left(\frac{2m\pi}{2N+1}\right) + 2\,C\,U_1 - U_2 \quad (3)$$

$$U_2 = U_1$$

$$U_1 = U_0$$

for values of m = 2N, 2N-1, ..., 1

The coefficients are then:

$$A_J = \frac{2}{2N+1}\left(f(0) + C\,U_1 - U_2\right) \quad (4)$$

$$B_J = \frac{2}{2N+1}\,S\,U_1 \quad (5)$$

The values of C and S are updated to:

$$Q = C_1\,C - S_1\,S$$

$$S = C_1\,S + S_1\,C$$

$$C = Q$$

J is stepped by 1 and the sequence starting at equation (3) is now repeated until M+1 pairs of coefficients have been computed.

Subroutine FORIT

This subroutine produces the Fourier coefficients of a tabulated function.

Given:

1. Tabulated values of a function f(x) for x between 0 and 2π in steps of $2\pi/(2N+1)$

2. N such that there are 2N+1 tabulated data points: $2K\pi/(2N+1)$, K = 0, 1, 2, ..., 2N

3. M - the desired order of the Fourier coefficients where $0 \leq M \leq N$

the coefficients of the Fourier series which approximate the given function are calculated as follows:

$$C_1 = \cos\left(\frac{2\pi}{2N+1}\right) \quad (1)$$

$$S_1 = \sin\left(\frac{2\pi}{2N+1}\right) \quad (2)$$

$$U_2 = 0$$

$$U_1 = 0$$

$$C = 1$$

$$S = 0$$

$$J = 1$$

The following recursive sequence is used to compute U_0, U_1, and U_2

$$U_0 = f\left(\frac{2m\pi}{2N+1}\right) + 2 C U_1 - U_2 \quad (3)$$

$$U_2 = U_1$$

$$U_1 = U_0$$

for values of m = 2N, 2N-1, ..., 1

The coefficients are then:

$$A_J = \frac{2}{2N+1}\left(f(0) + C U_1 - U_2\right) \quad (4)$$

$$B_J = \frac{2}{2N+1} S U_1 \quad (5)$$

The values of C and S are updated to:

$$Q = C_1 C - S_1 S$$

$$S = C_1 S + S_1 C$$

$$C = Q$$

j is stepped by 1 and the sequence starting at equation (3) is now repeated until M+1 pairs of coefficients have been computed.

Subroutines HARM and DHARM

Given three integers $M_\nu, \nu = 1, 2, 3$ and a three-dimensional array of complex numbers $A(k_1, k_2, k_3)$ where $k_\nu = 0, 1, \ldots, N_\nu - 1$ and $N_\nu = 2^{M_\nu}$, this subroutine computes the three-dimensional, complex Fourier series:

$$X(j_1, j_2, j_3) = \sum_{k_1=0}^{N_1-1} \sum_{k_2=0}^{N_2-1} \sum_{k_3=0}^{N_3-1} A(k_1, k_2, k_3) \; e^{2\pi i \left(\frac{j_1 \cdot k_1}{N_1} + \frac{j_2 \cdot k_2}{N_2} + \frac{j_3 \cdot k_3}{N_3} \right)} \quad (1)$$

where

$$j_\nu = 0, 1, \ldots, N_\nu - 1 \text{ and } \nu = 1, 2, 3.$$

The inverse series may also be computed:

$$A(k_1, k_2, k_3) = \frac{1}{N_1 * N_2 * N_3} \sum_{j_1=0}^{N_1-1} \sum_{j_2=0}^{N_2-1} \sum_{j_3=0}^{N_3-1} X(j_1, j_2, j_3) \; e^{-2\pi i \left(\frac{j_1 \cdot k_1}{N_1} + \frac{j_2 \cdot k_2}{N_2} + \frac{j_3 \cdot k_3}{N_3} \right)} \quad (2)$$

For one dimension, the algorithm for the complex Fourier transform of complex numbers A (k) is:

$$X(j) = \sum_{k=0}^{N-1} A(k) \, w^{jk} \quad (3)$$

where $w = e^{\frac{2\pi i}{N}}$, $N = 2^M$, $j = 0, 1, 2, \ldots, N - 1$ expresses X(j) as a function of the M arguments $j_{M-1}, j_{M-2}, \ldots, j_1, j_0$ of the binary representation of j:

$$j = j_{M-1} \cdot 2^{M-1} + \ldots + j_1 2 + j_0, \; j_\nu = 0 \text{ or } 1$$

Then (3) can be written:

$$X(j_{M-1}, \ldots, j_1, j_0) = \sum_{k_0=0}^{1} \sum_{k_1=0}^{1} \cdots \sum_{k_{M-1}=0}^{1} A(k_{M-1}, \ldots, k_0) w^{j \cdot k_{M-1} \cdot 2^{M-1} + \ldots + j \cdot k_0 \cdot 2^0} \quad (4)$$

Then $w^{jk_{M-1}2^{M-1}} = w^{j \cdot k_{M-1} 2^{M-1}}$ since $e^{2\pi i} = 1$, and the innermost sum in (4) yields an array:

$$A_1(j_0, k_{M-2}, \ldots, k_0) = \sum_{k_{M-1}=0}^{1} A(k_{M-1}, \ldots, k_0) w^{j_0 \cdot k_{M-1} \cdot 2^{M-1}} \quad (5)$$

Successive arrays $A_2, \ldots, A_M$ obtained by summing over $k_{M-2}, \ldots, k_0$ respectively are computed. The general formula is:

$$A_L(j_0, \ldots, j_{L-1}, k_{M-L-1}, \ldots, k_0) = \sum_{k_{M-L}=0}^{1} A_{L-1}(j_0, \ldots, j_{L-2}, k_{M-L}, \ldots, k_0) w^{(j_{L-1} \cdot 2^{L-1} + \ldots + j_0) \, k_{M-L} 2^{M-L}} \quad (6)$$

The final array will be the desired X. The storage indexing convention used is to let the M arguments of $A_L(j_0, \ldots, k_0)$ be the binary representation of the index of the storage location for $A_L(j_0, \ldots, k_0)$. In this way, each step of the algorithm involves fetching from two storage locations and returning results in the same two locations, thereby saving storage. However, the elements of the final array:

$$X(j_{M-1}, \ldots, j_1, j_0) = A_M(j_0, k_1, \ldots, j_{M-1})$$

are in the wrong order. The program reverses the order of bits in bit representations to compensate.

A modification of the above algorithm is made for three dimensions, and another modification is made in the L-loop to save computations.

```

Subroutines RHARM and DRHARM

Given 2N real numbers $X_0, X_1, \ldots, X_{2N-1}$, the subroutine computes Fourier coefficients $a_0, a_1, b_1, a_2, b_2, \ldots, a_{N-1}, b_{N-1}, a_N$ in the equation:

$$X_j = \frac{1}{2}a_0 + \sum_{k=1}^{N-1} \left(a_k \cos\left(\frac{\pi \cdot j \cdot k}{N}\right) + b_k \sin\left(\frac{\pi \cdot j \cdot k}{N}\right)\right) + \frac{1}{2}a_N (-1)^j$$

where

$$j = 0,\ 1, \ldots,\ 2N-1$$

The subroutine HARM is called to compute the complex coefficients:

$$A_k = \frac{1}{N} \sum_{j=0}^{N-1} (X_{2j} - iX_{2j+1})\, e^{\frac{2\pi i}{N} \cdot j \cdot k},$$

$$k = 0, 1, 2, \ldots, N-1$$

Then for $k = 1, 2, \ldots, \frac{N}{2} - 1, \frac{N}{2}$ (the bar is conjugation):

$$A'_k = \frac{1}{2}(\bar{A}_k + A_{N-k})$$

$$A''_k = \frac{1}{2}(\bar{A}_{N-k} - A_k)$$

and:

$$C_k = \frac{1}{2}(A'_k + \bar{A}''_k\, e^{(\frac{\pi}{2} - \frac{\pi}{N}k)i})$$

$$\text{for } k = 1, 2, \ldots, \frac{N}{2} - 1, \frac{N}{2}$$

$$C_{N-k} = \frac{1}{2}(\bar{A}'_k - A''_k\, e^{(\frac{\pi}{N-k} - \frac{\pi}{2})i})$$

$$\text{for } k = 1, 2, \ldots, \frac{N}{2} - 1$$

Let:

$$C_o = \frac{1}{2}(\text{Re } A_o - \text{Im } A_o)$$

$$C_N = \frac{1}{2}(\text{Re } A_o + \text{Im } A_o)$$

Finally:

$$a_o = 2 \text{ Re } (C_o)$$

$$a_k = 2 \text{ Re } (C_k)$$

$$b_k = -2 \text{ Im } (C_k)$$

$$a_N = 2 \text{ Re } (C_N)$$

Subroutines APMM and DAPMM

These subroutines determine a linear combination of M linearly independent given continuous real functions, which constitute the Chebyshev approximation of a given real function over a discrete range.

1. Mathematical background

Let us consider a set of discrete data $\{x_k, f_k = f(x_k)\}$, $k = 1, \ldots, N$, which defines a real valued function f(x) over a discrete range, and M real continuous given functions $\{\varphi_i(x)\}$, $i = 1, \ldots, M$, on an interval containing $[x_1, x_N]$.

The problem is to determine a set of M real coefficients $\{a_i\}$ that minimizes

$$w = \operatorname*{Max}_{1 \le k \le N} \left| \varphi(x_k) - f_k \right|, \text{ where } \varphi(x) = \sum_{i=1}^{M} a_i \varphi_i(x)$$

This problem can be expressed in terms of linear programming. At first, let us shift the unknowns so that the resulting ones are nonnegative:

$$b_i = a_i + b_{M+1}, \quad i = 1, \ldots, M,$$

where

$$b_{M+1} = - \operatorname{Min} [0, a_1, \ldots, a_M]$$

At each point, the error of approximation is given by

$$e_k = \varphi(x_k) - f_k$$

or

$$e_k = \sum_{i=1}^{M+1} b_i \varphi_i(x_k) - f_k$$

where

$$\varphi_{M+1}(x) = -\sum_{i=1}^{M} \varphi_i(x)$$

By definition

$$w = \operatorname*{Max}_{1 \le k \le N} \left| e_k \right|$$

If we put $\varphi_{ik} = \varphi_i(x_k)$, the original problem can be expressed as: Minimize w, subject to:

$$w + \sum_{i=1}^{M+1} \varphi_{ik} b_i \geq f_k$$

$$w - \sum_{i=1}^{M+1} \varphi_{ik} b_i \geq f_k$$

$$b_i \geq 0 \text{ for } i = 1, \ldots, M+1$$

$$w \geq 0$$

In practice, it is more convenient to solve the following dual problem in the nonnegative variables $\{s_k, t_k\}$, $k = 1, \ldots, N$:

$$\text{Maximize } \sum_{k=1}^{N} f_k (s_k - t_k), \text{ subject to:}$$

$$\sum_{k=1}^{N} (s_k + t_k) \leq 1$$

$$\sum_{k=1}^{N} \varphi_{ik} (s_k - t_k) \leq 0, \quad i = 1, \ldots, M+1$$

$$s_k \geq 0, \; t_k \geq 0, \text{ for } k = 1, \ldots, N$$

Using the variables of the dual problem as slacks, these n + 2 constraints can be written as equalities:

$$w + \sum_{k=1}^{N} (s_k + t_k) = 1$$

$$b_i + \sum_{k=1}^{N} \varphi_{ik} (s_k - t_k) = 0$$

The dual problem is solved by means of a revised simplex method (inverse matrix algorithm) using the following initial simplex tableau where w, b_1, $\ldots, b_{M+1}$, are basic variables:

Note that the entries in the transformed top row under w, $b_1, \ldots, b_{M+1}$ will be the optimal solution to the primal, that is, w and the b_i's.

A condensed tableau is used for calculation. The correspondence between the subscripts of the full tableau and these of the condensed one is given by means of the index vector IHE.

When the procedure has reached the optimum, the top row contains on return:

w	Maximum error of approximation
b_i, $i = 1, \ldots, M+1$	Coefficients from which we can get the unknowns by $a_i = b_i - b_{M+1}$ for $i = 1, \ldots, M$
s_k, $k = 1, \ldots, N$	The error at the given points, according to $e_k = s_k - w$

	Variables	$s_1 \ldots s_N$	$t_1 \ldots t_N$	w	b_1	b_2	$\ldots$	b_{M+1}
Top Row	Maximize	$f_1 \ldots f_N$	$-f_1 \ldots -f_N$	0	0	0	$\ldots$	0
	1	$= 1 \ldots 1$	$1 \ldots 1$	1	0	0	$\ldots$	0
	0	$= \varphi_{11} \ldots \varphi_{1N}$	$-\varphi_{11} \ldots -\varphi_{1N}$	0	1	0	$\ldots$	0
	0	$= \varphi_{21} \ldots \varphi_{2N}$	$-\varphi_{21} \ldots -\varphi_{2N}$	0	0	1	$\ldots$	0
	0	$= \varphi_{M+1,1} \; \varphi_{M+1,N}$	$-\varphi_{M+1,1} \; -\varphi_{M+1,N}$		0	0	$\ldots$	1

2. Programming considerations

For economy of storage requirements, the full simplex tableau is not stored, but only the top row at any iteration step. Therefore, we must update an inverse matrix T which allows us to generate the needed pivot column at any iteration step from the corresponding initial column. The procedure terminates for the following reasons:

a. An optimal top row is reached, indicated by the resultant error parameter IER, which is set to zero. All the relevant data are contained in this top row. The corresponding subscripts are stored in a part of the integer vector IHE.

b. No suitable pivot can be found. The resultant error parameter IER is set to -1.

c. The number of iterations ITER has reached the internal maximum N+M. The error parameter IER is set to 1 as a warning.

The subroutines APMM and DAPMM contain two tests for loss of significance:

a. The first test is made when an initial column is multiplied by the rows of matrix T. The corresponding result DSUM is set equal to zero if the following inequality is valid:

$$\left|DSUM\right| \leqq HELP * EPS$$

where HELP is the absolutely greatest intermediate sum formed during calculation of the scalar product-sum DSUM, and EPS is an internal tolerance:

$$EPS = \begin{cases} 10^{-5} & \text{in APMM} \\ 10^{-14} & \text{in DAPMM} \end{cases}$$

b. The second test is made when a new element in the top row TOP is generated. The new element $\overline{TOP_i}$ is calculated from the previous value TOP_i by the addition

$$\overline{TOP_i} = TOP_i + DSUM_i$$

The new value $\overline{TOP_i}$ is replaced by zero if

$$\left|TOP_i + DSUM_i\right| \leqq \left|DSUM_i\right| * EPS$$

where EPS is the above-mentioned internal tolerance.

Some remarks are in order:

a. In cases where the given approximating functions are polynomials, APMM and DAPMM are more efficient when used with orthogonal polynomials than with ordinary polynomials. The number of iterations required usually decreases with orthogonal functions, and the magnitude of the roundoff errors may be significantly reduced. When using an ordinary polynomial approximating function it seems that the roundoff errors are due to the wide range of values of the elements $\varphi_{i,k}$ in the initial tableau.

b. If approximation by normal Chebyshev polynomials, shifted Chebyshev polynomials, Legendre polynomials, Laguerre polynomials, or Hermite polynomials is desired, the subroutines CNP, CSP, LEP, LAP, or HEP, respectively from the SSP (Scientific Subroutine Package) can be used as the external subroutine FCT.

Numerical Quadrature

Subroutines QTFG and DQTFG

These subroutines perform the integration of a monotonically tabulated function by trapezoidal rule.

To compute the vector of integral values:

$$z_i = z(x_i) = \int_{x_1}^{x_i} y(x)\,dx \quad (i = 1,2,\ldots,n)$$

for a given table $(x_i, y_i; i = 1,2,\ldots,n)$ of monotonic arguments and their function values, the trapezoidal rule is used. It is assumed that the function to be integrated is continuous and can be differentiated at least twice. Starting with integral value $z_1 = 0$, successive integral values z_i $(i = 2,3,..,n)$ are computed, using the trapezoidal rule in the following form:

$$z_1 = z_{i-1} + \frac{x_i - x_{i-1}}{2}(y_i + y_{i-1}) \quad (i = 2,3,\ldots,n)$$

Local truncation error at each step is:

$$R_i = -\frac{1}{12}(x_i - x_{i-1})^3 \cdot y''(\xi_i) \quad (\xi_i \quad [x_{i-1}, x_i])$$

However, these truncation errors may accumulate.

Subroutines QTFE and DQTFE

These subroutines perform the integration of an equidistantly tabulated function by trapezoidal rule.

To compute the vector of integral values:

$$\left.\begin{aligned} z_i = z(x_i) &= \int_a^{x_i} y(x)\,dx \\ \text{with } x_i &= a + (i-1)\,h \end{aligned}\right\} (i = 1,2,3,\ldots,n)$$

for a table of function values y_i $(i = 1,2,\ldots,n)$, given at equidistant points $x_i = a + (i-1)\cdot h$ $(i = 1,2,\ldots,n)$, the trapezoidal rule is used. It is assumed that the function to be integrated is continuous and can be differentiated at least twice. Starting with the integral value $z_1 = 0$, successive integral values z_i $(i = 2,3,\ldots,n)$ are computed, using the trapezoidal rule in the following form:

$$z_i = z_{i-1} + \frac{h}{2}(y_i + y_{i-1}) \qquad (i=2,3,\ldots,n)$$

with a given increment h of argument values.

As local truncation error at each step is:

$$R_i = -\frac{1}{12} h^3 \cdot y''(\xi_i) \qquad (\xi_i \in [x_{i-1}, x_i])$$

the global truncation error R in z_n appears as follows:

$$R = -\frac{1}{12}(n-1)\,h^3\,y''(\xi) \qquad (\xi \in [x_1, x_n])$$

or

$$R = -\frac{\ell}{12} \cdot h^2 \cdot y''(\xi)$$

where ℓ is the length of the whole integration interval.

Subroutines QSF and DQSF

These subroutines perform the integration of an equidistantly tabulated function by Simpson's rule. To compute the vector of integral values:

$$z_i = z(x_i) = \int_a^{x_i} y(x)\,dx \quad \text{with } x_i = a + (i-1)\,h \qquad (i=1,2,\ldots,n)$$

for a table of function values $y_i\,(i=1,2,\ldots,n)$, given at equidistant points $x_i = a+(i-1)\,h\ (i=1,2,\ldots,n)$, Simpson's rule together with Newton's 3/8 rule or a combination of these two rules is used. Local truncation error is of the order h^5 in all cases with more than three points in the given table. Only z_2 has a truncation error of the order h^4 if there are only three points in the given table. No action takes place if the table consists of less than three sample points.

The function to be integrated is assumed to be continuous and differentiable (three or four times, depending on the rule used).

Formulas used in this subroutine (z_j are integral values, y_j function values) are:

$$z_j = z_{j-1} + \frac{h}{3}(1.25\,y_{j-1} + 2y_j - 0.25\,y_{j+1}) \qquad (1)$$

$$z_j = z_{j-2} + \frac{h}{3}(y_{j-2} + 4y_{j-1} + y_j) \quad \text{(Simpson's rule)} \qquad (2)$$

$$z_j = z_{j-3} + \frac{3}{8}h\,(y_{j-3} + 3y_{j-2} + 3y_{j-1} + y_j) \qquad (3)$$

(Newton's 3/8 rule)

$$z_j = z_{j-5} + \frac{h}{3}(y_{j-5} + 3.875\,y_{j-4} + 2.625\,y_{j-3} + 2.625\,y_{j-2} + 3.875\,y_{j-1} + y_j) \qquad (4)$$

[combination of (2) and (3)]

Sometimes formula (2) is used in the following form:

$$z_j = z_{j+2} - \frac{h}{3}(y_j + 4\,y_{j+1} + y_{j+2}) \qquad (5)$$

Local truncation errors of formulas (1) . . . (4) are, respectively:

$$R_1 = \frac{1}{24}h^4\,y'''\ (\xi_1) \quad (\xi_1 \in [x_{j-1},\ x_{j+1}])$$

$$R_2 = -\frac{1}{90}h^5\,y''''\ (\xi_2) \quad (\xi_2 \in [x_{j-2},\ x_j])$$

$$R_3 = -\frac{3}{80}h^5\,y''''\ (\xi_3) \quad (\xi_3 \in [x_{j-3},\ x_j])$$

$$R_4 = -\frac{1}{144}h^5\,y''''\ (\xi_4) \quad (\xi_4 \in [x_{j-5},\ x_j])$$

However, these truncation errors may accumulate.

Subroutines QHFG and DQHFG

These subroutines perform the integration of a monotonically tabulated function with first derivative by a Hermitian formula of first order. To compute the vector of integral values:

$$z_i = z(x_i) = \int_{x_1}^{x_i} y(x)\,dx \quad (i = 1, 2, \ldots, n)$$

for a given table x_i, y_i, y_i' $(i = 1, 2, \ldots, n)$ of monotonic arguments and their function and derivative values, a first-order Hermitian formula is used. It is assumed that the function to be integrated is continuous and can be differentiated at least four times. Starting with the integral value $z_1 = 0$, successive integral values z_i $(i = 2, 3, \ldots, n)$ are computed by means of the following formula:

$$z_i = z_{i-1} + \frac{x_i - z_{i-1}}{2}\left[y_{i-1} + y_i + \frac{x_i - x_{i-1}}{6}(y'_{i-1} - y'_i)\right]$$

$$(i = 2, 3, \ldots, n)$$

Local truncation error at each step is:

$$R_i = \frac{(x_i - x_{i-1})^5}{720} \cdot y^{(4)}(\xi_i) \quad (\xi_i \in [x_{i-1}, x_i])$$

However, these truncation errors may accumulate.

Subroutines QHFE and DQHFE

These subroutines perform the integration of an equidistantly tabulated function with first derivative by a Hermitian formula of first order. To compute the vector of integral values:

$$z_i = z(x_i) = \int_a^{x_i} y(x)\,dx \Bigg\} (i = 1, 2, \ldots, n)$$

with $x_i = a + (i-1)\,h$

for a table of function and first derivative values y_i, y_i' $(i = 1, 2, \ldots, n)$, given at equidistant points $x_i = a + (i - 1)\,h$, a first-order Hermitian formula is used. It is assumed that the function to be integrated is continuous and can be differentiated at least four times. Starting with the integral value $z_1 = 0$, successive integral values z_i $(i = 2, 3, \ldots, n)$ are computed by means of the following formula:

$$z_i = z_{i-1} + \frac{h}{2}\cdot\left[y_{i-1} + y_i + \frac{h}{6}\,(y'_{i-1} - y'_i)\right]$$

$$(i = 1, 2, \ldots, n)$$

with a given increment h of argument values.

As the local truncation error at each step is:

$$R_i = \frac{h^5}{720}\cdot y^{(4)}(\xi_i) \quad (\xi_i \in [\,x_{i-1},\, x_i\,])$$

the global truncation error R in z_n appears as follows:

$$R = \frac{1}{720}\,(n-1)\,h^5\,y^{(4)}(\xi) \quad (\xi \in [x_1,\, x_n\,])$$

or

$$R = \frac{\ell}{720}\,h^4\,y^{(4)}(\xi)$$

where ℓ is the length of the whole integration interval.

Subroutines QHSG and DQHSG

These subroutines perform the integration of a monotonically tabulated function with first and second derivatives by a Hermitian formula of second order. To compute the vector of integral values:

$$z_i = z(x_i) = \int_{x_1}^{x_i} y(x)\,dx \quad (i = 1,2,\ldots,n)$$

for a given table x_i, y_i, y_i', y_i'' $(i=1,2,\ldots,n)$ of monotonic arguments and their function and first and second derivative values, a second-order Hermitian formula is used. It is assumed that the function to be integrated is continuous and can be differentiated at least six times. Starting with the integral value $z_1 = 0$, successive integral values z_i $(i = 2,3,\ldots,n)$ are computed by means of the following formula:

$$z_i = z_{i-1} + \frac{x_i - x_{i-1}}{2}\left\{y_{i-1} + y_i + \frac{x_i - x_{i-1}}{5}\left[y'_{i-1} - y'_i + \frac{x_i - x_{i-1}}{12}\,(y''_{i-1} + y''_i)\right]\right\} \quad (i=2,3,\ldots,n)$$

Local truncation error at each step is:

$$R_i = -\frac{(x_i - x_{i-1})^7}{100\ 800}\,y^{(6)}(\xi_i) \quad (\xi_i \in [x_{i-1}\ \ x_i])$$

However, these truncation errors may accumulate.

Subroutines QHSE and DQHSE

These subroutines perform the integration of an equidistantly tabulated function with first and second derivatives by a Hermitian formula of second order.

To compute the vector of integral values:

$$\left.\begin{aligned} z_i = z(x_i) &= \int_a^{x_i} y(x)\,dx \\ \text{with } x_i &= a + (i-1)\,h \end{aligned}\right\} (i = 1,2,\ldots,n)$$

for a table of function and first and second derivative values y_i, y'_i, y''_i $(i = 1,2,\ldots,n)$, given at equidistant points $x_i = a + (i-1)\,h$, a second-order Hermitian formula is used. It is assumed that the function to be integrated is continuous and can be differentiated at least six times. Starting with the integral value $z_1 = 0$, successive integral values z_i $(i = 2,3,\ldots,n)$ are computed by means of the following formula:

$$z_i = z_{i-1} + \frac{h}{2}\left\{y_{i-1} + y_i + \frac{h}{5}\left[y'_{i-1} - y'_i + \frac{h}{12}\left(y''_{i-1} + y''_i\right)\right]\right\} \quad (i=2,3,\ldots,n)$$

with a given increment h of argument values.

As the local truncation error at each step is:

$$R_i = -\frac{h^7}{100\,800}\,y^{(6)}(\xi_i) \quad (\xi_i \in [x_{i-1}, x_i]),$$

the global truncation error R in z_n appears as follows:

$$R = -\frac{1}{100\,800}\,(n-1)\,h^7\,y^{(6)}(\xi) \quad (\xi \in [x_1, xn])$$

or

$$R = -\frac{\ell}{100\,800}\,h^6\,y^{(6)}(\xi)$$

where ℓ is the length of the whole integration interval.

Subroutines QATR and DQATR

These subroutines perform the integration of a given function by the trapezoidal rule together with Romberg's extrapolation method in order to compute an approximation for:

$$y = \int_a^b f(x)\,dx \qquad (1)$$

Successively dividing the interval $[a,b]$ into 2^i equidistant subintervals ($i = 0,1,2,\ldots$) and using the following notations:

$$h_i = \frac{b-a}{2^i}\ ;\ x_{i,k} = a + k \cdot h_i,\ f_{i,k} = f(x_{i,k})$$

$$(k = 0,1,2,\ldots,2^i)$$

the trapezoidal rule gives approximations $T_{o,i}$ to the integral value y:

$$T_{o,i} = h_i\left\{\sum_{k=0}^{2^i} f_{i,k} - \frac{1}{2}(f(a) + f(b))\right\} \qquad (2)$$

Then the following can be written:

$$T_{o,i} = y + \sum_{r=1}^{\infty} C_{o,2r} \cdot h_i^{2r}$$

with unknown coefficients $C_{o,2r}$ which do not depend on i. Thus there is a truncation error of the order h_i^2.

Knowing two successive approximations, $T_{o,i}$ and $T_{o,i+1}$, an extrapolated value can be generated:

$$T_{1,i} = T_{o,\,i+1} + \frac{T_{o,i+1} - T_{o,i}}{2^2 - 1} \qquad (3)$$

This is a better approximation to y because:

$$T_{1,i} = y + \frac{1}{2^2-1}\sum_{r=1}^{\infty} C_{o,2r}\,(2^2 h_{i+1}^{2r} - h_i^{2r})$$

Noting that $2^2 h_{i+1}^2 - h_i^2 = 0$ and setting:

$$C_{1,2r} = \frac{1}{2^2-1}\,(2^2 - 2^{2r}) \cdot C_{o,2r}$$

$T_{1,i}$ becomes:

$$T_{1,i} = y + \sum_{r=2}^{\infty} C_{1,2r}\, h_{i+1}^{2r}$$

This gives a truncation error of the order h_{i+1}^4.

Knowing $T_{o,\,i+2}$ also, $T_{1,\,i+1}$ can be generated (formula 3), and:

$$T_{2,i} = T_{1,\,i+1} + \frac{T_{1,i+1} - T_{1,i}}{2^4 - 1} \qquad (4)$$

Thus:

$$T_{2,i} = y + \sum_{r=3}^{\infty} C_{2,2r} \cdot h_{i+2}^{2r}$$

with $C_{2,2r} = \frac{1}{2^4-1}\,(2^4 - 2^{2r})\,C_{1,2r}$

with a truncation error of the order h_{i+2}^6. Observe that the order of truncation error increases by 2 at each new extrapolation step.

The subroutine uses the scheme shown in Figure 25 for computation of T-values and generates the upward diagonal in the one-dimensional storage array AUX, using the general formula:

$$T_{k,j} = T_{k-1,j+1} + \frac{T_{k-1,j+1} - T_{k-1,j}}{2^{2k}-1} \quad (k+j=i,$$

$$j = i-1, i-2, \ldots, 2, 1, 0) \qquad (5)$$

and storing:

$T_{o,i}$ into AUX (i+1)

$T_{1,i-1}$ into AUX (i)

....

$T_{k,0}$ into AUX (1)

Truncation error		$O(h_i^2)$	$O(h_i^4)$	$O(h_i^6)$	$O(h_i^8)\ldots$
step length h_i	i \ j	0	1	2	3 ...
b-a	0	$T_{o,0}$	$T_{1,0}$	$T_{2,0}$	$T_{3,0}$ ...
$\frac{b-a}{2}$	1	$T_{o,1}$	$T_{1,1}$	$T_{2,1}$	⋮
$\frac{b-a}{4}$	2	$T_{o,2}$	$T_{1,2}$	⋮	
$\frac{b-a}{8}$	3	$T_{o,3}$	⋮		
⋮	⋮	⋮			

Figure 25. Computation of T-values (QATR)

The procedure stops if the difference between two successive values of AUX (1) is less than a given tolerance, or if the values of AUX (1) start oscillating, thus showing the influence of rounding errors.

Subroutines QG2, QG3,..., QG10, DQG4, DQG8, DQG12, DQG16, DQG24, DQG32

These subroutines perform the integration of a given function by Gaussian quadrature formulas.

To compute:

$$y = \int_a^b f(x)\,dx$$

Gaussian quadrature formulas with n = 2,3,..., 10 (or n = 4,8,12,16,24,32) points are used. Transforming the range x = a...b into t = -1...1 by:

$$t = \frac{2x - (a+b)}{b - a}, \quad x = \frac{b-a}{2}t + \frac{b+a}{2}$$

the result is:

$$y = \frac{b-a}{2} \cdot \int_{-1}^{1} \varphi(t)\,dt \text{ with } \varphi(t) = f\left(\frac{b-a}{2} \cdot + \frac{b+a}{2}\right)$$

Using:

$$\int_{-1}^{1} \varphi(t)\,dt = \sum_{k=1}^{n} \left[A_k^{(n)} \varphi(t_k^{(n)})\right] (n = 2,3,\ldots)$$

with coefficients $A_k^{(n)}$ and nodes $t_k^{(n)}$ (note that $t_k^{(n)}$ are the roots of Legendre polynomials of degree n), the result is the approximations:

$$y_n = (b-a) \cdot \sum_{k=1}^{n} \left\{ \frac{A_k^{(n)}}{2} \cdot f\left[(b-a) \cdot \frac{t_k^{(n)}}{2} + \frac{b+a}{2}\right]\right\} (n = 2,3,\ldots), \quad (1)$$

which are exact whenever f(x) is a polynomial up to the degree 2n-1.

The $A_k^{(n)}$ and $t_k^{(n)}$ are symmetric with respect to t = 0:

$$A_k^{(n)} = A_{n-k+1}^{(n)}, \quad t_k^{(n)} = -t_{n-k+1}^{(n)}$$

Subroutines QL2, QL3, ..., QL10; DQL4, DQL8, DQL12, DQL16, DQL24, DQL32

These subroutines perform the integration of a given function by Gaussian-Laguerre quadrature formulas:

To compute:

$$y = \int_0^\infty e^{-x} f(x)\,dx$$

Gaussian-Laguerre quadrature formulas with $n = 2,3,\ldots, 10$ (or $n = 4,8,12,16,24,32$) points are used to get the approximations:

$$y_n = \sum_{k=1}^{n} \left[A_k^{(n)} \cdot f\left(x_k^{(n)}\right) \right] \quad (n = 2,3,\ldots) \qquad (1)$$

which are exact whenever f(x) is a polynomial up to the degree 2n-1. Note that nodes $x_k^{(n)}$ are the roots of the Laguerre polynomials $L_n(x)$ of degree n.

Subroutines QH2, QH3, ..., QH10; DQH8, DQH16, DQH24, DQH32, DQH48, DQH64

These subroutines perform the integration of a given function by Gaussian-Hermite quadrature formulas.

To compute:

$$y = \int_{-\infty}^{+\infty} e^{-x^2} f(x)\, dx$$

Gaussian-Hermite quadrature formulas with n = 2,3, ..., 10 (or n = 8, 16, 24, 32, 48, 64) points are used to get the approximations:

$$y_n = \sum_{x=1}^{n} A_k^{(n)} f(x_k^{(n)}) \qquad (n = 2,3, \ldots) \qquad (1)$$

which are exact whenever f(x) is a polynomial up to the degree 2n-1. Note that the nodes $x_k^{(n)}$ are the roots of the Hermite polynomials $H_n(x)$ of degree n. As $A_k^{(n)}$ and $x_k^{(n)}$ are symmetric with respect to x=0, therefore:

$$A_k^{(n)} = A_{n-k+1}^{(n)}, \quad x_k^{(n)} = -x_{n-k+1}^{(n)}$$

Note: In case of an even function $f(x) = \phi(x^2)$, the transformation $t=x^2$ transforms the given integral into:

$$y = \int_0^{\infty} \frac{e^{-t} \varphi(t)}{\sqrt{t}}\, dt$$

which is a form suitable to subroutines QA2, QA3, ..., QA10 and DQA4, ..., DQA32. Using these subroutines saves approximately half of the computation time.

Subroutines QA2, QA3, ..., QA10, DQA4, DQA8, DQA12, DQA16, DQA24, DQA32

These subroutines perform the integration of a given function by associated Gaussian-Laguerre quadrature formulas:

To compute:

$$y = \int_0^\infty \frac{e^{-x} f(x)}{\sqrt{x}} \, dx$$

generalized Gaussian-Laguerre quadrature formulas with n = 2,3,..., 10 (or n = 4,8,12,16,24,32) points are used to get approximations:

$$y_n = \sum_{k=1}^{n} A_k^{(n)} f(x_k^{(n)}) \quad (n= 2,3,\ldots) \quad (1)$$

which are exact whenever f(x) is a polynomial up to the degree 2n-1. Note that the nodes $x_k^{(n)}$ are the roots of the associated Laguerre polynomials $L_n^{(-\frac{1}{2})}(x)$ of degree n.

Numerical Differentiation

Subroutines DGT3 and DDGT3

These subroutines compute a vector $Z=(z_1,\ldots,z_n)$ of derivative values, given vectors $X=(x_1,\ldots,x_n)$ of argument values and $Y=(y_1,\ldots y_n)$ of corresponding function values. Except at the endpoints x_1 and x_n, z_i is the derivative at x_i of the Lagrangian interpolation polynomial of degree 2 relevant to the three successive points (x_{i-1}, y_{i-1}), (x_i, y_i) and (x_{i+1}, y_{i+1}).

1. Mathematical background

For $i = 1,\ldots, n-2$ we must find a_i, b_i, and c_i such that

$$\bar{y}_i(x) = a_i x^2 + b_i x + c_i$$

passes through (x_i, y_i), (x_{i+1}, y_{i+1}), and (x_{i+2}, y_{i+2}).

The desired derivative values z_i are given by:

$$z_i = \begin{cases} y_1'(x_1) = 2a_1x_1 + b_1 & \text{if } i=1 \\ y_{i-1}'(x_i) = 2a_{i-1}x_i + b_{i-1} & \text{if } i=2,\ldots,n-1 \\ y_{n-2}'(x_n) = 2a_{n-2}x_n + b_{n-2} & \text{if } i=n \end{cases}$$

An easy computation yields:

$$z_i = \begin{cases} \dfrac{y_2-y_1}{x_2-x_1} + \dfrac{y_3-y_1}{x_3-x_1} - \dfrac{y_3-y_2}{x_3-x_2} & \text{if } i=1 \\ \dfrac{y_i-y_{i-1}}{x_i-x_{i-1}} + \dfrac{y_{i+1}-y_i}{x_{i+1}-x_i} - \dfrac{y_{i+1}-y_{i-1}}{x_{i+1}-x_{i-1}} & \text{if } i=2,\ldots,n-1 \\ \dfrac{y_n-y_{n-1}}{x_n-x_{n-1}} + \dfrac{y_n-y_{n-2}}{x_n-x_{n-2}} - \dfrac{y_{n-1}-y_{n-2}}{x_{n-1}-x_{n-2}} & \text{if } i=n \end{cases} \quad (1)$$

Assuming that the vectors X and Y represent a portion of a three-times differentiable function, z_i involves a truncation error T_i where:

$$T_i = \begin{cases} \frac{1}{6}(x_1-x_2)(x_1-x_3)y'''(\xi_1) & \text{if } i=1 \\ \frac{1}{6}(x_i-x_{i-1})(x_i-x_{i+1})y'''(\xi_i) & \text{if } i=2,\ldots,n-1 \\ \frac{1}{6}(x_n-x_{n-2})(x_n-x_{n-1})y'''(\xi_n) & \text{if } i=n \end{cases}$$

and ξ_i is in the closed interval determined by the three argument values used in computing z_i, $i = 1,\ldots,n$.

2. Programming considerations

The subroutines compute the z_i in serial order according to (1). If $n < 3$, there is no computation, and the error parameter is set to -1. If two of the three arguments x_{j-2}, x_{j-i}, x_j are identical, $j=3,\ldots,n$, the computation is prematurely terminated, and the error parameter IER is set to j. However, $z_1,\ldots,z_{j-1}$ are returned if $j > 3$. In this case z_{j-i} is computed treating x_{j-1} as the right-hand endpoint. If there is no error, IER is set to zero at the end of the computation. The output vector Z can have the same storage allocation as X or Y.

Subroutines DET3 and DDET3

These subroutines compute a vector $Z=(z_1,\ldots,z_n)$ of derivative values, given a vector $Y=(y_1,\ldots,y_n)$ of function values whose entries y_i correspond to n equidistantly spaced argument values x_i, with $x_i - x_{i-1} = h$ for $i=2,\ldots,n$. Except at the endpoints x_1 and x_n, z_i is the derivative at x_i of the Lagrangian interpolation polynomial of degree 2 relevant to the three successive points (x_{i-1}, y_{i-1}), (x_i, y_i), and (x_{i+1}, y_{i+1}).

1. Mathematical background

The procedure is that described for subroutines DGT3 and DDGT3, but here we have the additional relation $x_i - x_{i-1} = h$, a constant, for $i=2,\ldots,n$. This leads to the following expression for the z_i:

$$z_i = \begin{cases} \frac{1}{2h}(-y_3 + 4y_2 - 3y_1) & \text{if } i=1 \\ \frac{1}{2h}(y_{i+1} - y_{i-1}) & \text{if } i=2,\ldots,n-1 \\ \frac{1}{2h}(3y_n - 4y_{n-1} + y_{n-2}) & \text{if } i=n \end{cases} \qquad (1)$$

Assuming that the vector Y represents the function values of a portion of a three-times differentiable function, z_i involves a truncation error T_i where:

$$T_i = \begin{cases} \frac{h^2}{3} y'''(\xi_1),\ \xi_1 \in [x_1, x_3] & \text{if } i=1 \\ \frac{-h^2}{6} y'''(\xi_i),\ \xi_i \in [x_{i-1}, x_{i+1}] & \text{if } i=2,\ldots,n-1 \\ \frac{h^2}{3} y'''(\xi_n),\ \xi_n \in [x_{n-2}, x_n] & \text{if } i=n \end{cases}$$

In addition to these truncation errors, roundoff errors may be of considerable magnitude. Supposing that each of the ordinates y_i can be in error by $\pm\epsilon$, $\epsilon > 0$, the magnitude $|R_i|$ of the corresponding error R_i in the calculation of z_i can be as large as:

$$|R_i| = \begin{cases} \frac{4\epsilon}{|h|} & \text{if } i=1, n \\ \frac{\epsilon}{|h|} & \text{if } i=2,\ldots,n-1 \end{cases}$$

Since small truncation errors generally require small $|h|$, while small roundoff errors generally require large $|h|$, it is reasonable to choose h so that $|T_i| \approx |R_i|$.

If $M = \sup y'''(\xi)$, where $\xi \in [x_1, x_n]$, and if we regard only the inner points $x_2, \ldots, x_{n-1}$, we find that

$$h_{\text{optimum}} \approx \pm 1.8 \sqrt[3]{\epsilon/M},$$

and the magnitude $|E_i|$ of the total possible error E_i in z_i is given by:

$$|E_i| \approx \begin{cases} 3.3 \sqrt[3]{\epsilon^2 M} & \text{if } i = 1, n \\ 1.1 \sqrt[3]{\epsilon^2 M} & \text{if } i = 2, \ldots, n-1 \end{cases}$$

2. Programming considerations

The subroutines compute the z_i in serial order according to (1). If $n < 3$ or if $h = 0$, there is no computation, and the error parameter IER is set to -1 or 1 respectively. Otherwise IER is set to zero at the end of the computation. The output vector Z can have the same storage allocation as Y.

Subroutines DET5 and DDET5

These subroutines compute a vector $Z=(z_1,\ldots,z_n)$ of derivative values, given a vector $Y=(y_1,\ldots,y_n)$ of function values whose entries y_i correspond to n equidistantly spaced argument values x_i, with $x_i - x_{i-1} = h$ for $i=2,\ldots,n$. Except at the points x_1, x_2, x_{n-1}, and x_n, z_i is the derivative at x_i of the Lagrangian interpolation polynomial of degree 4 relevant to the five successive points (x_{i+k}, y_{i+k}), $k=-2,-1,\ldots,2$.

1. Mathematical background

For $i=1,\ldots,n-4$ we must find a_i, b_i, c_i, d_i, and e_i such that

$$\bar{y}_i(x) = a_i x^4 + b_i x^3 + c_i x^2 + d_i x + e_i$$

passes through (x_{i+k}, y_{i+k}) for $k=0,\ldots,4$.

The desired derivative values z_i are given by:

$$z_i = \begin{cases} \bar{y}_1'(x_i) = 4a_1x_i^3 + 3b_1x_i^2 + 2c_1x_i + d_1 & \text{if } i=1,2 \\ \bar{y}_{i-2}'(x_i) = 4a_{i-2}x_i^3 + 3b_{i-2}x_i^2 + 2c_{i-2}x_i + d_{i-2} & \text{if } i=3,\ldots,n-2 \\ \bar{y}_{n-4}'(x_i) = 4a_{n-4}x_i^3 + 3b_{n-4}x_i^2 + 2c_{n-4}x_i + d_{n-4} & \text{if } i=n-1,n \end{cases}$$

Using the fact that $x_i - x_{i-1} = h$, a constant, for $i=2,\ldots,n$, we get:

$$z_i = \begin{cases} \frac{1}{12h}(-25y_1 + 48y_2 - 36y_3 + 16y_4 - 3y_5) & \text{if } i=1 \\ \frac{1}{12h}(-3y_1 - 10y_2 + 18y_3 - 6y_4 + y_5) & \text{if } i=2 \\ \frac{1}{12h}(y_{i-2} - 8y_{i-1} + 8y_{i+1} - y_{i+2}) & \text{if } i=3,\ldots,n-2 \\ \frac{1}{12h}(-y_{n-4} + 6y_{n-3} - 18y_{n-2} + 10_{n-1} + 3y_n) & \text{if } i=n-1 \\ \frac{1}{12h}(3y_{n-4} - 16y_{n-3} + 36y_{n-2} - 48y_{n-1} + 25y_n) & \text{if } i=n \end{cases} \quad (1)$$

Assuming that the vector Y represents the function values of a portion of a five-times differentiable function, z_i involves a truncation error T_i where:

$$T_i = \begin{cases} \frac{h^4}{5}y^v(\xi_1), & \xi_1 \epsilon [x_1, x_5] & \text{if } i=1 \\ -\frac{h^4}{20}y^v(\xi_2), & \xi_2 \epsilon [x_1, x_5] & \text{if } i=2 \\ \frac{h^4}{30}y^v(\xi_i), & \xi_i \epsilon [x_{i-2}, x_{i+2}] & \text{if } i=3,\ldots,n-2 \\ -\frac{h^4}{20}y^v(\xi_{n-1}), & \xi_{n-i} \epsilon [x_{n-4}, x_n] & \text{if } i=n-1 \\ \frac{h^4}{5}y^v(\xi_n), & \xi_n \epsilon [x_{n-4}, x_n] & \text{if } i=n \end{cases}$$

In addition to the truncation errors, roundoff errors may be of considerable magnitude. Supposing that the ordinates y_i can be in error by $\pm\epsilon$, $\epsilon > 0$, the magnitude $|R_i|$ of the corresponding error R_i in the computation of z_i can be as large as:

$$|R_i| = \begin{cases} \frac{32\epsilon}{3|h|} & \text{if } i=1,n \\ \frac{19\epsilon}{6|h|} & \text{if } i=2,n-1 \\ \frac{3\epsilon}{2|h|} & \text{if } i=3,\ldots,n-2 \end{cases}$$

Since small truncation errors generally require small $|h|$, while small roundoff errors generally require large $|h|$, it is reasonable to choose h so that $|T_i| \approx |R_i|$.

If $M = \sup_{\xi \in [x_1, x_n]} y^{v}(\xi)$, and if we regard only the inner points $x_3, \ldots, x_{n-2}$, we find that

$$h_{optimum} \approx 2.1 \sqrt[5]{\epsilon/M}$$

and the magnitude $|E_i|$ of the total possible error E_i in z_i is given by:

$$|E_i| \approx \begin{cases} 9 \sqrt[5]{\epsilon^4 M} & \text{if } i=1, n \\ 2.5 \sqrt[5]{\epsilon^4 M} & \text{if } i=2, n-1 \\ 1.4 \sqrt[5]{\epsilon^4 M} & \text{if } i=3, \ldots, n-2 \end{cases}$$

2. Programming considerations

The subroutines compute the z_i in serial order according to (1). If $n < 5$ or if $h = 0$, there is no computation, and the error parameter IER is set to -1 or 1, respectively. Otherwise IER is set to zero at the end of the computation. The output vector Z may have the same storage allocation as Y.

Subroutines DCAR and DDCAR

Suppose that $y = y(t)$ is eleven-times differentiable in a neighborhood of radius $R > 0$ of the point x. These subroutines compute an approximation Z to $y'(x)$ by applying Richardson's and Romberg's extrapolation method to successively computed central divided differences, using function values in a closed interval of radius $|h|$ about the point x, $0 < |h| < R$.

1. Mathematical background

Suppose, first, that $y = y(t)$ is analytic at x; that is, y has a Taylor series expansion about the point x with radius of convergence $R > 0$. Let h be such that $0 < |h| < R$. For each positive integer n a step size h_1 with $0 < h_1 \leq |h|$ is computed as described below, and a sequence h_k of increments is generated, where

$$h_k = \frac{n-k+1}{n} h_1 \qquad \text{for } k=2,\ldots,n.$$

From the sequence $(x-h_k, x+h_k)$ of point pairs $(k=1,\ldots,n)$, the sequence of central divided differences

$$T_{0,k} = \frac{y(x+h_k) - y(x-h_k)}{2h_k} \qquad \text{for } k=1,\ldots,n \qquad (1)$$

is computed, which forms the first column of the triangular Romberg scheme. The central divided differences $T_{0,k}$ represent the slopes of the secants s_k in Figure 26.

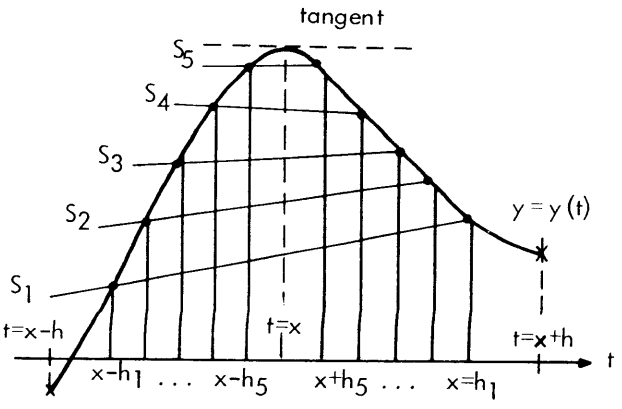

Figure 26. A sequence of secants for a given function $y = y(t)$ and a given argument $t = x$ for the case $n = 5$, $h > 0$

From the Taylor series expansions of $y(x+h_k)$ and $y(x-h_k)$ it follows that

$$T_{0,k} = y'(x) + \frac{h_k^2}{3!} y'''(x) + \frac{h_k^4}{5!} y^{v}(x) + \ldots \text{ for } k=1,\ldots,n$$

so that, as an approximation to $y'(x)$, $T_{0,k}$ involves a truncation error of order h_k^2.

Knowing the two divided differences $T_{0,k}$ and $T_{0,k+1}$, we are able to generate the extrapolated value

$$T_{1,k} = T_{0,k+1} + \frac{T_{0,k+1} - T_{0,k}}{a_{1,k} - 1}$$

where (2)

$$a_{1,k} = \left(1 + \frac{1}{n-k}\right)^2$$

$T_{1,k}$ is a better approximation to $y'(x)$ since

$$T_{1,k} = y'(x) - \frac{1}{5!} \frac{1}{a_{1,k}} h_k^4 y^{v}(x) - \frac{1}{7!} \frac{1}{a_{1,k}} \left(1 + \frac{1}{a_{1,k}}\right) h_k^6 y^{vii}(x) - \ldots,$$

which involves a truncation error of order h_k^4.

If we also know $T_{0,k+2}$, then we can generate $T_{1,k+1}$ using formula (2), and further, we can compute the extrapolated value

$$T_{2,k} = T_{1,k+1} + \frac{T_{1,k+1} - T_{1,k}}{a_{2,k} - 1}$$

where (3)

$$a_{2,k} = \left(1 + \frac{2}{n-(k+1)}\right)^2$$

which involves a truncation error of order h_k^6.

Generally, the order of the truncation error is increased by 2 with each new extrapolation step; in particular, $T_{i,j}$ will involve a truncation error of order

$$h_j^{2i+2}, \quad i = 0,\ldots,n-1, \quad j = 1,\ldots,n.$$

Figure 27 shows the arrangement of the T-values in the triangular Romberg scheme. The T-values are computed following the upward diagonals, using the general formula:

$$T_{m,k-m} = T_{m-1,k-m+1} + \frac{T_{m-1,k-m+1} - T_{m-1,k-m}}{\frac{m}{n-(k+1)}\left(2+\frac{m}{n-(k+1)}\right)}$$

for m = 1, . . . , k-1 for fixed k, k = 2, . . . , n (4)

Truncation error		$O(h_k^2)$	$O(h_k^4)$	$O(h_k^6)$	$O(h_k^8)$	$O(h_k^{10})$
Stepsize	m / k	0	1	2	3	4
h_1	1	$T_{0,1}$	$T_{1,1}$	$T_{2,1}$	$T_{3,1}$	$T_{4,1}$
$h_2=0.8h_1$	2	$T_{0,2}$	$T_{1,2}$	$T_{2,2}$	$T_{3,2}$	
$h_2=0.6h_1$	3	$T_{0,3}$	$T_{1,3}$	$T_{2,3}$		
$h_4=0.4h_1$	4	$T_{0,4}$	$T_{1,4}$			
$h_5=0.2h_1$	5	$T_{0,5}$				

Figure 27. The triangular Romberg scheme of T-values for the case n = 5

Numerical experience shows that the accuracy of the results depends heavily on roundoff errors in the central divided differences $T_{0,k}$. Therefore, the choice of the absolutely smallest step size, h_n, is based on the following considerations.
Let

$$v = \begin{cases} 1 & \text{in single-precision computation} \\ 3 & \text{in double-precision computation} \end{cases},$$

$$h_0 = \min\,(n \cdot 10^{-v}, |h|)$$

Set

$$Y = \tfrac{1}{2}(y(x+h_0) + y(x-h_0))$$

and

$$T = \tfrac{1}{2}(y(x+h_0) - y(x-h_0))/h_0$$

Y and T are approximations to y(x) and y'(x), respectively.

Assuming that the errors in the function values y(t) for $t \in [x-|h|, x+|h|]$ are bounded by

$$\epsilon = \begin{cases} Y \cdot 10^{-D} & \text{if } |Y| > 1 \\ 10^{-D} & \text{if } |Y| \le 1 \end{cases}$$

formula (1) shows that the roundoff error in the computation of $T_{0,n}$ is bounded by

$$R(T_{0,n}) = \frac{\epsilon}{h_n} = \begin{cases} \dfrac{Y \cdot 10^{-D}}{h_n} & \text{if } |Y| > 1 \\ \dfrac{10^{-D}}{h_n} & \text{if } |Y| \le 1 \end{cases}$$

where D is the number of significant digits in the floating-point representation of numbers. Suppose, also, that we are willing to tolerate a roundoff error

$$R'(T_{0,n}) = \begin{cases} T \cdot 10^{-D+v} & \text{if } |T| > 1 \\ 10^{-D+v} & \text{if } |T| \le 1 \end{cases}$$

Then we must have $R(T_{0,n}) \le R'(T_{0,n})$, which is satisfied when

$$h_n = \frac{\max(1, |Y|)}{\max(1, |T|)} \cdot 10^{-v} \qquad (5)$$

Finally we set

$$h_1 = \min(n \cdot h_n, |h|) \qquad (6)$$

guaranteeing that the evaluation of the function y = y(t) is restricted to the closed interval $[x-|h|, x+|h|]$.

2. Programming considerations

Numerical experience shows that, because of increasing roundoff errors, it is generally fruitless to perform more than five extrapolations. Thus, the subroutines use n = 5, and consequently it is only necessary that y = y(t) be eleven-times differentiable, rather than analytic. It is easy to see that in the case n = 5, y = y(t) must be evaluated at twelve points in the closed interval $[x-|h|, x+|h|]$.

The parameter lists of both subroutines contain the decision parameter IH. If the user wants the maximum step size to equal |h|, he must set IH = 0. In all other cases (IH ≠ 0) the procedure determines the maximum step size by itself, using formulas (5) and (6) with n = 5. Step size h_1 and all the other step sizes h_k (k = 2, . . . , 5) are successively stored in the single storage location HH.

As previously explained, the computation of the T-values is performed along the upward diagonals of the triangular Romberg scheme. Therefore, only a one-dimensional internal storage vector,

named AUX, with five storage locations is necessary. Figure 28 shows the storage administration and the sequence of computations (numbers in parentheses).

AUX(1)	$T_{0,5}^{(11)}$				
AUX(2)	$T_{0,4}^{(7)}$	$T_{1,4}^{(12)}$			
AUX(3)	$T_{0,3}^{(4)}$	$T_{1,3}^{(8)}$	$T_{2,3}^{(13)}$		
AUX(4)	$T_{0,2}^{(2)}$	$T_{1,2}^{(5)}$	$T_{2,2}^{(9)}$	$T_{3,2}^{(14)}$	
AUX(5)	$T_{0,1}^{(1)}$	$T_{1,1}^{(3)}$	$T_{2,1}^{(6)}$	$T_{3,1}^{(10)}$	$T_{4,1}^{(15)}$

Figure 28. Storage administration and order of computation

Each extrapolation loop, the computation of the elements on an upward diagonal, is terminated as soon as the absolute values of the differences between adjacent diagonal elements stop decreasing, showing the influence of roundoff errors. The computed T-value that differs least in absolute value from its immediately preceding diagonal neighbor is the desired value Z.

3. Accuracy of results

Tests of the single-precision (double-precision) subroutine on the functions $y(t) = t^2$, $1/t$, e^t, tan t, and sin t showed that the accuracy obtained using the step size determined by the subroutine was 3-4 (11-12) significant digits near poles, 5-6(13-14) decimal places near points with horizontal tangents, and 5-6(13-14) significant digits otherwise.

Subroutines DBAR and DDBAR

Suppose that $y = y(t)$ is eleven-times differentiable in a neighborhood of radius $R > 0$ of the point x. These subroutines compute an approximation Z to $y'(x)$ by applying Richardson's and Romberg's extrapolation method to successively computed one-sided divided differences, using function values in a closed interval $[x, x+h]$, $0 < |h| < R$.

1. Mathematical background

Suppose, first, that $y = y(t)$ is analytic at x; that is, y has a Taylor series expansion about the point x with radius of convergence $R > 0$. Let h be such that $0 < |h| < R$. For each positive integer n, a step size h_1 with $0 < |h_1| \leq |h|$ is computed as described below, and a sequence h_k of increments is generated, where

$$h_k = \frac{n-k+1}{n} h_1$$

for $k = 2, \ldots, n$.

From the sequence $(x, x+h_k)$ of point pairs $(k = 1, \ldots, n)$, the sequence of one-sided divided differences

$$T_{0,k} = \frac{y(x+h_k) - y(x)}{h_k} \quad \text{for } k = 1, \ldots, n \qquad (1)$$

is computed, which forms the first column of the triangular Romberg scheme. These one-sided divided differences $T_{0,k}$ represent the slopes of the secants s_k in Figure 29, in the case $h > 0$.

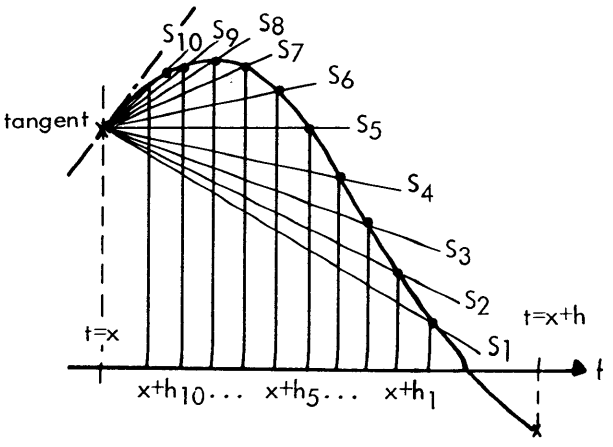

Figure 29. A sequence of secants for a given function $y = y(t)$ and a given argument $t = x$ for the case $n = 10$, $h > 0$

From the Taylor series expansion of $y(x+h_k)$ it follows that

$$T_{0,k} = y'(x) + \frac{h_k}{2!}y''(x) + \frac{h_k^2}{3!}y'''(x) + \ldots \text{ for } k = 1, \ldots, n$$

so that, as an approximation to $y'(x)$, $T_{0,k}$ involves a truncation error of order h_k. Knowing the two divided differences $T_{0,k}$ and $T_{0,k+1}$, we are able to generate the extrapolated value

$$T_{1,k} = T_{0,k+1} + \frac{T_{0,k+1} - T_{0,k}}{a_{1,k} - 1} \qquad (2)$$

where

$$a_{1,k} = \left(1 + \frac{1}{n-k}\right)$$

$T_{1,k}$ is a better approximation to $y'(x)$ since

$$T_{1,k} = y'(x) = \frac{1}{3!}\frac{1}{a_{i,k}-1}h_k^2 y'''(x)$$

$$- \frac{1}{4!}\frac{1}{a_{i,k}}\left(1 + \frac{1}{a_{i,k}}\right)h_k^3 y^{iv}(x)$$

..., which involves a truncation error of order h_k^2.

If we also know $T_{0,k+2}$, then we can generate $T_{1,k+1}$ using formula (2), and further, we can compute the extrapolated value

$$T_{2,k} = T_{1,k+1} + \frac{T_{1,k+1} - T_{1,k}}{a_{2,k} - 1}$$

where

$$a_{2,k} = \left(1 + \frac{2}{n-(k+1)}\right)$$

which involves a truncation error of order h_k^3.

Generally, the order of the truncation error is increased by 1 with each new extrapolation step; in particular, $T_{i,j}$ will involve a truncation error of order

$$h_j^{i+1},\ i = 0, \ldots, n-1,\ j = 1, \ldots, n.$$

Figure 30 shows the arrangement of the T-values in the triangular Romberg scheme. The T-values are computed following the upward diagonals, using the general formula

$$T_{m,k-m} = T_{m-1,k-m+1} + \frac{T_{m-1,k-m+1} - T_{m-1,k-m}}{\frac{m}{n-k+1}}$$

for $m = 1, \ldots, k-1$ for fixed k, $k = 2, \ldots, n$ (3)

Figure 30. The triangular Romberg scheme of T-values for the case n = 10

Numerical experience shows that the accuracy of the results depends heavily on roundoff errors in the one-sided divided differences $T_{0,k}$. Therefore, the choice of the absolutely smallest step size, h_n, is based on the following considerations.

Let

$$v = \begin{cases} 1 & \text{in single-precision computation} \\ 3 & \text{in double-precision computation} \end{cases}$$

Set

$$n_0 = \operatorname{sgn}(h) \cdot \min\left(\frac{n}{2} \cdot 10^{-v}, |h|\right)$$

$$T = (y(x+h_0) - y(x))/h_0.$$

T is an approximation to y'(x).

Assuming that the errors in the function values y(t) for $t \in [x, x+h]$ are bounded by

$$\epsilon = \begin{cases} |y(x)| \cdot 10^{-D} & \text{if } |y(x)| > 1 \\ 10^{-D} & \text{if } |y(x)| \le 1 \end{cases}$$

formula (1) shows that the roundoff error in the computation of $T_{0,n}$ is bounded by

$$R(T_{0,n}) = \frac{2\epsilon}{|h_n|} = \begin{cases} \dfrac{2\,|y(x)|\,10^{-D}}{|h_n|} & \text{if } |y(x)| > 1 \\ 2\dfrac{10^{-D}}{|h_n|} & \text{if } |y(x)| \le 1 \end{cases}$$

where D is the number of significant digits in the floating-point representation of numbers. Suppose, also, that we are willing to tolerate a roundoff error

$$R'(T_{0,n}) = \begin{cases} 2T \cdot 10^{-D+v} & \text{if } |T| > 1 \\ 2 \cdot 10^{-D+v} & \text{if } |T| \le 1 \end{cases}$$

Then we must have $R(T_{0,n}) \le R'(T_{0,n})$, which is satisfied when

$$h_n = \frac{\max(1, |y(x)|)}{\max(1, |T|)} \cdot 10^{-v} \qquad (4)$$

Finally, we set

$$h_1 = \operatorname{sgn}(h) \cdot \min(n \cdot |h_n|, |h|) \qquad (5)$$

guaranteeing that the evaluation of the function y = y(t) is restricted to the closed interval $[x, x+h]$.

2. Programming considerations

Numerical experience shows that, because of increasing roundoff errors, it is generally fruitless to perform more than ten extrapolations. Thus, the subroutines use n = 10, and consequently, it is only necessary that y = y(t) be eleven-times differentiable, rather than analytic. It is easy to see that in the case n = 10, y = y(t) must be evaluated at twelve points in the closed interval $[x, x+h]$.

The parameter lists of both subroutines contain the decision parameter IH. If the user wants the maximum step size to equal |h|, he must set IH = 0. In all other cases (IH ≠ 0) the procedure determines the maximum step size by itself, using formulas (4) and (5) with n = 10. Step size h_1 and all the other step sizes h_k (k = 2, . . . , 10) are successively stored in the single storage location HH.

As previously explained, the computation of the T-values is performed along the upward diagonals of the triangular Romberg scheme. Therefore, only a one-dimensional internal storage vector, named AUX, with ten storage locations is necessary. Figure 31 shows the storage administration and the sequence of computations (numbers in parentheses).

AUX(1)	$T_{0,10}^{(46)}$						
AUX(2)	$T_{0,9}^{(37)}$	$T_{1,9}^{(47)}$					
AUX(3)	$T_{0,8}^{(29)}$	$T_{1,8}^{(38)}$	$T_{2,8}^{(48)}$				
AUX(4)	$T_{0,7}^{(22)}$	$T_{1,7}^{(30)}$	$T_{2,7}^{(39)}$	...			
AUX(5)	$T_{0,6}^{(16)}$	$T_{1,6}^{(23)}$	$T_{2,6}^{(31)}$	...

AUX(9)	$T_{0,2}^{(2)}$	$T_{1,2}^{(5)}$	$T_{2,2}^{(9)}$	...	$T_{7,2}^{(44)}$	$T_{8,2}^{(54)}$	
AUX(10)	$T_{0,1}^{(1)}$	$T_{1,1}^{(3)}$	$T_{2,1}^{(6)}$	...	$T_{7,1}^{(36)}$	$T_{8,1}^{(45)}$	$T_{9,1}^{(55)}$

Figure 31. Storage administration and sequence of calculations

Each extrapolation loop, the computation of the elements on an upward diagonal, is terminated as soon as the absolute values of the differences between adjacent diagonal elements stop decreasing, showing the influence of roundoff errors. The computed T-value that differs least in absolute value from its immediately preceding diagonal neighbor is the desired value Z.

3. Accuracy of results

Tests of the single-precision (double-precision) subroutine on the functions $y(t) = t^2$, 1/t, e^t, tan t, and sin t showed that the accuracy obtained using the step size determined by the subroutine was 2-4 (10-12) significant digits near poles, 4-6(13-14) decimal places near points with horizontal tangents, and 4-6(11-13) significant digits otherwise.

Subroutine RK1

This subroutine integrates a given function using the Runge-Kutta technique and produces the final computed value of the integral.

The ordinary differential equation:

$$\frac{dy}{dx} = f(x,y) \tag{1}$$

with initial condition $y(x_0) = y_0$ is solved numerically using a fourth-order Runge-Kutta integration process. This is a single-step method in which the value of y at $x = x_n$ is used to compute $y_{n+1} = y(x_{n+1})$ and earlier values yn-1, yn-2, etc. are not used.

The relevant formulas are:

$$y_{n+1} = y_n + 1/6\,[k_0 + 2k_1 + 2k_2 + k_3] \tag{2}$$

where, for step size h:

$$\begin{cases} k_0 = h f(x_n, y_n) \\ k_1 = h f(x_n + h/2,\ y_n + k_0/2) \\ k_2 = h f(x_n + h/2,\ y_n + k_1/2) \\ k_3 = h f(x_n + h,\ y_n + k_2) \end{cases} \tag{3}$$

```

Subroutine RK2

This subroutine integrates a given function using the Runge-Kutta technique and produces tabulated values of the computed integral.

The ordinary differential equation:

$$\frac{dy}{dx} = f(x, y) \tag{1}$$

with initial condition $y(x_0) = y_0$ is solved numerically using a fourth-order Runge-Kutta integration process. This is a single-step method in which the value of y at $x = x_n$ is used to compute $y_{n+1} = y(x_{n+1})$ and earlier values y_{n-1}, y_{n-2}, etc. are not used

The relevant formulas are:

$$y_{n+1} = y_n + 1/6\,[k_0 + 2k_1 + 2k_2 + k_3] \tag{2}$$

where, for step size h:

$$\begin{cases} k_0 = h f(x_n, y_n) \\ k_1 = h f(x_n + h/2,\ y_n + k_0/2) \\ k_2 = h f(x_n + h/2,\ y_n + k_1/2) \\ k_3 = h f(x_n + h,\ y_n + k_2) \end{cases} \tag{3}$$

Subroutines RKGS and DRKGS

These subroutines use the Runge-Kutta method for the solution of initial-value problems.

The purpose of the Runge-Kutta method is to obtain an approximate solution of a system of first-order ordinary differential equations with given initial values. It is a fourth-order integration procedure which is stable and self-starting; that is, only the functional values at a single previous point are required to obtain the functional values ahead. For this reason it is easy to change the step size h at any step in the calculations. On the other hand, each Runge-Kutta step requires the evaluation of the right-hand side of the system four times, which is a great disadvantage compared with other methods of the same order of accuracy, especially predictor-corrector methods. Another disadvantage of the method is that neither the truncation errors nor estimates of them are obtained in the calculation procedure. Therefore, control of accuracy and adjustment of the step size h is done by comparison of the results due to double and single step size 2h and h.

Given the system of first-order ordinary differential equations:

$$y_1' = \frac{dy_1}{dx} = f_1(x, y_1, y_2, \ldots, y_n)$$

$$y_2' = \frac{dy_2}{dx} = f_2(x, y_1, y_2, \ldots, y_n)$$

$$\ldots\ldots\ldots\ldots$$

$$y_n' = \frac{dy_n}{dx} = f_n(x, y_1, y_2, \ldots, y_n)$$

and the initial values:

$$y_1(x_0) = y_{1,0},\ y_2(x_0) = y_{2,0},\ \ldots,\ y_n(x_0) = y_{n,0}$$

and using the following vector notations:

$$Y(x) = \begin{pmatrix} y_1(x) \\ y_2(x) \\ \cdot \\ \cdot \\ \cdot \\ y_n(x) \end{pmatrix},\quad F(x, Y) = \begin{pmatrix} f_1(x, Y) \\ f_2(x, Y) \\ \cdot \\ \cdot \\ \cdot \\ f_n(x, Y) \end{pmatrix},\quad Y_0 = \begin{pmatrix} y_{1,0} \\ y_{2,0} \\ \cdot \\ \cdot \\ \cdot \\ y_{n,0} \end{pmatrix}$$

where Y, F and Y_0 are column vectors, the given problem appears as follows:

$$Y' = \frac{dY}{dx} = F(x, Y) \text{ with } Y(x_0) = Y_0$$

With respect to storage requirements and compensation of accumulated roundoff errors, Gill's modification of the classical Runge-Kutta formulas is preferred. Thus, starting at x_0 with $Y(x_0) = Y_0$ and vector $Q_0 = 0$, the resulting vector $Y_4 = Y(x_0 + h)$ is computed by the following formulas:

$$K_1 = h \cdot F(x_0, Y_0) \quad ; \quad Y_1 = Y_0 + \frac{1}{2}(K_1 - 2Q_0) \quad ;$$

$$Q_1 = Q_0 + 3\left[\frac{1}{2}(K_1 - 2Q_0)\right] - \frac{1}{2}K_1$$

$$K_2 = h \cdot F\left(x_0 + \frac{h}{2}, Y_1\right) \quad ; \quad Y_2 = Y_1 + \left(1 - \sqrt{\frac{1}{2}}\right)(K_2 - Q_1) \quad ;$$

$$Q_2 = Q_1 + 3\left[\left(1 - \sqrt{\frac{1}{2}}\right)(K_2 - Q_1)\right] - \left(1 - \sqrt{\frac{1}{2}}\right)K_2 \qquad (1)$$

$$K_3 = h \cdot F\left(x_0 + \frac{h}{2}, Y_2\right) \quad ; \quad Y_3 = Y_2 + \left(1 + \sqrt{\frac{1}{2}}\right)(K_3 - Q_2) \quad ;$$

$$Q_3 = Q_2 + 3\left[\left(1 + \sqrt{\frac{1}{2}}\right)(K_3 - Q_2)\right] - \left(1 + \sqrt{\frac{1}{2}}\right)K_3$$

$$K_4 = h \cdot F(x_0 + h, Y_3) \quad ; \quad Y_4 = Y_3 + \frac{1}{6}(K_4 - 2Q_3) \quad ;$$

$$Q_4 = Q_3 + 3\left[\frac{1}{6}(K_4 - 2Q_3)\right] - \frac{1}{2}K_4$$

where K_1, K_2, K_3, K_4, Y_1, Y_2, Y_3, Y_4, Q_1, Q_2, Q_3, Q_4 are all column vectors with n components. If the procedure were carried out with infinite precision (that is, no rounding errors), vector Q_4 defined above would be zero. In practice this is not true, and Q_4 represents approximately three times the roundoff error in Y_4 accumulated during one step. To compensate for this accumulated roundoff, Q_4 is used as Q_0 for the next step. Also $(x_0 + h)$ and Y_4 serve as x_0 and Y_0 respectively at the next step.

For initial control of accuracy, an approximation for $Y(x_0 + 2h)$ called $Y^{(2)}(x_0 + 2h)$ is computed using the step size 2h, and then an approximation called $Y^{(1)}(x_0 + 2h)$, using two times the step size h. From these two approximations, a test value δ for accuracy is generated in the following way:

$$\delta = \frac{1}{15}\sum_{i=1}^{n} a_i \cdot \left| y_i^{(1)} - y_i^{(2)} \right| \qquad (2)$$

where the coefficients a_i are error-weights specified in the input of the procedure.

Test value δ is an approximate measure for the local truncation error at point x_0+2h. If δ is greater than a given tolerance ϵ_2, increment h is halved and the procedure starts again at the point x_0. If δ is less than ϵ_2, the results $Y^{(1)}(x_0+h)$ and $Y^{(1)}(x_0+2h)$

are assumed to be correct. They are then handed, together with $x_0 + h$ and $x_0 + 2h$ and the derivatives at these points -- that is, the values of $F[x_0 + h, Y^{(1)}(x_0+h)]$ and $F[x_0+2h, Y^{(1)}(x_0+2h)]$ respectively -- to a user-supplied output subroutine.

If δ is less than $\epsilon_1 = \epsilon_2/50$, the next step is carried out with the doubled increment. However, care is taken in the procedure that the increment never becomes greater than the increment h specified as an input parameter, and further that all points $x_0 + j \cdot h$ (where $j = 1, 2, \ldots$) which are situated between the lower and upper bound of the integration interval are included in the output. Finally, the increment of the last step of the procedure is chosen in such a way that the upper bound of the integration interval is reached exactly.

The entire input of the procedure is:

1. Lower and upper bound of the integration interval, initial increment of the independent variable, upper bound ϵ_2 of the local truncation error
2. Initial values of the dependent variables and weights for the local truncation errors in each component of the dependent variables
3. The number of differential equations in the system
4. As external subroutine subprograms, the computation of the right-hand side of the system of differential equations; for flexibility in output, an output subroutine
5. An auxiliary storage array named AUX with 8 rows and n columns

Output is done in the following way. If a set of approximations to the dependent variables Y(x) is found to be of sufficient accuracy, it is handed -- together with x, the derivative $F[x, Y(x)]$, the number of bisections of the initial increment, the number of differential equations, the lower and upper bound of the interval, the initial step size, error bound ϵ_2, and a parameter for terminating subroutine RKGS or DRKGS -- to the output subroutine. Because of this output subroutine, the user has the opportunity to choose his own output format, to handle the output values as he wants, to change the upper error bound, and to terminate subroutine RKGS or DRKGS at any output point. In particular, the user is able to drop the output of some intermediate points, printing only the result values at the special points $x_0 + n \cdot h$ ($n = 0, 1, 2, \ldots$). The user may also perform intermediate computation using the integration results before continuing the process.

For better understanding of the flowchart and of the FORTRAN program, Figure 32 shows the allocation of special intermediate result vectors within the storage array AUX.

Subroutines HPCG and DHPCG

These subroutines use Hamming's modified predictor-corrector method for the solution of general initial-value problems.

The purpose of Hamming's modified predictor-corrector method is to obtain an approximate solution of a general system of first-order ordinary differential equations with given initial values. It is a stable fourth-order integration procedure that requires the evaluation of the right-hand side of the system only two times per step. This is a great advantage compared with other methods of the same order of accuracy, especially the Runge-Kutta method, which requires the evaluation of the right-hand side four times per step. Another advantage is that at each step the calculation procedure gives an estimate for the local truncation error; thus the procedure is able, without a significant amount of calculation time, to choose and change the step size h. On the other hand, Hamming's predictor-corrector method itself is not self-starting; that is, the functional values at a single previous point are not enough to get the functional values ahead. Therefore, to obtain the starting values, a special Runge-Kutta procedure followed by one iteration step is added to the predictor-corrector method.

Given the general system of first-order ordinary differential equations:

$$y_1' = \frac{dy_1}{dx} = f_1(x, y_1, y_2, \ldots, y_n)$$

$$y_2' = \frac{dy_2}{dx} = f_2(x, y_1, y_2, \ldots, y_n)$$

$$\ldots\ldots\ldots\ldots$$

$$y_n' = \frac{dy_n}{dx} = f_n(x, y_1, y_2, \ldots, y_n)$$

and the initial values:

$$y_1(x_0) = y_{1,0},\ y_2(x_0) = y_{2,0},\ \ldots,\ y_n(x_0) = y_{n,0}$$

and using the following vector notations:

$$Y(x) = \begin{pmatrix} y_1(x) \\ y_2(x) \\ \vdots \\ y_n(x) \end{pmatrix},\quad F(x,Y) = \begin{pmatrix} f_1(x,Y) \\ f_2(x,Y) \\ \vdots \\ f_n(x,Y) \end{pmatrix},\quad Y_0 = \begin{pmatrix} y_{1,0} \\ y_{2,0} \\ \vdots \\ y_{n,0} \end{pmatrix}$$

where Y, F, and Y_0 are column vectors, the given problem appears as follows:

$$Y' = \frac{dY}{dx} = F(x,Y) \text{ with } Y(x_0) = Y_0$$

For stability purposes, the modification by Hamming of Milne's classical modified predictor-corrector method is preferred. Thus, knowing the results at the equidistant points x_{j-3}, x_{j-2}, x_{j-1} and x_j, the results at point $x_{j+1} = x_j + h$ are computed by the formulas below.

Predictor:
$$P_{j+1} = Y_{j-3} + \frac{4h}{3}(2Y'_j - Y'_{j-1} + 2Y'_{j-2}) \quad (1)$$

Modifier:
$$M_{j+1} = P_{j+1} - \frac{112}{121}(P_j - C_j)\ ;$$
$$M'_{j+1} = F(x_{j+1}, M_{j+1}) \quad (2), (3)$$

Corrector:
$$C_{j+1} = \frac{1}{8}\left[9Y_j - Y_{j-2} + 3h(M'_{j+1} + 2Y'_j - Y'_{j-1})\right] \quad (4)$$

Final value:
$$Y_{j+1} = C_{j+1} + \frac{9}{121}(P_{j+1} - C_{j+1}) \quad (5)$$

where Y, Y', P, M, M', F and C are column vectors with n components. Formulas (1) and (4) have local truncation errors:

$$T_1 = \frac{14}{45} h^5 Y^{(5)}(\xi_1) \text{ with } \xi_1 \in (x_{j-3}, x_{j+1})$$

and

$$T_2 = -\frac{1}{40} h^5 Y^{(5)}(\xi_2) \text{ with } \xi_2 \in (x_{j-2}, x_{j+1})$$

respectively, such that

$$C_{j+1} - P_{j+1} = \frac{121}{360} h^5 Y^{(5)}(\xi) \quad [\xi \in (x_{j-3}, x_{j+1})]$$

Assuming that $Y^{(5)}(x)$ does not vary to any great extent in the interval (x_{j-3}, x_{j+1}), it follows that:

$$T_2 \approx \frac{9}{121} (P_{j+1} - C_{j+1})$$

This formula shows that the components of column vector $P_{j+1} - C_{j+1}$ are measures for the local truncation errors in the components of column vector Y_{j+1}, and therefore control of accuracy and adjustment of step size h can be done by generating the following test value:

$$\delta = \sum_{i=1}^{n} a_i \cdot |p_{j+1,i} - c_{j+1,i}| \qquad (6)$$

where the coefficients a_i (i = 1, 2, ..., n) are error-weights specified in the input of the procedure.

If δ is greater than a given tolerance ϵ†, increment h is halved and the procedure computes $Y_{j+1/2}$ -- that is, $Y(x_j + \frac{h}{2})$ -- after having interpolated $Y_{j-1/2} = Y(x_j - \frac{h}{2})$ and $Y_{j-3/2} = Y(x_j - \frac{3}{2}h)$, with previous increment h, using the following sixth-order interpolation formulas):

$$Y_{j-1/2} = \frac{1}{256} (80Y_j + 135Y_{j-1} + 40Y_{j-2} + Y_{j-3}) + \frac{h}{2} \cdot \frac{15}{128} (-Y'_j + 6Y'_{j-1} + Y'_{j-2}) \qquad (7)$$

$$Y_{j-3/2} = \frac{1}{256} (12Y_j + 135Y_{j-1} + 108Y_{j-2} + Y_{j-3}) + \frac{h}{2} \cdot \frac{3}{128} (-Y'_j - 18Y'_{j-1} + 9Y'_{j-2}) \qquad (8)$$

If δ is less than ϵ, the result Y_{j+1} is assumed to be correct and is handed, together with x_{j+1} and the vector of derivatives $Y'_{j+1} = F(x_{j+1}, Y_{j+1})$, to a user-supplied output subroutine.

†Numerical experience seems to show that the procedure does not exceed a global relative error approximately equal to ϵ.

If δ is less than $\epsilon/50$, the next step is carried out with the doubled increment; however, care is taken in the procedure that the increment never gets greater than the increment h specified as an input parameter, and further, that among the output are all points $x_0 + j \cdot h$ (where j = 0, 1, 2, ..., and h is the input step size) which are situated between the lower and the upper bound of the integration interval.

Changing the step size by halving or doubling requires changing of $P_j - C_j$ or $P_{j+1} - C_{j+1}$, respectively. Using the following interpolation formula:

$$Y_j = Y_{j-3} + \frac{3}{8} h(Y'_{j-3} + 3Y'_{j-2} + 3Y'_{j-1} + Y'_j) - \frac{3}{80} h^5 Y^{(5)}(\xi_3) \quad [\xi_3 \in (x_{j-3}, x_j)]$$

and assuming that $Y^{(5)}(x)$ does not vary to any great extent in this interval, $P_j - C_j$ can be written as:

$$P_j - C_j \approx \frac{242}{27} (Y_j - Y_{j-3}) - \frac{121}{36} h(Y'_j + 3Y'_{j-1} + 3Y'_{j-2} + Y'_{j-3})$$

When halving increment h, this formula becomes:

$$P_j - C_j \approx \frac{242}{27} (Y_j - Y_{j-3/2}) - \frac{121}{36} \cdot \frac{h}{2} (Y'_j + 3Y'_{j-1/2} + 3Y'_{j-1} + Y'_{j-3/2}) \qquad (9)$$

and when doubling:

$$P_{j+1} - C_{j+1} \approx \frac{242}{27} (Y_{j+1} - Y_{j-5}) - \frac{121}{36} \cdot 2h(Y'_{j+1} + 3Y'_{j-1} + 3Y'_{j-3} + Y'_{j-5}) \qquad (10)$$

Starting Hamming's modified predictor-corrector method requires the functional and derivative values at four preceding equidistant points; that is, x_0, x_1, x_2 and x_3. The values Y_0 and $Y'_0 = F(x_0, Y_0)$ are specified by input. For computation of Y_1, Y'_1, Y_2, Y'_2, Y_3 and Y'_3 and for adjustment of the step size h to accuracy requirements, a special Runge-Kutta procedure suggested by Ralston is used. Starting at x_j, result values at point $x_{j+1} = x_j + h$ are computed using the following formulas:

$$K_1 = h \cdot Y'_j \tag{11}$$

$$k_2 = h \cdot F(x_j + 0.4h,\ Y_j + 0.4K_1) \tag{12}$$

$$K_3 = h \cdot F(x_j + 0.45573725421878943\,h,\ Y_j + 0.29697760924775360\ K_1 + 0.15875964497103583\ K_2) \tag{13}$$

$$K_4 = h \cdot F(x_j + h,\ Y_j + 0.21810038822592047\ K_1 - 3.0509651486929308\ K_2 + 3.8328647604670103\ K_3) \tag{14}$$

$$Y_{j+1} = Y_j + 0.17476028226269037\ K_1 - 0.55148066287873294\ K_2 + 1.2055355993965235\ K_3 + 0.17118478121951903\ K_4 \tag{15}$$

where Y_j, Y_{j+1}, K_1, K_2, K_3 and K_4 are all column vectors with n components.

These formulas are not very stable, but this does not matter because they are used only in three successive steps (j = 0, 1, 2). On the other hand, they have the smallest bound of truncation error of all fourth-order Runge-Kutta procedures. Therefore they are best suited to start other integration methods which are not self-starting.

For initial control of accuracy and adjustment of step size h, in starting the procedure an approximation for $Y_2 = Y(x_0 + h)$, named $Y_2^{(1)}$, is computed using the step size h, and then an approximation named $Y_2^{(2)}$, using the step size h/2 twice. From these two approximations a test value for accuracy is generated in the following way:

$$\delta = \frac{1}{15} \sum_{i=1}^{n} a_i \cdot \left| y_{2,i}^{(1)} - y_{2,i}^{(2)} \right| \tag{16}$$

If δ is greater than ϵ, increment h is halved, and the procedure starts again at point x_0.

If δ is less than ϵ, the results $Y_1^{(2)} = Y(x_0 + \frac{h}{2})$ and $Y_2^{(2)} = Y(x_0 + h)$ are assumed to be correct, and a third step follows, which computes the results at point $x_0 + \frac{3}{2}h$ -- that is, $Y_3 = Y(x_0 + \frac{3}{2}h)$. The step size h/2 of these three steps is handed as initial step size h to the predictor-corrector method.

It is very important that the starting values be as accurate as possible, because errors in these starting values may increase during the following predictor-corrector procedure. Therefore the starting values computed by the Runge-Kutta method are refined by one iteration step using the following fourth-order interpolation formulas:

$$Y_1 = Y_0 + \frac{h}{24}(9\ Y'_0 + 19\ Y'_1 - 5\ Y'_2 + Y'_3) \tag{17}$$

$$Y_2 = Y_0 + \frac{h}{3}(Y'_0 + 4\ Y'_1 + Y'_2) \tag{18}$$

$$Y_3 = Y_0 + \frac{3h}{8}(Y'_0 + 3\ Y'_1 + 3\ Y'_2 + Y'_3) \tag{19}$$

Use of these must be considered an iteration procedure; that is, first the result values of the Runge-Kutta method are used in the right-hand side of formula (17) to compute a refined Y_1. After computing the refined $Y'_1 = F(x_1, Y_1)$, the refined vector Y_2 is generated using formula (18). Finally, the refined $Y'_2 = F(x_2, Y_2)$ is used, together with the other values, in the right-hand side of formula (19) to compute the refined vector Y_3. During this iteration, the refined data sets x_j, Y_j, Y'_j are handed, together with the number of bisections of the initial step size (specified by input), to the output subroutine.

It can be shown that, using this iterative procedure, the initial column vector $P_3 - C_3$ used in formula (2) for j=3 is equal to zero.

The entire input of the procedure is:

1. Lower and upper bound of the integration interval, initial step size h of the independent variable, and upper bound ϵ of the local truncation error
2. Initial values Y_0 of the dependent variables and weights a_i (i = 1, 2, ..., n) for the local truncation errors in each component of the dependent variables
3. The number n of differential equations in the system
4. As external subroutine subprograms, the computation of the right-hand side of the system of differential equations; for flexibility in output, an output subroutine
5. An auxiliary storage array named AUX with 16 rows and n columns

Output is done in the following way. If a set of approximations to the dependent variables Y(x) is found to be of sufficient accuracy, it is handed -- together with x, the derivative Y' (x), the number of bisections of the initial increment, the number of differential equations, the lower and upper bound of the interval, the initial step size, error bound ε, and a parameter for terminating subroutine HPCG or DHPCG -- to the output subroutine. By means of this output subroutine, the user has the opportunity to choose his own output format, to handle the output values as he wants, to change the upper error bound, and to terminate subroutine HPCG or DHPCG at any output point. In particular, the user is able to drop the output of some intermediate points, printing only the result values at the special points $x_0 + j \cdot h$(where j = 0, 1, 2, ..., and h is the initial step size specified by input). The user may also perform intermediate computations using the integration results before continuing the process.

For better understanding of the flowchart and of the FORTRAN program, the allocation of special intermediate-result vectors within the storage array AUX is given in Figure 33.

function vector $Y_{j-6} = Y(x_{j-6})$	1. row (AUX (1) in flowchart)
function vector $Y_{j-5} = Y(x_{j-5})$	2. row (AUX (2) in flowchart)
function vector $Y_{j-4} = Y(x_{j-4})$	3. row (AUX (3) in flowchart)
function vector $Y_{j-3} = Y(x_{j-3})$	4. row (AUX (4) in flowchart)
function vector $Y_{j-2} = Y(x_{j-2})$	5. row (AUX (5) in flowchart)
function vector $Y_{j-1} = Y(x_{j-1})$	6. row (AUX (6) in flowchart)
function vector $Y_j = Y(x_j)$	7. row (AUX (7) in flowchart)
derivative vector $Y'_{j-6} = Y'(x_{j-6})$	8. row (AUX (8) in flowchart)
derivative vector $Y'_{j-5} = Y'(x_{j-5})$	9. row (AUX (9) in flowchart)
derivative vector $Y'_{j-4} = Y'(x_{j-4})$	10. row (AUX (10) in flowchart)
derivative vector $Y'_{j-3} = Y'(x_{j-3})$	11. row (AUX (11) in flowchart)
derivative vector $Y'_{j-2} = Y'(x_{j-2})$	12. row (AUX (12) in flowchart)
derivative vector $Y'_{j-1} = Y'(x_{j-1})$	13. row (AUX (13) in flowchart)
derivative vector $Y'_j = Y'(x_j)$	14. row (AUX (14) in flowchart)
vector of error weights	15. row (AUX (15) in flowchart)
vector $P_j - C_j$	16. row (AUX (16) in flowchart)

C                    SPECIFIES THE PARAMETERS OF THE INTERVAL AND OF    DHCG 170
C                    ACCURACY AND WHICH SERVES FOR COMMUNICATION BETWEENDHCG 180
C                    OUTPUT SUBROUTINE (FURNISHED BY THE USER) AND      DHCG 190
C                    SUBROUTINE DHPCG. EXCEPT PRMT(5) THE COMPONENTS    DHCG 200
C                    ARE NOT DESTROYED BY SUBROUTINE DHPCG AND THEY ARE DHCG 210
C           PRMT(1)- LOWER BOUND OF THE INTERVAL (INPUT),               DHCG 220
C           PRMT(2)- UPPER BOUND OF THE INTERVAL (INPUT),               DHCG 230
C           PRMT(3)- INITIAL INCREMENT OF THE INDEPENDENT VARIABLE      DHCG 240
C                    (INPUT),                                           DHCG 250
C           PRMT(4)- UPPER ERROR BOUND (INPUT). IF ABSOLUTE ERROR IS    DHCG 260
C                    GREATER THAN PRMT(4), INCREMENT GETS HALVED.       DHCG 270
C                    IF INCREMENT IS LESS THAN PRMT(3) AND ABSOLUTE     DHCG 280
C                    ERROR LESS THAN PRMT(4)/50, INCREMENT GETS DOUBLED.DHCG 290
C                    THE USER MAY CHANGE PRMT(4) BY MEANS OF HIS        DHCG 300
C                    OUTPUT SUBROUTINE.                                 DHCG 310
C           PRMT(5)- NO INPUT PARAMETER. SUBROUTINE DHPCG INITIALIZES   DHCG 320
C                    PRMT(5)=0. IF THE USER WANTS TO TERMINATE          DHCG 330
C                    SUBROUTINE DHPCG AT ANY OUTPUT POINT, HE HAS TO    DHCG 340
C                    CHANGE PRMT(5) TO NON-ZERO BY MEANS OF SUBROUTINE  DHCG 350
C                    OUTP. FURTHER COMPONENTS OF VECTOR PRMT ARE        DHCG 360
C                    FEASIBLE IF ITS DIMENSION IS DEFINED GREATER       DHCG 370
C                    THAN 5. HOWEVER SUBROUTINE DHPCG DOES NOT REQUIRE  DHCG 380
C                    AND CHANGE THEM. NEVERTHELESS THEY MAY BE USEFUL   DHCG 390
C                    FOR HANDING RESULT VALUES TO THE MAIN PROGRAM       DHCG 400
C                    (CALLING DHPCG) WHICH ARE OBTAINED BY SPECIAL       DHCG 410
C                    MANIPULATIONS WITH OUTPUT DATA IN SUBROUTINE OUTP.  DHCG 420
C           Y      - DOUBLE PRECISION INPUT VECTOR OF INITIAL VALUES     DHCG 430
C                    (DESTROYED). LATERON Y IS THE RESULTING VECTOR OF   DHCG 440
C                    DEPENDENT VARIABLES COMPUTED AT INTERMEDIATE        DHCG 450
C                    POINTS X.                                          DHCG 460
C           DERY   - DOUBLE PRECISION INPUT VECTOR OF ERROR WEIGHTS     DHCG 470
C                    (DESTROYED). THE SUM OF ITS COMPONENTS MUST BE     DHCG 480
C                    EQUAL TO 1. LATERON DERY IS THE VECTOR OF          DHCG 490
C                    DERIVATIVES, WHICH BELONG TO FUNCTION VALUES Y AT  DHCG 500
C                    INTERMEDIATE POINTS X.                             DHCG 510
C           NDIM   - AN INPUT VALUE, WHICH SPECIFIES THE NUMBER OF      DHCG 520
C                    EQUATIONS IN THE SYSTEM.                           DHCG 530
C           IHLF   - AN OUTPUT VALUE, WHICH SPECIFIES THE NUMBER OF     DHCG 540
C                    BISECTIONS OF THE INITIAL INCREMENT. IF IHLF GETS   DHCG 550
C                    GREATER THAN 10, SUBROUTINE DHPCG RETURNS WITH     DHCG 560
C                    ERROR MESSAGE IHLF=11 INTO MAIN PROGRAM.           DHCG 570
C                    ERROR MESSAGE IHLF=12 OR IHLF=13 APPEARS IN CASE   DHCG 580
C                    PRMT(3)=0 OR IN CASE SIGN(PRMT(3)).NE.SIGN(PRMT(2)-DHCG 590
C                    PRMT(1)) RESPECTIVELY.                             DHCG 600
C           FCT    - THE NAME OF AN EXTERNAL SUBROUTINE USED. IT        DHCG 610
C                    COMPUTES THE RIGHT HAND SIDES DERY OF THE SYSTEM   DHCG 620
C                    TO GIVEN VALUES OF X AND Y. ITS PARAMETER LIST     DHCG 630
C                    MUST BE X,Y,DERY. THE SUBROUTINE SHOULD NOT        DHCG 640
C                    DESTROY X AND Y.                                   DHCG 650
C           OUTP   - THE NAME OF AN EXTERNAL OUTPUT SUBROUTINE USED.    DHCG 660
C                    ITS PARAMETER LIST MUST BE X,Y,DERY,IHLF,NDIM,PRMT.DHCG 670
C                    NONE OF THESE PARAMETERS (EXCEPT, IF NECESSARY,    DHCG 680
C                    PRMT(4),PRMT(5),...) SHOULD BE CHANGED BY          DHCG 690
C                    SUBROUTINE OUTP. IF PRMT(5) IS CHANGED TO NON-ZERO,DHCG 700
C                    SUBROUTINE DHPCG IS TERMINATED.                    DHCG 710
C           AUX    - DOUBLE PRECISION AUXILIARY STORAGE ARRAY WITH 16   DHCG 720
C                    ROWS AND NDIM COLUMNS.                             DHCG 730

Subroutines HPCL and DHPCL

These subroutines use Hamming's modified predictor-corrector method for the solution of linear initial - value problems. The purpose of this version of Hamming's modified predictor-corrector method is to obtain an approximate solution of a linear system of first-order ordinary differential equations with given initial values.† It is a stable fourth-order integration procedure, requiring the evaluation of the right-hand side of the system only two times per step. This is a great advantage compared with other methods of the same order of accuracy, especially the Runge-Kutta method, which requires the evaluation of the right-hand side four times per step. Another advantage is that at each step the calculation procedure gives an estimate for the local truncation error; thus the procedure is able -- without a significant amount of calculation time -- to choose and change the step size h. On the other hand, Hamming's predictor-corrector method is not self-starting; that is, the functional values at a single previous point are not enough to obtain the functional values ahead. Therefore, to get the starting values, a special Runge-Kutta procedure followed by one iteration step is added to the predictor-corrector method.

Given the linear system of first-order ordinary differential equations:

$$y'_1 = \frac{dy_1}{dx} = a_{11}(x)\,y_1 + a_{12}(x)\,y_2 + \ldots + a_{1n}(x)\,y_n + f_1(x)$$

$$y'_2 = \frac{dy_2}{dx} = a_{21}(x)\,y_1 + a_{22}(x)\,y_2 + \ldots + a_{2n}(x)\,y_n + f_2(x)$$

$$\ldots\ldots\ldots\ldots\ldots\ldots$$

$$y'_n = \frac{dy_n}{dx} = a_{n1}(x)\,y_1 + a_{n2}(x)\,y_2 + \ldots + a_{nn}(x)\,y_n + f_n(x)$$

---

† Solution can be done with subroutines HPCG and DHPCG too. The main reason for this special version, suitable to systems of linear differential equations, is that external subroutines furnished by the user for the solution of linear boundary-value problems can be used without changes by subroutine HPCL or DHPCL for the solution of corresponding linear initial-value problems.

and the initial values:

$$y_1(x_0) = y_{1,0},\ y_2(x_0) = y_{2,0},\ \ldots,\ y_n(x_0) = y_{n,0}$$

and using the following vector and matrix notations:

$$Y(x) = \begin{pmatrix} y_1(x) \\ y_2(x) \\ \vdots \\ y_n(x) \end{pmatrix}, \qquad f(x) = \begin{pmatrix} f_1(x) \\ f_2(x) \\ \vdots \\ f_n(x) \end{pmatrix},$$

$$A(x) = \begin{pmatrix} a_{11}(x)\ a_{12}(x) \ldots a_{1n}(x) \\ a_{21}(x)\ a_{22}(x) \ldots a_{2n}(x) \\ \cdots\cdots \\ a_{n1}(x)\ a_{n2}(x) \ldots a_{nn}(x) \end{pmatrix}$$

$$\text{and } Y_0 = \begin{pmatrix} y_{1,0} \\ y_{2,0} \\ \vdots \\ y_{n,0} \end{pmatrix}$$

where Y, F and Y_0 are column vectors and A is an n by n square matrix, the given problem appears as follows:

$$Y' = \frac{dY}{dx} = A(x) * Y + F(x) \text{ with } Y(x_0) = Y_0$$

For stability purposes, the modification by Hamming of Milne's classical modified predictor-corrector method is preferred. Thus, knowing the results at the equidistant points x_{j-3}, x_{j-2}, x_{j-1} and x_j, the results at point $x_{j+1} = x_j + h$ are computed by the formulas given below.

Predictor:
$$P_{j+1} = Y_{j-3} + \frac{4h}{3}(2Y'_j - Y'_{j-1} + 2Y'_{j-2}) \qquad (1)$$

Modifier:
$$M_{j+1} = P_{j+1} - \frac{112}{121}(P_j - C_j) \qquad (2)$$

$$M'_{j+1} = A(x_{j+1}) * M_{j+1} + F(x_{j+1}) \qquad (3)$$

Corrector:
$$C_{j+1} = \frac{1}{8}\left[9Y_j - Y_{j-2} + 3h(M'_{j+1} + 2Y'_j - Y'_{j-1})\right] \qquad (4)$$

Final Value:
$$Y_{j+1} = C_{j+1} + \frac{9}{121}(P_{j+1} - C_{j+1}) \qquad (5)$$

where Y, Y', P, M, M' and C are all column vectors with n components, and A is an n by n square matrix. Formulas (1) and (4) have local truncation errors:

$$T_1 = \frac{14}{45}h^5 Y^{(5)}(\xi_1) \text{ with } \xi_1 \in (x_{j-3}, x_{j+1})$$

and

$$T_2 = -\frac{1}{40}h^5 Y^{(5)}(\xi_2) \text{ with } \xi_2 \in (x_{j-2}, x_{j+1})$$

respectively such that

$$C_{j+1} - P_{j+1} = \frac{121}{360}h^5 Y^{(5)}(\xi) \text{ with } \xi \in (x_{j-3}, x_{j+1})$$

Assuming that $Y^{(5)}(x)$ does not vary to any great extent in the interval (x_{j-3}, x_{j+1}), it follows that:

$$T_2 \approx \frac{9}{121}(P_{j+1} - C_{j+1})$$

This formula shows that the components of column vector $P_{j+1} - C_{j+1}$ are measures for the local truncation errors in the components of column vector Y_{j+1}. Therefore, control of accuracy and adjustment of step size h can be done by generating the following test value:

$$\delta = \sum_{i=1}^{n} a_i \cdot \left| P_{j+1,i} - c_{j+1,i} \right| \qquad (6)$$

where the coefficients a_i $(i = 1, 2, \ldots, n)$ are error-weights specified in the input of the procedure.

If δ is greater than a given tolerance ε†, increment h is halved and the procedure computes $Y_{j-\frac{1}{2}}$ -- that is, $Y(x_j + \frac{h}{2})$ -- after having interpolated $Y_{j-\frac{1}{2}} = Y(x_j - \frac{h}{2})$ and $Y_{j-\frac{3}{2}} = Y(x_j - \frac{3h}{2})$, with previous increment h, using the following sixth-order interpolation formulas:

$$Y_{j-\frac{1}{2}} = \frac{1}{256}(80Y_j + 135Y_{j-1} + 40Y_{j-2} + Y_{j-3}) + \frac{h}{2} \cdot \frac{15}{128}(-Y'_j + 6Y'_{j-1} + Y'_{j-2}) \qquad (7)$$

† Numerical experience seems to show that the procedure does not exceed a global relative error approximately equal to ε.

$$Y_{j-\frac{3}{2}} = \frac{1}{256}(12\,Y_j + 135\,Y_{j-1} + 108\,Y_{j-2} + Y_{j-3}) + \frac{h}{2} \cdot \frac{3}{128}(-Y'_j - 18\,Y'_{j-1} + 9\,Y'_{j-2}) \quad (8)$$

If δ is less than ε, the result Y_{j+1} is assumed to be correct and is handed, together with x_{j+1} and the vector of derivatives Y'_{j+1}, to a user-supplied output subroutine.

If δ is less than $\varepsilon/50$, the next step is carried out with the doubled increment. However, care is taken in the procedure, so that the increment never becomes greater than the increment h specified as an input parameter, and further that among the output are all points $x_0 + j \cdot h$ (where $j = 0, 1, 2, \ldots$, and h is the input step size) which are situated between the lower and the upper bound of the integration interval.

Changing the step size by halving or doubling requires changing of $P_j - C_j$ or $P_{j+1} - C_{j+1}$ respectively. Using the following interpolation formula:

$$Y_j = Y_{j-3} + \frac{3}{8}h\,(Y'_{j-3} + 3Y'_{j-2} + 3Y'_{j-1} + Y_j) - \frac{3}{80}h^5\,Y^{(5)}(\xi_3)$$

with

$$\xi_3\ \varepsilon(x_{j-3},\ x_j)$$

and assuming that $Y^{(5)}(x)$ does not vary to any great extent in this interval, $P_j - C_j$ can be written in the following form:

$$P_j - C_j \approx \frac{242}{27}(Y_j - Y_{j-3}) - \frac{121}{36}h\,(Y'_j + 3Y'_{j-1} + 3Y'_{j-2} + Y'_{j-3})$$

When halving increment h, this formula becomes:

$$P_j - C_j \approx \frac{242}{27}(Y_j - Y_{j-\frac{3}{2}}) - \frac{121}{36} \cdot \frac{h}{2}(Y'_j + 3Y'_{j-\frac{3}{2}} + 3Y'_{j-1} + Y'_{j-\frac{3}{2}}) \quad (9)$$

and when doubling:

$$P_{j+1} - C_{j+1} \approx \frac{242}{27}(Y_{j+1} - Y_{j-5}) - \frac{121}{36} \cdot 2h\,(Y'_{j+1} + 3Y'_{j-1} + 3Y'_{j-3} + Y'_{j-5}) \quad (10)$$

Starting Hamming's modified predictor-corrector method requires the functional and derivative values at four preceding equidistant points: x_0, x_1, x_2 and x_3. The values Y_0 and $Y'_0 = A(x_0) * Y_0 + F(x_0)$ are specified by input. For computation of Y_1, Y'_1, Y_2, Y'_2, Y_3 and Y'_3 and for adjustment of step size h to accuracy requirements, a special Runge-Kutta procedure suggested by Ralston is used. Starting at x_j, result values at point $x_{j+1} = x_j + h$ are computed using the following formulas:

$$K_1 = h \cdot Y'_j \quad (11)$$

$$K_2 = h \cdot [A(x_j + 0.4\,h) * (Y_j + 0.4\,K_1) + F(x_j + 0.4\,h)] \quad (12)$$

$$K_3 = h \cdot [A(x_j + 0.45573725421878943\,h) * (Y_j + 0.29697760924775360\,K_1 + 0.15875964497103583\,K_2) + F(x_j + 0.45573725421878943\,h)] \quad (13)$$

$$K_4 = h \cdot [A(x_j + h) * (Y_j + 0.21810038822592047\,K_1 - 3.0509651486929308\,K_2 + 3.8328647604670103\,K_3) + F(x_j + h)] \quad (14)$$

$$Y_{j+1} = Y_j + 0.17476028226269037\,K_1 - 0.55148066287873294\,K_2 + 1.2055355993965235\,K_3 + 0.17118478121951903\,K_4 \quad (15)$$

where Y_j, Y_{j+1}, Y'_j, K_1, K_2, K_3 and K_4 are all column vectors with n components, and A is an n by n square matrix. These formulas are not very stable, but this does not matter because they are used only in three successive steps ($j = 0, 1, 2$). On the other hand, they have the smallest bound of truncation errors of all fourth-order Runge-Kutta procedures. Therefore they are best suited to start other integration methods which are not self-starting.

For initial control of accuracy and adjustment of step size h, in starting the procedure an approximation for $Y_2 = Y(x_0 + h)$ called $Y_2^{(1)}$ is computed using the step size h, and then an approximation called $Y_2^{(2)}$, using the step size h/2 twice. From these two approximations, a test value δ for accuracy is generated in the following way:

$$\delta = \frac{1}{15} \sum_{i=1}^{n} a_i \cdot \left| y_{2,i}^{(1)} - y_{2,i}^{(2)} \right| \qquad (16)$$

If δ is greater than ε, increment h is halved and the procedure starts anew at point x_0.

If δ is less than ε, the results $Y_1^{(2)} = Y(x_0 + \frac{h}{2})$ and $Y_2^{(2)} = Y(x_0 + h)$ are assumed to be correct and a third step follows which computes the results at point $x_0 + \frac{3h}{2}$ -- that is, $Y_3 = Y(x_0 + \frac{3}{2}h)$.

The step size h/2 of these three steps is used as initial step size h in the predictor-corrector method.

It is very important that the starting values be as accurate as possible, because errors in these starting values may increase during the following predictor-corrector procedure. Therefore the starting values computed by the Runge-Kutta method are refined by one iteration step using the following fourth-order interpolation formulas:

$$Y_1 = Y_0 + \frac{h}{24}(9\,Y'_0 + 19\,Y'_1 - 5\,Y'_2 + Y'_3) \qquad (17)$$

$$Y_2 = Y_0 + \frac{h}{3}(Y'_0 + 4\,Y'_1 + Y'_2) \qquad (18)$$

$$Y_3 = Y_0 + \frac{3h}{8}(Y'_0 + 3\,Y'_1 + 3\,Y'_2 + Y'_3) \qquad (19)$$

which must be considered as an iteration procedure. That is, first the result values of the Runge-Kutta method are handed to the right-hand side of formula (17) to compute a refined Y_1. After having computed the refined Y'_1, the refined vector Y_2 is generated using formula (18). Finally, refined Y'_2 is used, together with the other values, in the right-hand side of formula (19) to compute the refined vector Y_3. During this iteration, the refined data sets x_j, Y_j, Y'_j are handed, together with the number of bisections of the initial step size (specified by input), to the output subroutine.

It can be shown that, using this iterative procedure, the initial column vector $P_3 - C_3$ used in formula (2) for j = 3 is equal to zero.

The entire input of the procedure is:

1. Lower and upper bound of the integration interval, initial step size h of the independent variable, and upper bound ε of the local truncation error

2. Initial values Y_0 of the dependent variables and weights a_i (i = 1,2, ..., n) for the local truncation errors in each component of the dependent variables

3. The number n of differential equations in the system

4. As external subroutine subprograms, the computation of the right-hand side matrix A of the system of linear differential equations and of the inhomogeneous vector F; for flexibility in output, an output subroutine

5. An auxiliary storage array with 16 rows and n columns

6. An n by n matrix as auxiliary storage array

Output is done in the following way. If a set of approximations to the dependent variables Y (x) is found to be of sufficient accuracy, it is handed -- together with x, the derivative Y' (x), the number of bisections of the initial increment, the number of differential equations, the lower and upper bound of the interval, the initial step size, error bound ε, and a parameter for terminating subroutine HPCL or DHPCL -- to the output subroutine. By means of this output subroutine, the user has the opportunity to choose his own output format, to handle the output values as he wants, to change the upper error bound and to terminate subroutine HPCL or DHPCL at any output point. In particular, the user is able to drop the output of some intermediate points, printing only the result values at the special points $x_0 + j \cdot h$, where j = 0, 1, 2, ..., and he is the initial step size specified by input. The user may also perform intermediate computation using the integration results before continuing the process. For better understanding of the flowchart and of the FORTRAN program, see the allocation of special intermediate result vectors within the storage array AUX, shown previously in Figure 12.

Subroutines LBVP and DLBVP

These subroutines generate an approximate solution of a given linear boundary-value problem consisting of a system of linear first-order ordinary differential equations with linear boundary conditions. Solution is done by the method of adjoint equations, which generates successively adjoint initial-value problems. By means of the solutions of these adjoint initial-value problems (done by Hamming's modified predictor-corrector method) it is possible to generate missing boundary conditions, which are necessary to compute initial values suitable to the given boundary-value problem (done by subroutine GELG or DGELG: solution of simultaneous linear equations by means of Gauss elimination). Thus the boundary-value problem is reduced to a linear initial-value problem, which is finally solved by Hamming's modified predictor-corrector method also.

Given the system of n linear first-order ordinary differential equations:

$$\left.\begin{aligned}
y'_1 \equiv \frac{dy_1}{dx} &= a_{11}(x)y_1 + a_{12}(x)y_2 + \cdots \\
&\quad + a_{1n}(x)y_n + f_1(x) \\
y'_2 \equiv \frac{dy_2}{dx} &= a_{21}(x)y_1 + a_{22}(x)y_2 + \cdots \\
&\quad + a_{2n}(x)y_n + f_2(x) \\
&\cdots\cdots \\
y'_n \equiv \frac{dy_n}{dx} &= a_{n1}(x)y_1 + a_{n2}(x)y_2 + \cdots \\
&\quad + a_{nn}(x)y_n + f_n(x)
\end{aligned}\right\}$$

together with n boundary conditions:

$$\left.\begin{aligned}
&b_{11}y_1(x_l)+b_{12}y_2(x_l)+\cdots+b_{1n}y_n(x_l)+c_{11}y_1(x_u) \\
&+c_{12}y_2(x_u)+\cdots+c_{1n}y_n(x_u) = r_1 \\
&b_{21}y_1(x_l)+b_{22}y_2(x_l)+\cdots+b_{2n}y_n(x_l)+c_{21}y_1(x_u) \\
&\quad +c_{22}y_2(x_u)+\cdots+c_{2n}y_n(x_u) = r_2 \\
&\cdots\cdots \\
&b_{n1}y_1(x_l)+b_{n2}y_2(x_l)+\cdots+b_{nn}y_n(x_l)+c_{n1}y_1(x_u) \\
&\quad +c_{n2}y_2(x_u)+\cdots+c_{nn}y_n(x_u) = r_n
\end{aligned}\right\}$$

where x_l and x_u are the lower and upper bound respectively of the integration interval, and using the following vector and matrix notations:

$$Y(x) = \begin{pmatrix} y_1(x) \\ y_2(x) \\ \vdots \\ y_n(x) \end{pmatrix}, \quad F(x) = \begin{pmatrix} f_1(x) \\ f_2(x) \\ \vdots \\ f_n(x) \end{pmatrix},$$

$$Y_l = \begin{pmatrix} y_1(x_l) \\ y_2(x_l) \\ \vdots \\ y_n(x_l) \end{pmatrix}, \quad Y_u = \begin{pmatrix} y_1(x_u) \\ y_2(x_u) \\ \vdots \\ y_n(x_u) \end{pmatrix},$$

$$R = \begin{pmatrix} r_1 \\ r_2 \\ \vdots \\ r_n \end{pmatrix},$$

$$A(x) = \begin{pmatrix} a_{11}(x)a_{12}(x)\ldots a_{1n}(x) \\ a_{21}(x)a_{22}(x)\ldots a_{2n}(x) \\ \ldots \\ a_{n1}(x)a_{n2}(x)\ldots a_{nn}(x) \end{pmatrix}$$

$$B = \begin{pmatrix} b_{11}b_{12}\ldots b_{1n} \\ b_{21}b_{22}\ldots b_{2n} \\ \ldots \\ b_{n1}b_{n2}\ldots b_{nn} \end{pmatrix} \quad \text{and}$$

$$C = \begin{pmatrix} c_{11}c_{12}\ldots c_{1n} \\ c_{21}c_{22}\ldots c_{2n} \\ \ldots \\ c_{n1}c_{n2}\ldots c_{nn} \end{pmatrix}$$

where Y(x), F(x), Y_l, Y_u and R are column vectors with n components, and A(x), and B and C are n by n square matrices, the given problem appears as follows:

$$Y' \equiv \frac{dY}{dx} = A(x) * Y + F(x) \tag{1}$$

with

$$B * Y_l + C * Y_u = R \tag{2}$$

The first problem is to generate new boundary conditions. Assuming that B has fewer zero-columns than C†, the procedure eliminates Y_u from the boundary conditions and generates a system of simultaneous linear equations for the unknown initial values $y_1(x_l)$, $y_2(x_l)$, ..., $y_n(x_l)$. This is done in the following way.

Assuming that the k^{th} column of matrix C (k = 1, 2, ..., n) contains at least one nonzero element (that is, $y_k(x_u)$ appears in the boundary conditions), the following adjoint linear initial-value problem is generated and solved by Hamming's modified predictor-corrector method:

$$\left.\begin{aligned} z'_1(x) &\equiv \frac{dz_1}{dx} = -a_{11}(x)z_1 - a_{21}(x)z_2 - \ldots \\ &\quad - a_{n1}(x)z_n \\ z'_2(x) &\equiv \frac{dz_2}{dx} = -a_{12}(x)z_1 - a_{22}(x)z_2 - \ldots \\ &\quad - a_{n2}(x)z_n \\ &\ldots \\ z'_n(x) &\equiv \frac{dz_n}{dx} = -a_{1n}(x)z_1 - a_{2n}(x)z_2 - \ldots \\ &\quad - a_{nn}(x)z_n \end{aligned}\right\}$$

with initial values:

$$z_1(x_u) = 0, \; z_2(x_u) = 0, \ldots, z_{k-1}(x_u) = 0, \; z_k(x_u) = 1, \; z_{k+1}(x_u) = 0, \ldots, z_n(x_u)$$

or in vector and matrix notations††:

$$Z' \equiv \frac{dZ}{dx} = -A^T(x) * Z \tag{3}$$

with initial values $Z(x_u) = E_k$ (4)

† If this is not the case, the procedure interchanges x_l with x_u and B with C, in order to get a minimum number of adjoint initial-value problems.

†† As vectors Z and Z' are actually stored in the same storage arrays as Y and Y', in the flowchart and the FORTRAN program they are also named Y and DERY.

where $A^T(x)$ is the transpose of $A(x)$, and E_k is the column vector with only one nonzero element; that is, 1 as k^{th} element.

Assuming that $Z_k(x)$ is the solution of this k^{th} adjoint initial-value problem, and using equations (1) and (3), then:

$$\frac{d}{dx}\left[\sum_{i=1}^{n} z_i^{(k)}(x) \cdot y_i(x)\right] = \frac{d}{dx}\left[Z_k^T(x) * Y(x)\right]$$

$$= Z_k^T(x) * Y'(x) + Z'^T(x) * Y(x)$$

$$= Z_k^T * (A * Y + F) + (-A^T * Z_k)^T * Y$$

$$= Z_k^T * A * Y + Z_k^T * F - Z_k^T * A * Y$$

$$= Z_k^T * F$$

from which it follows that:

$$\frac{d}{dx}\left[\sum_{i=1}^{n} z_i^{(k)}(x) \cdot y_i(x)\right] = \left[\sum_{i=1}^{n} z_i^{(k)}(x) \cdot f_i(x)\right]$$

Integrating this equation from x_l up to x_u the result is:

$$\sum_{i=1}^{n} z_i^{(k)}(x_u) \cdot y_i(x_u) - \sum_{i=1}^{n} z_i^{(k)}(x_l)\, y_i(x_l)$$

$$= \int_{x_l}^{x_u} \left[\sum_{i=1}^{n} z_i^{(k)}(x) \cdot f_i(x)\right] dx$$

or:

$$y_k(x_u) = \sum_{i=1}^{n} z_i^{(k)}(x_l) \cdot y_i(x_l) - sum_k(x_l) \qquad (5)$$

with:

$$sum_k(x_l) = \int_{x_u}^{x_l} \left[\sum_{i=1}^{n} z_i^{(k)}(x) \cdot f_i(x)\right] dx \qquad (6)$$

Elimination of $y_k(x_u)$ in the boundary conditions can be done by the following transformation formulas, which transform matrix B_{k-1} and column vector R_{k-1} into matrix B_k and column vector R_k (with $B_0 = B$ and $R_0 = R$) on the storage locations of B and R:

$$\left.\begin{aligned} b_{ij}^{(k)} &= b_{ij}^{(k-1)} + c_{ik} \cdot z_j^{(k)}(x_l) \quad (j = 1, 2, \ldots, n) \qquad (7) \\ r_i^{(k)} &= r_i^{(k-1)} + c_{ik} \cdot sum_k(x_l) \qquad (8) \end{aligned}\right\} (i = 1, 2, \ldots, n)$$

If the k^{th} column of matrix C contains only zero-elements (that is, $y_k(x_u)$ does not appear in the boundary conditions), elimination of $y_k(x_u)$ is not necessary, and k can at once be increased by one.

If at least all $y_k(x_u)$ ($k = 1, 2, \ldots, n$) in the boundary conditions are eliminated, the remaining system of simultaneous linear equations

$$B_n * Y_l = R_n \qquad (9)$$

is solved by Gauss elimination (subroutine GELG or DGELG). However, this is only possible if matrix B_n is not singular. In case of a singular matrix B_n (that is, the pivot element at any elimination step is exactly equal to zero), the procedure is bypassed, giving an error message which shows that the given boundary-value problem has no or more than one solution, or that the method of adjoint equations was not able to find a solution because one or more of the generated new boundary conditions were linear combinations of the given boundary conditions.

There is another critical case in the solution of equation (9), indicated by a warning given by subroutine GELG or DGELG which means possible loss of significance in the Gauss elimination of at least as many significant digits as specified by the upper bound ε of the local truncation error in the integration procedures. If this warning appears, it is highly probable that matrix B_n is singular too. But as this may not necessarily be the case, the procedure goes on after having given a warning to the user's output subroutine in the form of a negative number of bisections of the initial step size together with the resulting initial values of the finally generated initial-value problem (first set of output values). The absolute value of this "warning parameter" indicates the step of the Gauss algorithm immediately preceding the detection of the loss of significance.

After the vector of initial values Y_l is computed (that is after the boundary-value problem is reduced to an initial-value problem), the final step to solve the generated initial-value problem is done by

Hamming's modified predictor-corrector method, incorporated in subroutines LBVP and DLBVP.

Both the solution of adjoint linear initial-value problems described above and the solution of the finally generated linear initial-value problem equivalent to the given boundary-value problem are done by means of Hamming's modified predictor-corrector method for systems of linear differential equations. An extensive description of this method can be found in the mathematical description of subroutines HPCL and DHPCL (except that control of accuracy and adjustment of step size is done differently). Therefore it will be sufficient to give a short description of this method in the form of a notation of the formulas used.

1. Problem to be solved --
System of linear differential equations $Y' = L(x, Y)$ with initial values $Y(x_0) = Y_0$, $Y'(x_0) = L(x_0, Y_0) = Y'_0$
For adjoint initial-value problems, this is:

$$Y' \equiv L(x, Y) = -A^T(x) * Y$$

$$x_0 = x_u,\ Y(x_0) = E_k,\ Y'(x_0) = -A^T(x_0) * E_k,\ h = \frac{1}{16}(x_1 - x_u)$$

and for the finally generated initial-value problem:

$$Y' = L(x, Y) = A(x) * Y + F(x)$$

$$x_0 = x_1,\ Y_0 = Y_1,\ Y'_0 = A(x_1) * Y_1 + F(x_1)$$

2. Hamming's modified predictor-corrector formulas -- (h represents the step size adjusted to accuracy requirements) for j = 3, 4, 5, ... (that means at points $x_j = x_3, x_4, x_5, \ldots$)

Predictor:
$$P_{j+1} = Y_{j-3} + \frac{4}{3}h\,(2\,Y'_j - Y'_{j-1} + 2\,Y'_{j-2}) \quad (10)$$

Modifier:
$$M_{j+1} = P_{j+1} - \frac{112}{121}(P_j - C_j) \quad (11)$$

$$M'_{j+1} = L(x_{j+1}, M_{j+1}) \quad (12)$$

Corrector:
$$C_{j+1} = \frac{1}{8}\left[9\,Y_j - Y_{j-2} + 3\,h \cdot (M'_{j+1} + 2Y'_j - Y'_{j-1})\right] \quad (13)$$

Final value:
$$Y_{j+1} = C_{j+1} + \frac{9}{121}(P_{j+1} - C_{j+1}) \quad (14)$$

3. Test value for control of accuracy and adjustment of step size h in predictor-corrector part ("local truncation error")†:

$$\delta = \max_i \frac{a_i \cdot |p_{j+1,\,i} - c_{j+1,\,i}|}{\max(1, |y_{j+1,\,i}|)} \quad (15)$$

with error weights $a_i = 1$ $(i=1,2,\ldots,n)$ for the adjoint initial-value problems, and given by input for the finally generated initial-value problem.
Adjustment of step size h: halving, if $\delta > \varepsilon$
doubling, if $\delta \leqq \varepsilon/50$
with the upper bound ε for the local truncation error given by input.

4. Formulas for interpolating intermediate points in case of halving the step size h:

$$Y_{j-1/2} \equiv Y(x_j - \frac{h}{2}) = \frac{1}{256}(80Y_j + 135Y_{j-1} + 40Y_{j-2} + Y_{j-3}) - \frac{h}{2} \cdot \frac{15}{128} \cdot (Y'_j - 6Y'_{j-1} - Y'_{j-2}) \quad (16)$$

$$Y_{j-3/2} \equiv Y(x_j - \frac{3h}{2}) = \frac{1}{256}(12Y_j + 135Y_{j-1} + 108Y_{j-2} + Y_{j-3}) - \frac{h}{2} \cdot \frac{3}{128} \cdot (Y'_j + 18Y'_{j-1} - 9Y'_{j-2}) \quad (17)$$

5. Changing vectors $P_j - C_j$ in case of halving, or $P_{j+1} - C_{j+1}$ in case of doubling the step size h:

$$P_j - C_j = \frac{242}{27}(Y_j - Y_{j-3/2}) - \frac{121}{36} \cdot \frac{h}{2}(Y'_j + 3Y'_{j-1/2} + 3Y'_{j-1} + Y'_{j-3/2}) \quad (18)$$

$$P_{j+1} - C_{j+1} = \frac{242}{27}(Y_{j+1} - Y_{j-5}) - \frac{121}{36} \cdot 2h\,(Y'_{j+1} + 3Y'_{j-1} + 3Y'_{j-3} + Y'_{j-5}) \quad (19)$$

† The terms from which δ is generated by searching for the maximum are weighted relative errors if the absolute values of $y_{j+1,i}(x)$ are greater than 1, and weighted absolute errors if the absolute values are not greater than 1.

6. Starting Hamming's modified predictor-corrector method by means of three Runge-Kutta steps:

For $j = 0, 1, 2$

$$K_1 = h \cdot Y'_j \tag{20}$$

$$K_2 = h \cdot L(x_j + 0.4h,\ Y_j + 0.4K_1) \tag{21}$$

$$K_3 = h \cdot L(x_j + 0.4557372542187894\,3\ h,\ Y_j + 0.29697760924775360\ K_1 + 0.15875964497103583\ K_2) \tag{22}$$

$$K_4 = h \cdot L(x_j + h,\ Y_j + 0.21810038822592047\ K_1 - 3.0509651486929308\ K_2 + 3.8328647604670103\ K_3) \tag{23}$$

$$Y_{j+1} = Y_j + 0.17476028226269037\ K_1 - 0.55148066287873294\ K_2 + 1.2055355993965235\ K_3 + 0.17118478121951903\ K_4 \tag{24}$$

7. Test value for control of accuracy and adjustment of step size h in the Runge-Kutta part ("local truncation error")†:

$$\delta = \frac{1}{15} \cdot \max_i \frac{a_i \left| y^{(1)}_{2,i} - y^{(2)}_{2,i} \right|}{\max\left(1, \left| y^{(2)}_{2,i} \right|\right)} \tag{25}$$

with error weights $a_i = 1$ ($i = 1, 2, \ldots, n$) for adjoint initial-value problems and given by input for the finally generated initial-value problem. Step size h is adjusted by halving if $\delta > \varepsilon$, with the upper bound ε of the local truncation error given by input.

† The terms from which δ is generated by searching for the maximum are weighted relative errors if the absolute values of $y^{(2)}_{2,i}$ are greater than 1, and weighted absolute errors if the absolute values are not greater than 1.

8. Iteration formulas for refinement of Runge-Kutta results:

$$Y_1 = Y_0 + \frac{h}{24}(9\,Y'_0 + 19\,Y'_1 - 5\,Y'_2 + Y'_3) \tag{26}$$

$$Y_2 = Y_0 + \frac{h}{3}(Y'_0 + 4\,Y'_1 + Y'_2) \tag{27}$$

$$Y_3 = Y_0 + \frac{3h}{8}(Y'_0 + 3Y'_1 + 3Y'_2 + Y'_3) \tag{28}$$

As transformation formulas (7) and (8) show, the output of Hamming's modified predictor-corrector method for the solution of any adjoint initial-value problem must contain only the vector $Z_k(x_1)$ of function values at the lower bound x_1 (actually stored in vector Y) and the integral value $sum_k(x_1)$. With respect to the predictor-corrector method, which is a fourth-order integration procedure generating function vectors $Z_k(x)$ (in storage array Y) and derivative vectors $Z'_k(x)$ (in storage array DERY) at intermediate (not necessarily equidistant) points x, the following fourth-order Hermitian integration formula -- using the function and the first derivative values of the function to be integrated -- is suitable to accumulate integral values $sum_k(x)$ and finally $sum_k(x_1)$:

$$sum_k(x+h) = sum_k(x) + \frac{h}{2}\left\{ g_k(x) + g_k(x+h) + \frac{h}{6}\left[g'_k(x) - g'_k(x+h) \right] \right\} \tag{29}$$

using the instantaneous step size h of the predictor-corrector method, and with:

$$g_k(x) = \sum_{i=1}^{n} z_i^{(k)}(x)\, f_i(x) = Z_k^T(x) + F(x) \tag{30}$$

and:

$$g'_k(x) = \sum_{i=1}^{n} \left[\frac{dz_i^{(k)}}{dx} \cdot f_i(x) + z_i^{(k)}(x) \cdot \frac{df_i}{dx} \right] = \frac{dZ_k^T}{dx} * F(x) + Z_k^T(x) * \frac{dF}{dx} \tag{31}$$

Therefore, generation of sum_k (x+h) is done by means of the following formulas:

$$g_u^{(k)} = g_k(x+h) = \sum_{i=1}^{n} z_i^{(k)}(x+h)\, f_i(x+h)$$

$$= Z_k^T(x+h) * F(x+h) \tag{32}$$

$$dg_u^{(k)} = g'_k(x+h) = \sum_{i=1}^{n} \left[z'^{(k)}_i(x+h)\, f_i(x+h) + z_i^{(k)}(x+h)\, f'_i(x+h) \right] = Z'^T_k(x+h) * F(x+h)$$

$$+ Z_k^T(x+h) * F'(x+h) \tag{33}$$

$$sum_k(x+h) = sum_k(x) + \frac{h}{2}\left[g_1^{(k)} + g_u^{(k)} + \frac{h}{6}(dg_1^{(k)} - dg_u^{(k)}) \right] \tag{34}$$

After these three formulas have been evaluated, $g_u^{(k)}$ becomes $g_1^{(k)}$, and $dg_u^{(k)}$ becomes $dg_1^{(k)}$. Initial values of $g_1^{(k)}$ and $dg_1^{(k)}$ are generated, using formulas (30) and (31) at point $x = x_u$, leading to:

$$g_1^{(k)} = g_k(x_u) = f_k(x_u) \tag{35}$$

and:

$$dg_1^{(k)} = g'_k(x_u) = f'_k(x_u) - \sum_{i=1}^{n} a_{ki}(x_u) \cdot f_i(x_u) \tag{36}$$

The entire input of subroutines LBVP and DLBVP is:

1. Lower and upper bound x_l and x_u of the integration interval, initial step size h of the independent variable and upper bound ε (≤ 1) of the local "relative" truncation error in integration procedures

2. Coefficient matrices B and C of vectors Y_l and Y_u in boundary conditions and right-hand side vector R

3. Vector of error weights a_i (i = 1, 2, ..., n) for the local "relative" truncation error in each component of the dependent variables ($a_i \leq 1$ for all i)

4. The number n of differential equations and boundary conditions

5. As external subroutine subprograms, the computation of the right-hand side matrix A(x) of the system of linear differential equations, and the computation of the inhomogeneous vector F(x) and of its derivative F'(x); for flexibility in output, an output subroutine

6. A one-dimensional auxiliary storage array with n storage locations, an n by n auxiliary storage array, and a two-dimensional auxiliary storage array (named AUX in flowchart, FORTRAN subroutine, and mathematical description) with 20 rows and n columns

Output is done in the following way. If a set of approximations to the dependent variables Y(x) is found to be of sufficient accuracy (that is $\delta \leq \varepsilon$), it is handed -- together with x, the vector of derivatives Y' (x), the number of bisections of the initial increment, the number of differential equations, the lower and upper bound of the integration interval, the initial step size, error bound ε, and a parameter for terminating subroutine LBVP or DLBVP -- to the output subroutine. By means of this output subroutine, the user has the opportunity to choose his own output format, to handle the output values as he wants, to change the upper error bound and to terminate subroutine LBVP or DLBVP at any output point (for example, in case of possible loss of accuracy in Gauss elimination). In particular, the user is able to drop the output of some intermediate points, printing only the result values at the special points $x_0 + j \cdot h$, where j = 0, 1, 2, ..., and h is the initial step size specified by input. The user may also perform intermediate computations using the integration results before continuing the process.

For better understanding of the flowchart and of the FORTRAN program, Figure 34 shows the allocation of special intermediate result vectors within the storage array AUX.

Subroutine GMMMA

This subroutine computes the value of the gamma function for a given argument x.
The calculation of the gamma function, $\Gamma(x)$ is defined for $x > 0$ by:

$$\Gamma(x) = \int_0^{\infty} t^{x-1} \cdot e^{-t}\, dt \qquad (1)$$

This function satisfies the recurrence relation:

$$\Gamma(x) = (x-1) \cdot \Gamma(x-1) \qquad (2)$$

which defines $\Gamma(x)$ for any x not a negative integer.

Note that when x is a positive integer, $\Gamma(x) = (x-1)!$

To compute $\Gamma(x)$ for $x > 1$, apply the recurrence (2), r times until $1 < x - r = y \leq 2$. Thus, for $x > 1$:

$$\Gamma(x) = (x-1)\ (x-2)\ \ldots\ (x-r)\ \ \Gamma(y) \qquad (3)$$

$\Gamma(y)$ is computed from the following formula:

$$\begin{aligned}\Gamma(y) \approx 1 &- 0.57710166(y-1) + 0.98585399(y-1)^2 \\ &- 0.87642182(y-1)^3 + 0.83282120(y-1)^4 \\ &- 0.56847290(y-1)^5 + 0.25482049(y-1)^6 \\ &- 0.05149930(y-1)^7\end{aligned} \qquad (4)$$

For $x < 1$, the recurrence (2) is taken in the direction of decreasing n, giving:

$$\Gamma(x) = \frac{\Gamma(y)}{x(x+1)\ (x+2)\ \ldots\ (x+r-1)} \qquad (5)$$

where $1 < x + r = y \leq 2$.

As before, $\Gamma(y)$ is computed using equation (4).

Subroutine DLGAM

This subroutine computes the double-precision natural logarithm of the gamma function of a given double-precision argument, x, where $10^{-9} < x < 10^{70}$. The Euler-McLaurin expansion, to the seventh derivative term, is used. For $x > 0$:

$$\log \Gamma(x) \simeq (x - 1/2) \log x + 1/2 \log 2\pi - x + 1/12\, x - 1/360\, x^3 + 1/1260\, x^5 - 1/1680\, x^7 \qquad (1)$$

This expression is very accurate for $x > 18$. If $x \leq 18$, x is replaced by $z = k + x$, where k is an integer such that $z > 18$. Log $\Gamma(z)$ is then evaluated by (1), and $\log x + \log (x + 1) + \ldots + \log (x + k - 1)$ is subtracted to obtain the desired result.

If x is between 10^{10} and 10^{70}, terms of lowest order in (1) are neglected, and $\log \Gamma(x)$ is computed as:

$$\log \Gamma(x) = x (\log (x) - 1) \qquad (2)$$

Subroutine DLGAM is available in a double-precision format only. If the single-precision value of the log gamma function of a given single-precision argument is desired, subroutine GMMMA should be used along with the FORTRAN-supplied natural logarithm function.

For reference see M. Abramowitz and I.A. Stegun, Handbook of Mathematical Functions. U.S. Department of Commerce, National Bureau of Standards Applied Mathematics Series, 1966, equation 6.1.41.

Subroutine BESJ

This subroutine computes the J Bessel function for a given argument and integer order by using the recurrence relationship:

$$F_{n+1}(x) + F_{n-1}(x) = \left(\frac{2n}{x}\right) F_n(x) \qquad (1)$$

The desired Bessel function is:

$$J_n(x) = \frac{F_n(x)}{\alpha} \qquad (2)$$

where:

$$\alpha = F_0(x) + 2 \sum_{m=1}^{M-2} F_{2m}(x) \qquad (3)$$

M is initialized at M_0.

M_0 is the greater of M_A and M_B where;

$$M_A = \begin{cases} [x+6] & \text{if } x < 5 \\ [1.4x+60/x] & \text{if } x \geq 5 \end{cases}$$

$$M_B = [n+x/4+2]$$

F_{M-2}, F_{M-3}, ..., F_2, F_1, F_0 is evaluated using equation (1) with $F_M = 0$ and $F_{M-1} = 10^{-30}$. Values of α and $J_n(x)$ are then computed using equations (3) and (2) respectively.

The computation is repeated for M+3.

The values of $J_n(x)$ for M and M+3 are compared:

$$\text{If } \left| J_n(x)_M - J_n(x)_{M+3} \right| \leq \delta \left| J_n(x)_{M+3} \right|$$

this value is accepted as $J_n(x)$; if not, the computation is repeated by adding 3 to M and using this as a new value for M. If M reaches M_{MAX} before the desired accuracy is obtained, execution is terminated. M_{MAX} is defined as:

$$M_{MAX} = \begin{cases} \left[20 + 10x - \frac{x^2}{3}\right] & \text{for } x \leq 15 \\ [90 + x/2] & \text{for } x > 15 \end{cases} \qquad (4)$$

```

Subroutine BESY

This subroutine computes the Y Bessel function for a given argument x and order n. The recurrence relation:

$$Y_{n+1}(x) = \left(\frac{2n}{x}\right) \cdot Y_n(x) - Y_{n-1}(x) \qquad (1)$$

is used for this evaluation.

For $x > 4$

$$Y_0(x) = \sqrt{\frac{2}{\pi x}} \left(P_0(x) \sin\left(x - \frac{\pi}{4}\right) + Q_0(x) \cos\left(x - \frac{\pi}{4}\right) \right) \qquad (2)$$

$$Y_1(x) = \sqrt{\frac{2}{\pi x}} \left(-P_1(x) \cos\left(x - \frac{\pi}{4}\right) + Q_1(x) \sin\left(x - \frac{\pi}{4}\right) \right) \qquad (3)$$

$P_0(x)$, $Q_0(x)$, $P_1(x)$, and $Q_1(x)$ are:

$$\frac{1}{\sqrt{2\pi}} P_0\left(\frac{4}{t}\right) = 0.3989422793 - 0.0017530620t^2 + 0.0001734300t^4 - 0.0000487613t^6 + 0.0000173565t^8 - 0.0000037043t^{10} \qquad (4)$$

$$t\frac{1}{\sqrt{2\pi}} Q_0\left(\frac{4}{t}\right) = -0.0124669441 + 0.0004564324t^2 - 0.0000869791t^4 + 0.0000342468t^6 - 0.0000142078t^8 + 0.0000032312t^{10} \qquad (5)$$

$$\frac{1}{\sqrt{2\pi}} P_1\left(\frac{4}{t}\right) = 0.3989422819 + 0.0029218256t^2 - 0.0002232030t^4 + 0.0000580759t^6 - 0.0000200920t^8 + 0.0000042414t^{10} \qquad (6)$$

$$t\frac{1}{\sqrt{2\pi}} Q_1\left(\frac{4}{t}\right) = 0.0374008364 - 0.0006390400t^2 - 0.0001064741t^4 - 0.0000398708t^6 - 0.0000162200t^8 - 0.0000042414t^{10} \qquad (7)$$

where $t = \frac{4}{x}$

For $x \leq 4$

$$Y_0(x) = \frac{2}{\pi} \sum_{m=0}^{15} (-1)^m \left(\frac{x}{2}\right)^{2m} \frac{1}{(m!)^2} \left[\log\frac{x}{2} + \gamma - H_m \right] \qquad (8)$$

where:

$$H_m = \begin{cases} \sum_{r=1}^{m} \frac{1}{r} & \text{if } m \geq 1 \\ 0 & \text{if } m = 0 \end{cases} \qquad (9)$$

and γ = Euler's constant = 0.5772156649

$$Y_1(x) = -\frac{2}{\pi x} + \frac{2}{\pi} \sum_{m=1}^{16} (-1)^{m+1} \left(\frac{x}{2}\right)^{2m-1} \frac{1}{m!\,(m-1)!} \cdot \left[\log\frac{x}{2} + \gamma - H_m + \frac{1}{2m} \right] \qquad (10)$$

Subroutine I0

This subroutine computes the modified Bessel function $I_0(x)$ for a given argument (x).

For $-3.75 \leq x \leq 3.75$; $t = x/3.75$

$$I_0(x) = 1 + 3.515623t^2 + 3.089942t^4 + 1.206749t^6 + 0.2659732t^8 + 0.0360768t^{10} + 0.0045813t^{12} + \epsilon$$

with $|\epsilon| < 1.6 \cdot 10^{-7}$

For $3.75 \leq |x| < \infty$; $t = 3.75/|x|$

$$\sqrt{|x|}\, e^{-|x|} I_0(x) = 0.3989423 + 0.01328592t + 0.00225319t^2 - 0.00157565t^3 + 0.00916281t^4 - 0.02057706t^5 + 0.02635537t^6 - 0.01647633t^7 + 0.00392377t^8 + \epsilon$$

with $|\epsilon| < 1.9 \cdot 10^{-7}$

Subroutine INUE

This subroutine computes the modified Bessel functions $I_1(x)$, $I_2(x)$, ..., $I_n(x)$ for a given argument x, where n is the given maximum order.

The recurrence relation

$$I_{k+1}(x) + \frac{2k}{x} I_k(x) - I_{k-1}(x) = 0 \qquad (1)$$

is used for this evaluation.

From (1) the values

$$G_k = I_k / I_{k-1} \qquad (2)$$

satisfy

$$G_k = \frac{1}{\frac{2k}{x} + G_{k+1}} \qquad (3)$$

Therefore, G_{n+1} may be calculated from the continued fraction

$$G_{n+1} = \frac{1}{\frac{2(n+1)}{x} + \frac{1}{\frac{2(n+2)}{x} + \frac{1}{\frac{2(n+3)}{x} + \cdots}}} \qquad (4)$$

This continued fraction is evaluated using the following forward A-B process:

Let $A_{-1} = 1$, $A_0 = 0$, $A_k = \frac{2(n+k)}{x} A_{k-1} + A_{k-2}$ (5)

$B_{-1} = 0$, $B_0 = 1$, $B_k = \frac{2(n+k)}{x} B_{k-1} + B_{k-2}$

for $k = 1, 2 \ldots$.

Then $G_{n+1} = \lim_{k \to \infty} \frac{A_k}{B_k}$ (6)

From G_{n+1} the values G_n, G_{n-1}, ..., G_1 are obtained

applying (3) successively, with $k = n, n-1, \ldots, 1$.

Finally the values I_1, I_2, ... I_n are computed using $I_k = G_k \cdot I_{k-1}$, where I_0 is the value of (7)
Bessel function I of order zero, for example, as obtained using subroutine I0.

Subroutine BESK

This subroutine computes the K Bessel function for a given argument x and order n. The recurrence relation:

$$K_{n+1}(x) = \frac{2n}{x} K_n(x) + K_{n-1}(x) \tag{1}$$

is used for this evaluation.

The initial values K_0 and K_1 are found as follows:

For x > 1:

$$K_0(x) = e^{-x}\sqrt{\frac{\pi}{2x}}\, G_0(x) \tag{2}$$

$$K_1(x) = e^{-x}\sqrt{\frac{\pi}{2x}}\, G_1(x) \tag{3}$$

where x = 1/t for t < 1:

$$G_0\left(\frac{1}{t}\right)\cdot\sqrt{\frac{\pi}{2}} = 1.2533141 - 0.1566642t + 0.08811128t^2 - 0.09139095t^3 + 0.1344596t^4 - 0.2299850t^5 + 0.3792410t^6 - 0.5247277t^7 + 0.5575368t^8 - 0.4262633t^9 + 0.2184518t^{10} - 0.06680977t^{11} + 0.009189383t^{12} \tag{4}$$

$$G_1\left(\frac{1}{t}\right)\cdot\sqrt{\frac{\pi}{2}} = 1.2533141 + 0.4699927t - 0.1468583t^2 + 0.1280427t^3 - 0.1736432t^4 + 0.2847618t^5 - 0.4594342t^6 + 0.6283381t^7 - 0.6632295t^8 + 0.5050239t^9 - 0.2581304t^{10} + 0.07880001t^{11} - 0.0108242t^{12} \tag{5}$$

For x ≤ 1:

γ = Euler's constant = 0.5772156649 (6)

$$K_0(x) = -\left(\gamma + \log\frac{x}{2}\right) + \sum_{s=1}^{6}\left(\frac{x}{2}\right)^{2s}\frac{1}{(s!)^2}\left[H_s - \left(\gamma + \log\frac{x}{2}\right)\right] \tag{7}$$

where:

$$H_s = \sum_{r=1}^{s}\frac{1}{r} \tag{8}$$

Subroutine EXPI

This subroutine computes the exponential integral for a given value of the argument x.

The exponential integral is defined as:

$$E_1(x) = -Ei(-x) = \int_x^\infty \frac{e^{-t}}{t}\,dt = \int_0^x \frac{1-e^{-t}}{t}\,dt - C - \ln(x)$$

where C = 0.57 ... is Euler's constant.

The integral

$\int_x^\infty \frac{e^{-t}}{t}\,dt$ has a logarithmic singularity at x = 0.

Therefore, it must be evaluated in the Cauchy Principal Value sense for negative values of x.

For x = 0 the routine returns -1.E75 as value of $E_1(x)$.

For $x \geq 1$:

$$AUX = xe^x E_1(x)$$

$$= (x^4 + 8.5733287401x^3 + 18.0590169730x^2 + 8.6347608925x + 0.2677737343)/(x^4 + 9.5733223454x^3 + 25.6329561486x^2 + 21.0996530827x + 3.9584969228) + \epsilon$$

with $|\epsilon| < 2.E-8.$

For $-3 \leq x \leq 1$:

$$AUX = (E_1(x) + \ln|x| + C)/x$$

$$= 9.999999E-1 - 2.500001E-1 \cdot x + 5.555682E-2 \cdot x^2 - 1.041576E-2 \cdot x^3 + 1.664156E-3 \cdot x^4 - 2.335379E-4 \cdot x^5 + 2.928433E-5 \cdot x^6 - 1.766345E-6 \cdot x^7 + 7.122452E-7 \cdot x^7 + \epsilon$$

with $|\epsilon| < 7.3E-8.$

For $-9 \leq x \leq -3$:

$$AUX = xe^{x}E_1(x)$$

$$= 1-(248.6697 + 224.4234x + 32.43665x^2 + 3.061037x^3 + 0.05176245x^4)/(180.7837 + 22.63818x + 38.93944x^2 + 3.995161x^3 + x^4) + \epsilon$$

with $|\epsilon| < 1.3E-7$.

For $-174 \leq x \leq -9$:

$$AUX = xe^{x}E_1(x)$$

$$= 1-(674.567029 + 57.4118330x - 6.05529232x^2 - x^3)/(1699.06552 + 841.654932x + 49.3133893x^2 - 8.01957683x^3 - 0.999792040x^4) + \epsilon$$

with $|\epsilon| < 3.8E-7$.

Subroutine SICI

This subroutine computes the sine and cosine integrals for a given value of the argument x.

These integrals are defined as:

$$si(x) = S_i(x) - \pi/2 = \int_0^x \frac{\sin(t)}{t}\,dt - \pi/2$$

$$ci(x) = C + \ln(x) + \int_0^x \frac{\cos(t)-1}{t}\,dt$$

where C is Euler's constant 0.57 ... .

The integral $\int \frac{\cos(t)}{t}\,dt$ has a logarithmic singularity at x = 0. Therefore, it must be evaluated in the Cauchy Principal Value sense for negative values of x.

For x = 0 the routine returns -1.E75 as value of ci(x).

For $x \leq 4$ and $t = 16-x^2$:

$$(si(x) + \pi/2)/x = 4.395509E\text{-}1 + 1.964882E\text{-}2\cdot t + 6.939889E\text{-}4\cdot t^2 + 1.374168E\text{-}5\cdot t^3 + 1.568988E\text{-}7\cdot t^4 + 1.753141E\text{-}9\cdot t^5 + \epsilon$$

with $|\epsilon| < 8.2E\text{-}8$

$$-(ci(x) - C - \ln|x|)/x^2 = 1.315308E\text{-}1 + 4.990920E\text{-}3\cdot t + 1.185999E\text{-}4\cdot t^2 + 1.725752E\text{-}6\cdot t^3 + 1.584996E\text{-}8\cdot t^4 + 1.386985E\text{-}10\cdot t^5 + \epsilon$$

with $|\epsilon| < 5.6E\text{-}9$.

For x > 4 and t = 4/x:

$$si(x) = -\left(\frac{4}{x}\right)(\cos(x)\cdot P(x) + \sin(x)\cdot Q(x)) + \epsilon$$

$$ci(x) = \left(\frac{4}{x}\right)(\sin(x)\cdot P(x) - \cos(x)\cdot Q(x)) + \epsilon$$

where:

$$|\epsilon| < \frac{1}{x} \cdot 2.3E\text{-}8 \text{ and}$$

$$P(x) = 2.500000E\text{-}1 - 6.646441E\text{-}7\cdot t - 3.122418E\text{-}2\cdot t^2 - 3.764000E\text{-}4\cdot t^3 + 2.601293E\text{-}2\cdot t^4 - 7.945556E\text{-}3\cdot t^5 - 4.400416E\text{-}2\cdot t^6 + 7.902034E\text{-}2\cdot t^7 - 6.537283E\text{-}2\cdot t^8 + 2.819179E\text{-}2\cdot t^9 - 5.108699E\text{-}3\cdot t^{10}$$

$$Q(x) = 2.583989E\text{-}10 + 6.250011E\text{-}2\cdot t - 1.134958E\text{-}5\cdot t^2 - 2.314617E\text{-}2\cdot t^3 - 3.332519E\text{-}3\cdot t^4 + 4.987716E\text{-}2\cdot t^5 - 7.261642E\text{-}2\cdot t^6 + 5.515070E\text{-}2\cdot t^7 - 2.279143E\text{-}2\cdot t^8 + 4.048069E\text{-}3\cdot t^9$$

Subroutine CS

This subroutine computes the Fresnel integrals for a given value of the argument x.

The Fresnel integrals are defined as:

$$C(x) = \frac{1}{\sqrt{2\pi}} \int_0^x \frac{\cos(t)}{\sqrt{t}}\, dt = \int_0^{\sqrt{\frac{2}{\pi}x}} \cos(\tfrac{\pi}{2}u^2)du$$

and

$$S(x) = \frac{1}{\sqrt{2\pi}} \int_0^x \frac{\sin(t)}{\sqrt{t}}\, dt = \int_0^{\sqrt{\frac{2}{\pi}x}} \sin(\tfrac{\pi}{2}u^2)du$$

The subroutine CS calculates both C(x) and S(x) simultaneously.

If x is negative, $|x|$ is used in CS.

For $0 \leq x \leq 4$ and $t = 16 - x^2$:

$$C(x)/\sqrt{x} = 1.840962E\text{-}1 + 1.102544E\text{-}2 \cdot t + 1.020418E\text{-}3 \cdot t^2 + 3.273308E\text{-}5 \cdot t^3 + 5.451182E\text{-}7 \cdot t^4 + 5.244297E\text{-}9 \cdot t^5 + 5.100785E\text{-}11 \cdot t^6 + \epsilon$$

with $|\epsilon| < 8.5E\text{-}9$

$$S(x)/\sqrt{x^3} = 8.026490E\text{-}2 + 6.121300E\text{-}3 \cdot t + 2.441816E\text{-}4 \cdot t^2 + 5.051141E\text{-}6 \cdot t^3 + 5.883158E\text{-}8 \cdot t^4 + 6.677681E\text{-}10 \cdot t^5 + \epsilon$$

with $|\epsilon| < 3.5E\text{-}8$.

For $x > 4$ and $t = 4/x$:

$$C(x) = \frac{1}{2} + \sqrt{\frac{4}{x}}\,(\sin(x) \cdot P(x) + \cos(x) \cdot Q(x)) + \epsilon$$

$$S(x) = \frac{1}{2} + \sqrt{\frac{4}{x}}\,(-\cos(x) \cdot P(x) + \sin(x) \cdot Q(x)) + \epsilon$$

where $|\epsilon| < 1.3E\text{-}8$ and

$$P(x) = 1.994712E\text{-}1 - 1.207998E\text{-}6 \cdot t - 9.314911E\text{-}3 \cdot t^2 - 4.027145E\text{-}4 \cdot t^3 + 7.428246E\text{-}3 \cdot t^4 - 7.271690E\text{-}3 \cdot t^5 + 3.401409E\text{-}3 \cdot t^6 - 6.633926E\text{-}4 \cdot t^7$$

and

$$Q(x) = 4.444091E\text{-}9 - 2.493322E\text{-}2 \cdot t - 1.606428E\text{-}5 \cdot t^2 + 5.972151E\text{-}3 \cdot t^3 - 3.095341E\text{-}4 \cdot t^4 - 6.792801E\text{-}3 \cdot t^5 + 7.970943E\text{-}3 \cdot t^6 - 4.169289E\text{-}3 \cdot t^7 + 8.768258E\text{-}4 \cdot t^8$$

Subroutines CEL1 and DCEL1

These subroutines compute the complete elliptic integral of the first kind. This is defined as:

$$K(k) = \int_0^{\pi/2} \frac{dt}{\sqrt{1-k^2 \sin^2 t}}, \quad 0 \le k < 1$$

An equivalent definition is:

$$K(k) = \int_0^{\infty} \frac{dx}{\sqrt{(1+x^2)(1+k_c^2 x^2)}}$$

where k_c is the complementary modulus:

$$k_c^2 + k^2 = 1, \quad 0 < k_c^2 \le 1$$

The subroutines CEL1, DCEL1 calculate K(k) for given modulus k. The calculation of RES = K(k) is based on the process of the arithmetic-geometric mean.

Starting with the pair of numbers:

$$a_0 = 2, \quad g_0 = 2 \cdot k_c$$

the sequences of numbers (a_n), (g_n) are generated using the definition:

$$a_n = (a_{n-1} + g_{n-1}), \quad g_n = 2\sqrt{a_{n-1} \cdot g_{n-1}}$$

This iterative process is stopped at the N^{th} step, when $a_N = g_N$.

If D is the number of decimal digits in the mantissa of floating-point numbers, then the equality $a_N = g_N$ must be interpreted as $|a_N - g_N|$ is less than $a_N \cdot 10^{-D}$.

Since the sequences $(2^{-(n+1)} a_n)$, $(2^{-(n+1)} g_n)$ converge quadratically to the same limit (arithmetic-geometric mean) the test for the end of iteration may be replaced by comparing $|a_{N-1} - g_{N-1}|$ against $a_{N-1} \cdot 10^{-D/2}$, thus saving one calculation of the geometric mean.

The value of $K(k) = \frac{2^N \pi}{a_N}$.

Subroutines CEL2 and DCEL 2

These subroutines compute the generalized complete elliptic integral of the second kind. This is defined as:

$$\text{cel 2 } (k;\ A,\ B) = \int_0^{\pi/2} \frac{A + (B - A)\sin^2 t}{\sqrt{1 - k^2 \sin^2 t}}\,dt$$

Equivalent is the definition:

$$\text{cel 2 } (k;\ A,\ B) = \int_0^{\infty} \frac{A + Bx^2}{(1 + x^2)\sqrt{(1 + x^2)(1 + k_c^2 x^2)}}\,dx$$

where k_c is the complementary modulus:

$$k_c^2 + k^2 = 1,\quad 0 < k_c^2 \leq 1$$

The subroutines CEL2, DCEL2 calculate cel 2 (k; A, B) for given modulus k and constants A, B. The calculation of RES = cel 2 (k; A, B) is based on the process of the arithmetic-geometric mean.

Starting with the pair of numbers:

$$a_0 = 2,\quad g_0 = 2 \cdot k_c$$

the sequences of numbers (a_n), (g_n) are generated using for definition:

$$a_n = (a_{n-1} + g_{n-1}),\quad g_n = 2\sqrt{a_{n-1}\, g_{n-1}}$$

This iteration process is stopped at the N^{th} step when $a_N = g_N$.

Further needed are the sequences (A_i), (B_i), defined by means of:

$$A_0 = A,\quad B_0 = B$$

$$A_n = B_{n-1}/a_{n-1} + A_{n-1}$$

$$B_n = 2(B_{n-1} + g_{n-1} \cdot A_{n-1})$$

If D is the number of decimal digits in the mantissa of floating-point numbers, the iteration process is stopped as soon as $(a_{N-1} - g_{N-1})$ is less than $a_{N-1} \cdot 10^{-D/2}$.

Since $(2^{-(n+1)}a_n)$, $(2^{-(n+1)}g_n)$ converge quadratically to the same limit (arithmetic-geometric mean), this implies that $(a_N - g_N)$ is less than $a_N \cdot 10^{-D}$.

The value of cel 2 (k, A, B) $= \frac{\pi}{4} \cdot \frac{A_N + 1}{a_N}$

Subroutines ELI1 and DELI1

These subroutines compute the elliptic integral of the first kind, where:

$$\text{eli 1 } (x,\ ck) = \int_0^x \frac{dt}{\sqrt{(1 + t^2)\ (1 + ck^2 t^2)}}$$

Equivalent definitions are:

$$\text{eli 1 } (x,\ ck) = \int_0^{\arctan x} \frac{dt}{\cos t \sqrt{1 + ck^2 \tan^2 t}}$$

$$= \int_0^{\arctan x} \frac{dt}{\sqrt{1 - k^2 \sin^2 t}}$$

where k is the modulus and ck the complementary modulus.

For reason of numerical stability, ck is chosen as input parameter instead of modulus k:

$$0 \leqq ck^2 < \infty \quad \text{and} \quad k^2 + ck^2 = 1.$$

This allows k to be any pure imaginary or real number such that $k^2 \leqq 1$. In standard notation:

$$F\ (\varphi,\ k) = \text{eli 1 } (\tan \varphi,\ ck)$$

Computation is based on the process of the arithmetic-geometric mean together with Landen's transformation:

$$\text{eli 1 } (x,\ ck) = \frac{1}{1 + ck}\ \text{eli 1 } (x_1,\ ck_1)$$

where:

$$ck_1 = \frac{2\sqrt{ck}}{1 + ck}$$

$$x_1 = \frac{(1 + ck)\ x}{1 - ck \cdot x^2}$$

$$\phi_1 = \arctan x_1$$

$$\sin\phi_1 = \frac{x_1}{\sqrt{1 + x_1^2}}$$

The iteration process begins with $ari_0 = 1$, $geo_0 = |ck|$, and the sequences (ari_n), (geo_n) are generated using for definition:

$$ari_{n+1} = ari_n + geo_n$$

$$geo_{n+1} = 2\sqrt{ari_n \cdot geo_n}$$

The iteration process is stopped at the N^{th} step when $ari_N = geo_N$.

Further needed is an iteration scheme for transformation of the argument x.

Setting $ang_i = \dfrac{ari_i}{x_i}$

then $ang_0 = 1/|x|$

$$ang_{n+1} = ang_n - \frac{ari_n \cdot geo_n}{ang_n}$$

Doing the iteration up to the N^{th} step (characterized by $ari_N = geo_N$):

$$\text{eli 1 } (x,\ ck) = \frac{ari_0}{ari_N}\ \text{eli 1 } (x_N,\ ck_N)$$

with $$\sin\phi_N = \frac{ari_N}{\pm\sqrt{ang_N^2 + ari_N^2}}$$

The sign determination of $\sin\phi_N$ must be done so that $\phi_i = \arctan x_i$ is continuously increasing with index i.

With $ari_N = geo_N$, then $ck_N = 1$, $k_N = 0$ and therefore:

$$\text{eli 1 } (x_N,\ ck_N) = \int_0^{\phi_N} dt = \phi_N$$

and the final result is:

$$\text{eli 1 } (x,\ ck) = \frac{\phi_N}{ari_N}$$

Degenerate cases of argument and modulus:

$x = 0$ gives result eli 1 = 0

$ck = 0$ gives result eli 1 = $\text{sgn } x \ln (|x| + \sqrt{1 + x^2})$

Subroutines ELI2 and DELI2

These subroutines compute the generalized elliptic integral of the second kind, where:

$$\text{eli 2 } (x,\ ck,\ a,\ b) = \int_0^x \frac{(a + bt^2)\,dt}{(1 + t^2)\sqrt{(1 + t^2)(1 + ck^2 t^2)}}$$

Equivalent are the definitions:

$$\text{eli 2 } (x,\ ck,\ a,\ b) = \int_0^{\arctan x} \frac{(a + b\tan^2 t)\,dt}{\sqrt{(1+\tan^2 t)(1+ck^2\tan^2 t)}}$$

$$= \int_0^{\arctan x} \frac{(a + (b-a)\sin^2 t)\,dt}{\sqrt{1 - k^2\sin^2 t}}$$

where k is the modulus and ck the complementary modulus.

For reasons of numerical stability, ck is chosen as input parameter instead of modulus k:

$$0 \leqq ck^2 < \infty \text{ and } k^2 + ck^2 = 1$$

This allows k to be any pure imaginary or real number such that $k^2 \leqq 1$.

In standard notation:

$$E(\varphi, k) = \text{eli 2 } (\tan\varphi,\ ck,\ 1,\ ck^2)$$
$$F(\varphi, k) = \text{eli 2 } (\tan\varphi,\ ck,\ 1,\ 1)$$

Computation is based on the process of the arithmetic-geometric mean together with Landen's transformation:

$$\text{eli 2 } (x, ck, a, b) = \frac{1}{1 + ck}\left(\text{eli 2 } (x_1,\ ck_1,\ a_1,\ b_1) + \frac{1}{2}(a - b)\frac{x_1}{\sqrt{1 + x_1^2}}\right)$$

where:

$$a_1 = \frac{1}{2}(a + b)$$

$$b_1 = \frac{1}{1 + ck}(b + a \cdot ck)$$

$$ck_1 = \frac{2\sqrt{ck}}{1 + ck}$$

$$a_1 - b_1 = \frac{1}{2}(a - b)\frac{1 - ck}{1 + ck}$$

$$x_1 = \frac{(1 + ck)x}{1 - ck \cdot x^2}$$

$$k_1 = \frac{1 - ck}{1 + ck}$$

$$\varphi_1 = \arctan x_1$$

$$\sin\varphi_1 = \frac{x_1}{\sqrt{1 + x_1^2}}$$

The iteration process begins with $ari_0 = 1$, $geo_0 = |ck|$, and the sequences (ari_n), (geo_n) are generated, using for definition:

$$ari_{n+1} = ari_n + geo_n$$

$$geo_{n+1} = 2\sqrt{ari_n \cdot geo_n}$$

The iteration process is stopped at the N^{th} step when $ari_N = geo_N$.

Further needed are the sequences (A_i), (B_i), defined by means of:

$A_i = a_i$, $B_i = b_i \cdot ari_i$; that is, by the iteration scheme

$$A_0 = a,\ B_0 = b$$

$$A_{n+1} = \frac{1}{2}\left(A_n + \frac{B_n}{ari_n}\right)$$

$$B_{n+1} = B_n + geo_n \cdot A_n$$

Finally an iteration scheme is needed for transformation of the argument x.

Setting $ang_i = \dfrac{ari_i}{x_i}$

gives $ang_0 = 1/|x|$

$$ang_{n+1} = ang_n - \frac{ari_n \cdot geo_n}{ang_n}$$

Doing the iteration scheme up to the N^{th} step (characterized by $ari_N = geo_N$):

$$eli\,2\,(x, ck, a, b) = \frac{ari_0}{ari_N}\, eli\,2\,(x_N, ck_N, a_N, b_N) + SUM$$

where

$$SUM = \frac{a-b}{2}\left(\frac{1}{ari_1}\sin\phi_1 + \frac{1}{ari_2}\,\frac{ari_0 - geo_0}{ari_1}\,\frac{\sin\phi_2}{2}\right.$$

$$\left. + \ldots + \frac{1}{ari_N}\cdot\frac{ari_0 - geo_0}{ari_1}\cdots\frac{ari_{N-2} - geo_{N-2}}{ari_{N-1}}\cdot\frac{\sin\phi_N}{2^{N-1}}\right)$$

with

$$\sin\phi_n = \frac{ari_n}{\pm\sqrt{ang_n^2 + ari_n^2}}$$

The sign determination of $\sin\phi_n$ must be done so that $\phi_i = \arctan x_i$ is continuously increasing with index i.

With $ari_N = geo_N$, then $ck_N = 1$, $k_N = 0$, and therefore

$$eli\,2\,(x_N, ck_N, a_N, b_N) = \int_0^{\phi_n}\left[a_N + (b_N - a_N)\sin^2 t\right]dt$$

$$= \frac{a_N + b_N}{2}\phi_N - \frac{1}{2}(b_N - a_N)\sin\phi_N\cos\phi_N$$

The final result is:

$$eli\,2\,(x, ck, a, b) = \frac{A_{N+1}}{ari_N}\cdot \arctan\frac{ari_N}{ang_N} + SUM +$$

$$\frac{1}{ari_N}\left(\frac{a_N - b_N}{2}\right)\sin\phi_N\cos\phi_N$$

Degenerate cases of argument and modulus:

x = 0 gives result eli 2 = 0

ck = 0 gives result

$$eli\,2 = \left[b\cdot\ln\left(|x| + \sqrt{1+x^2}\right) + (a-b)\frac{|x|}{\sqrt{1+x^2}}\right]\operatorname{sgn} x$$

```

the final result is the iteration scheme:

$$c_{N+1} = ari_{N+1} \cot(y \cdot ari_{N+1})$$

$$d_{N+1} = 1$$

$$c_n = d_{n+1} \cdot c_{n+1}$$

$$d_n = \frac{c_{n+1}^2 / ari_{n+2} + geo_{n+1}}{c_{n+1}^2 / ari_{n+2} + ari_{n+1}}$$

for $n = N, N-1, \ldots, 1.$

Then $c_1 = \cot\varphi$, and:

$$sn(x, k) = \frac{1}{\sqrt{1 + c_1^2}} = \frac{1}{\sqrt{1 + \cot^2\varphi}} = \sin\varphi$$

$$cn(x, k) = sn \cdot c_1 = \sin\varphi \cdot \cot\varphi = \cos\varphi$$

$$dn(x, k) = d_1 = \sqrt{1 - k^2 \sin^2\varphi}$$

APPENDIX A: ACCURACY OF SUBROUTINES

The subroutines in SSP can be broken down into three major categories from the standpoint of accuracy. They are (1) subroutines having little or no effect on accuracy, (2) subroutines whose accuracy is dependent on the characteristics of the input data, and (3) subroutines in which definite statements on accuracy can be made.

SUBROUTINES HAVING LITTLE OR NO EFFECT ON ACCURACY

The following subroutines do not materially affect the accuracy of the results, either because of the simple nature of the computation or because they do not modify the data:

ABSNT -- detection of missing data

ARRAY -- vector storage/double-dimensioned conversion

ATSE, DATSE -- table selection out of an equidistant table

ATSG, DATSG -- table selection out of a general table

ATSM, DATSM -- table selection out of a monotonic table

AVDAT -- data storage allocation

BISER -- biserial correlation coefficient

BOUND -- selection of observations within bounds

CADD -- add column of one matrix to column of another matrix

CCPY -- copy column of matrix into vector

CCUT -- partition by column

CHISQ -- χ^2 test for a contingency table

CINT -- interchange two columns

CONVT -- single-precision/double-precision conversion

CSRT -- sort matrix columns

CSUM -- sum the columns of a matrix

CTAB -- tabulate the columns of a matrix

CTIE -- adjoin two matrices by column

DCLA -- replace diagonal with scalar

DCPY -- copy diagonal of matrix into vector

FRAT, DFRAT -- used with ARAT
used with DARAT

GAUSS -- normal random numbers

GMADD -- add two general matrices

GMSUB -- subtract two general matrices

GMTRA -- transpose of a general matrix

KOLM2 -- Kolmogorov - Smirnov two-sample test

KRANK -- Kendall rank correlation

LOC -- location in compressed-stored matrix

MADD -- add two matrices

MCPY -- matrix copy

MFUN -- matrix transformation by a function

MOMEN -- first four moments

MPAIR -- Wilcoxin's signed rank test

MPRC, DMPRC -- permutations of rows or columns of a matrix

MSTR -- storage conversion

MSUB -- subtract two matrices

MTRA -- transpose a matrix

ORDER -- rearrangement of intercorrelations

PADD -- add two polynomials

PADDM -- multiply polynomial by constant and add to another polynomial

PCLA -- replace one polynomial by another

PERM -- inverse of permutation - transposition

PHI -- phi coefficient

PMPY -- multiply two polynomials

PNORM -- normalize coefficient vector of polynomial

PPRCN -- operations with permutations

PSUB -- subtract one polynomial from another

PVSUB -- substitute variable of polynomial by another polynomial

QTEST -- Cochran Q-test

RADD -- add row of one matrix to row of another matrix

RANDU -- uniform random numbers

RANK -- rank observations

RCPY -- copy row of matrix into vector

RCUT -- partition by row

RECP -- reciprocal function for MFUN

RINT -- interchange two rows

RSRT -- sort matrix rows

RSUM -- sum the rows of a matrix

RTAB -- tabulate the rows of a matrix

RTIE -- adjoin two matrices by row

SADD -- add scalar to matrix

SCLA -- matrix clear and add scalar

SCMA -- scalar-multiply column and add to another column

SDIV -- matrix divided by a scalar

SIGNT -- sign test

SMPY -- matrix multiplied by a scalar

SRANK -- Spearman rank correlation

SRATE -- survival rate

SRMA -- scalar-multiply row and add to another row

SSUB -- subtract scalar from a matrix

SUBMX -- build subset matrix

SUBST -- subset selection from observation matrix

TAB1 -- tabulation of data (one variable)

TAB2 -- tabulation of data (two variables)

TIE -- calculation of ties in ranked observations

TRACE -- cumulative percentage of eigenvalues

TTEST -- tests on population means

TWOAV -- Friedman two-way analysis of variance

UTEST -- Mann-Whitney U-test

WTEST -- Kendall coefficient of concordance

XCPY -- copy submatrix from given matrix

SUBROUTINES WHOSE ACCURACY IS DATA-DEPENDENT

The accuracy of the following subroutines cannot be predicted because it is dependent on the characteristics of the input data and on the size of the problem. The programmer using these subroutines must be aware of the limitations dictated by numerical analyses considerations. It cannot be assumed that the results are accurate simply because subroutine execution is completed. Subroutines in this category are:

ACFI, DACFI -- continued fraction interpolation

AHI, DAHI -- Aitken-Hermite interpolation

ALI, DALI -- Aitken-Lagrange interpolation

APCH, DAPCH -- construction of normal equations for a polynomial least-squares fit to a tabulated function

APFS, DAPFS -- solution of normal equations for least-squares fit

APLL, DAPLL -- construction of normal equations for least-squares fit to tabulated function

APMM, DAPMM -- Chebyshev approximation of tabulated functions

ARAT, DARAT -- least-squares rational approximation of tabulated functions

ATEIG -- eigenvalues of a real Hessenberg matrix

AUTO -- autocovariances

AVCAL -- Σ and Δ operation

CANOR -- canonical correlation

CNPS, DCNPS -- value of series expansion in Chebyshev polynomials

CORRE -- means, standard deviations, and correlations

CROSS -- cross covariances

CSPS, DCSPS -- value of series expansion in shifted Chebyshev polynomials

DBAR, DDBAR -- first derivative of a function at the border of the definition interval

DCAR, DDCAR -- first derivative of a function at the center of the definition interval

DET3, DDET3 -- differentiation of equidistantly tabulated functions using three points interpolation

DET5, DDET5 -- differentiation of equidistantly tabulated functions using five points interpolation

DGT3, DDGT3 -- differentiation of tabulated functions using three points interpolation

DISCR -- discriminant functions

DMATX -- means and dispersion matrix

EIGEN -- eigenvalues and eigenvectors of a real, symmetric matrix

EXSMO -- triple exponential smoothing

FACTR -- factorization of a matrix into a product of triangular matrices

FMCG, DFMCG -- unconstrained minimum of a function of several variables--conjugate gradient method

FMFP, DFMFP -- unconstrained minimum of a function of several variables--Davidon method

FORIF -- Fourier analysis of a given function

FORIT -- Fourier analysis of a tabulated function

GDATA -- data generation

GELB, DGELB -- system of general simultaneous linear equations with band-structured coefficients

GELG, DGELG -- system of general simultaneous linear equations by Gauss elimination

GELS, DGELS -- system of general simultaneous linear equations with symmetric coefficients

GMPRD -- product of two general matrices

GTPRD -- transpose product, general matrices

HARM, DHARM -- complex three-dimensional analysis

HEPS, DHEPS -- value of series expansion in Hermite polynomials

HPCG, DHPCG -- solution of general system of first-order ordinary differential equations with given initial values by Hamming's modified predictor-corrector method

HPCL, DHPCL -- solution of linear system of first-order ordinary differential equations with given initial values by Hamming's modified predictor-corrector method

HSBG -- reduction of a real matrix to Hessenberg form

KOLMO -- Kolmogorov-Smirnov one-sample test

LAPS, DLAPS -- value of series expansion in Laguerre

LBVP, DLBVP -- solution of system of linear first-order ordinary differential equations with linear boundary conditions by method of adjoint equations

LEPS, DLEPS -- value of series expansion in Legendre polynomials

LLSQ, DLLSQ -- solution of linear least-squares problems

LOAD -- factor loading

MCHB, DMCHB -- factorization of a symmetric positive definite band matrix

MATA -- transpose product of a matrix

MEANQ -- mean square operation

MFGR, DMFGR -- matrix factorization and rank determination

MFSD, DMFSD -- factorizes a symmetric positive definite matrix (square root method)

MFSS, DMFSS -- rank determination and factorization of symmetric positive semidefinite matrix

MINV -- matrix inversion

MISR -- missing value correlations

MLSS, DMLSS -- solve a system of linear equations with symmetric positive semidefinite matrix

MPRD -- matrix product

MTDS, DMTDS -- division of a matrix by a triangular matrix

MULTR -- multiple regression and correlation

NROOT -- eigenvalues and eigenvectors of a special nonsymmetric matrix

PCLD -- complete linear division

PDER -- derivative of a polynomial

PDIV -- divide polynomials

PECN, DPECN -- economization of a polynomial for symmetric range

PECS, DPECS -- economization of a polynomial for unsymmetric range

PFQB, DPFQB -- determination of a quadratic factor of a polynomial

PGCD -- greatest common divisor of two polynomials

PILD -- evaluate polynomial and its first derivative

PINT -- integral of a polynomial

POINT -- point biserial correlation

POLRT -- real and complex roots of a real polynomial

PQSD -- quadratic synthetic division of a polynomial

PRBM, DPRBM -- roots of a polynomial with real coefficients--Bairstow's method

PROBT -- probit analysis

PRQD, DPRQD -- roots of a real polynomial by QD algorithm with displacement

PVAL -- evaluate polynomial

QA2-QA10, DQA4-DQA32 -- integration of a given function by associated Gaussian-Laguerre quadrature formulas

QATR, DQATR -- integration of a given function by trapezoidal rule together with Romberg's extrapolation method

QG2-QG10, DQG4-DQG32 -- integration of a given function by Gaussian quadrature formulas

QH2 QH10, DQH8-DQH64 -- integration of a given function by Gaussian - Hermite quadrature formulas

QHFE, DQHFE -- integration of equidistantly tabulated function with first derivative by Hermitian formula of first order

QHFG, DQHFG -- integration of monotonically tabulated function with first derivative by Hermitian formula of first order

QHSG, DQHSG -- integration of monotonically tabulated function with first and second derivatives by Hermitian formula of first order

QHSE, DQHSE -- integration of equidistantly tabulated function with first and second derivatives by Hermitian formula of second order

QL2-QL10, DQL4-DQL32 -- integration of a given function by Gaussian-Laguerre quadrature formulas

QSF, DQSF -- integration of equidistantly tabulated function by Simpson's rule

QTFE, DQTFE integration of equidistantly tabulated function by trapezoidal rule

QTFG, DQTFG -- integration of monotonically tabulated function by trapezoidal rule

RHARM, DRHARM -- real one-dimensional analysis

RKI -- solution of first-order differential equation by Runge-Kutta method

RK2 -- tabulated solution of first-order differential equation by Runge-Kutta method

RKGS, DRKGS -- solution of system of first-order ordinary differential equations with given initial values by the Runge-Kutta method

RSLMC -- solution of a system of linear equations

RTMI, DRTMI -- determine root within a range by Mueller's iteration

RTNI, DRTNI -- refine estimate of root by Newton's iteration

RTWI, DRTWI -- refine estimate of root by Wegstein's iteration

SE13, DSE13 -- local least-squares smoothing of equidistantly tabulated functions

SE15, DSE15 local least-squares smoothing of equidistantly tabulated functions

SE35, DSE35 -- local least-squares smoothing of equidistantly tabulated functions

SG13, DSG13 -- local least-squares smoothing of tabulated functions

SIMQ -- solution of simultaneous linear, algebraic equations

SINV, DSINV -- inversion of a symmetric positive definite matrix

SMO -- application of filter coefficients (weights)

STPRG -- stepwise regression

TALLY -- totals, means, standard deviations, minimums, and maximums

TCNP, DTCNP -- transform series expansion in Chebyshev polynomials to a polynomial

TCSP, DTCSP -- transform series expansion in shifted Chebyshev polynomials to a polynomial

TETRA -- tetrachoric correlation

THEP, DTHEP -- transform series expansion in Hermite polynomials to a polynomial

TLAP, DTLAP -- transform series expansion in Laguerre polynomials to a polynomial

TLEP, DTLEP -- transform a series expansion in Legendre polynomials to a polynomial

TPRD -- transpose product

VARMX -- varimax rotation

SUBROUTINES WITH DEFINITE ACCURACY CHARACTERISTICS

The subroutines in this section have accuracy characteristics that can be specified on an individual basis. The mathematical descriptions for many of these subroutines contain information on truncation error of a strictly theoretical nature. The actual implementation of these subroutines on System/360 results in the accuracy noted in Table 1. The standard reference for comparing the accuracy of these subroutines is M. Abramowitz, I. A. Stegun, Handbook of Mathematical Functions, National Bureau of Standards, Washington, D. C., March 1965. However, in certain cases, other tables were used, as noted below. It should be remembered that in System /360 single-precision floating point, there are just over six significant figures.

Maximum differences below are given in terms of number of decimal places (D. P.) and/or number of significant digits (S. D.) which agree. The number of digits tabled should be considered when accuracy statements are viewed; that is, certain tables are given to only five places, whereas the algorithms used may be more accurate. In compiling maximum differences, the maximum was taken over the set of points indicated in the table. The average difference was normally much smaller.

The notation x = a (b) c implies that a, a + b, a + 2b, ... , c were the arguments (x) used.

TABLE 1

Name	Functions calculated	Functions checked with reference	Range checked with reference	Maximum difference
BDTR	$p=I_x(a,b)$	$I_x^{-1}(a,b)$ Tables by Leon H. Harter: New Tables of the Incomplete Gamma Function Ratio and of Percentage Points of the χ^2 and Beta Distribution, 1964	p=.0001, .0005 a=1 (1) 40 b=5(5) 40 p=.0100, .0500 a= 2 (2) 10 b=5 (5) 30	correct to 5 D. P.
		"t" distribution: $t(x,n)=$ $[1+I_z(c,d)]/2$ where $z=x^2/(x^2+n)$ c= 1/2 d= n/2 Tables: Biometrika vol. 1	x= .01, and x= .5 (.5) 4 for n= 1 (1) 24, and n= 30, 40, 60, 120	.5 in 5th D. P.

APPENDIX B: SAMPLE PROGRAM DESCRIPTIONS

DATA SCREENING

Problem Description

A set of observations is read along with information on propositions to be satisfied and limits on a selected variable. From this input a subset is obtained and a histogram of frequency over given class intervals is plotted for the selected variable. Total, average, standard deviation, minimum, and maximum are calculated for the selected variable. This procedure is repeated until all sets of input data have been processed.

Program

Description

The data screening sample program consists of a main routine, DASCR, and six subroutines; namely, SUBST, TAB1, LOC, BOOL, HIST, and MATIN. Three of these (SUBST, TAB1, LOC) are from the Scientific Subroutine Package. MATIN is a sample input routine. HIST is a program for plotting a histogram. For a description of subroutine BOOL see subroutine SUBST.

Capacity

The maximum size of matrix of observations has been set at 1000 elements, the number of observations at 200, and the number of conditions at 21. All of these can be increased as described under "Program Modification" below.

Input

Control Cards

A parameter card with the following format must precede each matrix of observations:

Columns	Contents	For Sample Problem
1 - 2	Blank	
3 - 6	Up to four-digit identification code (numeric only)	0001
7 - 10	Number of observations	0100
11 - 14	Number of variables	0004

Each matrix of observations must be followed by a card with a 9 punch in column 1. The condition matrix and bounds data are preceded by a card containing the number of conditions and the variable to be selected for analysis:

Columns	Contents	For Sample Problem
1 - 2	Number of conditions	02
3 - 4	Variable to be selected	03

A blank card after the last set of input data terminates the run.

Data Cards

1. For the observation matrix--data cards have seven fields of ten columns each. The decimal point may appear anywhere in a field. If no decimal point is included, it is assumed that the decimal point is to the right of the last digit. The number in each field may be preceded by blanks. All values for an observation are punched consecutively and may continue from card to card. However, a new observation must start in the first field of the next card.
2. For the condition matrix (see description in the subroutine SUBST)--each ten-column field contains a condition to be satisfied. The first two columns contain the variable number (right-justified), the third column the relational code, and the last seven columns of each field a floating-point number. This number may be punched anywhere in the seven-column field but must contain a decimal point. There may be as many as seven conditions per card and a total of three cards or 21 conditions.
3. For the UBO vector (see description in the subroutine TAB1)--the UBO vector is punched in three fields of ten columns each as a floating-point number with decimal point.

Deck Setup

The deck setup is shown in Figure 35.

Sample

A listing of input cards for the sample problem is presented in Figure 36. Card 002 is the parameter card for the matrix of observations. It shows that there are 100 observations and four variables in matrix number 1. Card 003 is the first observation, card 102 the last. Each observation represents an individual with four characteristics (variables). The variables are, in the order shown, (1) age in years, (2) height in inches, (3) weight in pounds, and (4) education in years.

Card 103 signals the end of the matrix of observations.

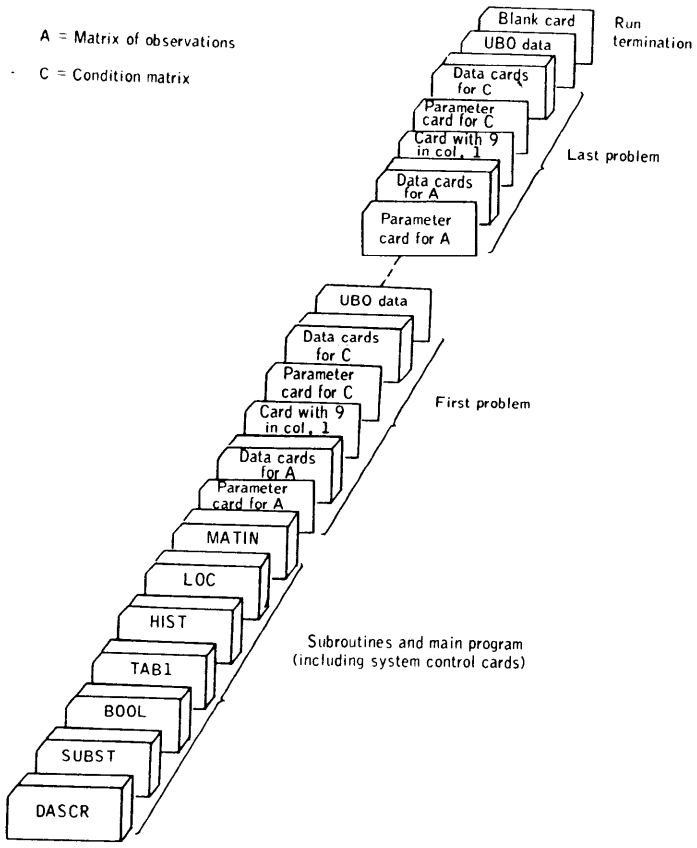

Figure 35. Deck setup (data screening)

Card 104 indicates that there are two conditions to be satisfied and that variable 3 (weight) is selected for analysis. Card 105 shows the condition matrix. The first condition states that variable 1 (age) must be less than or equal to 65, and therefore observations for individuals over 65 will be rejected. The second condition states that variable 4 (education) must be greater than eight years, and consequently observations for individuals with less than eight years of education will be rejected.

Card 106 contains the information on bounds and number of intervals for the selected variable. It shows that the lower bound is 120, the upper bound is 210, and that there are 20 intervals (including one for under lower bound and another for equal to or greater than upper bound).

Card 107 is a blank card for terminating the run.

Output

Description

The output consists of the subset vector showing which observations are rejected (zero) and accepted (nonzero), summary statistics for the selected variable, and a histogram of frequencies versus intervals for that variable.

Sample

The output listing for the sample problem is shown in Figure 37.

Program Modification

The size of the maximum problem to be solved can be increased or decreased by changing the DIMENSION statement in DASCR.

Subroutine BOOL can be replaced if the user wishes to use a different boolean expression (see description in subroutine SUBST). The boolean expression provided in the sample program is for both conditions to be satisfied:

$$T = R(1) * R(2)$$

Operating Instructions

The sample program for data screening is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and logical unit 6 is used for output. Data set 13 is used for intermediate storage.

Error Messages

The following error conditions will result in messages:

1. Reserved storage area is too small for matrix--DIMENSIONED AREA TOO SMALL FOR INPUT MATRIX. GO ON TO NEXT CASE.
2. Number of data cards does not correspond to that required by parameter card--INCORRECT NUMBER OF DATA CARDS FOR MATRIX. EXECUTION TERMINATED.

Error condition 1 allows the computer run to continue. Error condition 2, however, terminates execution and requires another run to process succeeding cases.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 42 seconds.

MULTIPLE LINEAR REGRESSION

Problem Description

Multiple linear regression analysis is performed for a set of independent variables and a dependent variable. Selection of different sets of independent variables and designation of a dependent variable can be made as many times as desired.

The sample problem for multiple linear regression consists of 30 observations with six variables as presented in Table 4. The first five variables are independent variables (predictors), and the last variable is the dependent variable (criteria). All five independent variables are used to predict the dependent variable in the first analysis, and only the second, third, and fifth variables are used to predict the dependent variable in the second analysis.

Table 4. Sample Data for Multiple Linear Regression

	Variables					
Observation	X_1	X_2	X_3	X_4	X_5	X_6
1	29	289	216	85	14	1
2	30	391	244	92	16	2
3	30	424	246	90	18	2

29	51	424	210	140	59	4
30	51	150	210	105	30	0

Program

Description

The multiple linear regression program consists of the main routine named REGRE, a special input subroutine named DATA, and four subroutines from the Scientific Subroutine Package: CORRE, ORDER, MINV, and MULTR.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to 40 variables, including both independent and dependent variables
2. Up to 99,999 observations, if observations are read into the computer one at a time by the special input subroutine named DATA. If all data are to be stored in core prior to the calculation of correlation coefficients, the limitation on the number of observations depends on the size of core storage available for input data
3. (12F6.0) format for input data cards.

Therefore, if a problem satisfies the above conditions, the sample program need not be modified. However, if there are more than 40 variables, dimension statements in the sample main program must be modified to handle this particular problem. Similarly, if input data cards are prepared using a different format, the input format in the input subroutine, DATA, must be modified. The general rules for program modification are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, REGRE. This card is prepared as follows:

Columns	Contents	For Sample Problem
1 - 6	Problem number (may be alphameric)	SAMPLE
7 - 11	Number of observations	00030
12 - 13	Number of variables	06
14 - 15	Number of selection cards (see below)	02

Leading zeros are not required to be keypunched.

Data Cards

Since input data are read into the computer one observation at a time, each row of data in Table 4 is keypunched on a separate card using the format (12F6.0). This format assumes twelve 6-column fields per card.

If there are more than twelve variables in a problem, each row of data is continued on the second and third cards until the last data point is keypunched. However, each row of data must begin on a new card.

Selection Card

The selection card is used to specify a dependent variable and a set of independent variables in a multiple linear regression analysis. Any variable in the set of original variables can be designated as a dependent variable, and any number of variables can be specified as independent variables. Selection of a dependent variable and a set of independent variables can be performed over and over again using the same set of original variables.

The selection card is prepared as follows:

Columns	Contents	For Sample Problem Selection 1	Selection 2
1 - 2	Option code for table of residuals: 00 if it is not desired 01 if it is desired	01	01
3 - 4	Dependent variable designated for the forthcoming regression	06	06
5 - 6	Number of independent variables included in the forthcoming regression (the subscript numbers of individual variables are specified below)	05	03
7 - 8	1st independent variable included	01	02
9 - 10	2nd independent variable included	02	03
11 - 12	3rd independent variable included	03	05
13 - 14	4th independent variable included	04	
15 - 16 etc.	5th independent variable included	05	

The input format of (36I2) is used for the selection card.

Deck Setup

The deck setup is shown in Figure 38.

Sample

The listing of input cards for the sample problem is presented in Figure 39.

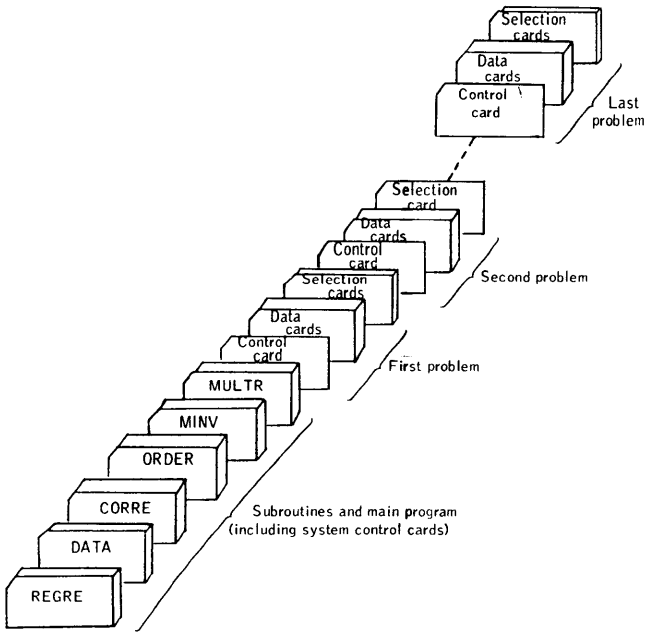

Figure 38. Deck setup (multiple linear regression)

Output

Description

The output of the sample program for multiple linear regression includes:

1. Means
2. Standard deviations
3. Correlation coefficients between the independent variables and the dependent variable
4. Regression coefficients
5. Standard errors of regression coefficients
6. Computed t-values
7. Intercept
8. Multiple correlation coefficients
9. Standard error of estimate
10. Analysis of variance for the multiple regression
11. Table of residuals (optional)

Sample

The output listing for the sample problem is shown in Figure 40.

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize

```

Figure 39. Input listing (multiple regression)

the user with the program modification, the following general rules are supplied in terms of the sample problem:

1. Changes in the dimension statements of the main program, REGRE
   a. The dimension of arrays XBAR, STD, D, RY, ISAVE, B, SB, T, and W must be greater than or equal to the number of variables, m. Since there are six variables in the sample problem, the value of m is 6.
   b. The dimension of array RX must be greater than or equal to the product of m x m. For the sample problem this product is 36 = 6 x 6.
   c. The dimension of array R must be greater than or equal to (m + 1)m/2. For the sample problem this number is 21 = (6 + 1)6/2.

2. Changes in the input format statement of the special input subroutine, DATA:

   Only the format statement for input data may be changed. Since sample data are either one-, two-, or three-digit numbers, rather than using six-column fields as in the sample problem, each row of data may be keypunched in six 3-column fields, and, if so, the format is changed to (6F3.0).

   The special input subroutine, DATA, is normally written by the user to handle different formats for different problems. The user may modify this subroutine to perform testing of input data, transformation of data, and so on.

Figure 40. Output listing (multiple regression)

Operating Instructions

The sample program for multiple linear regression is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output. A scratch tape (data set 13) is used as intermediate storage.

Error Messages

The following error conditions will result in messages:

1. The number of selection cards is not specified on the control card--NUMBER OF SELECTIONS NOT SPECIFIED. JOB TERMINATED.
2. The matrix of correlation coefficients is singular--THE MATRIX IS SINGULAR. THIS SELECTION IS SKIPPED.

Error condition 2 allows the computer run to continue; however, error condition 1 terminates execution of the job.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 42 seconds.

```

POLYNOMIAL REGRESSION

Problem Description

Powers of an independent variable are generated to calculate polynomials of successively increasing degrees. If there is no reduction in the residual sum of squares between two successive degrees of polynomials, the program terminates the problem before completing the analysis for the highest degree polynomial specified.

The sample problem for polynomial regression consists of 15 observations, as presented in Table 5. The highest degree polynomial specified for this problem is 4.

Program

Description

The polynomial regression program consists of the main routine named POLRG, a special plot subroutine named PLOT, and four subroutines from the Scientific Subroutine Package: GDATA, ORDER, MINV, and MULTR.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to 100 observations
2. Up to 10^{th} degree polynomial
3. (2F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions it is not necessary to modify the sample program. However, if there are more than 100 observations or if greater than 10^{th} degree polynomial is desired, dimension statements in the sample main program must be modified to handle this particular problem. Similarly, if input data cards are prepared using a different format, the input format in the sample main program must be modified. The general rules for program modification are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, POLRG. This card is prepared as follows:

Columns	Contents	For Sample Problem
1 - 6	Problem number (may be alphameric)	SAMPLE
7 - 11	Number of observations	00015
12 - 13	Highest degree polynomial to be fitted	04
14	Option code for plotting Y values and Y estimates: 0 if it is not desired 1 if it is desired	1

Leading zeros are not required to be keypunched.

Data Cards

Since input data are read into the computer one observation at a time, each pair of X and Y data in Table 5 is keypunched in that order on a separate card using the format (2F6.0).

Table 5. Sample Data for Polynomial Regression

X	Y
1	10
2	16
3	20
4	23

6	26
7	30
8	36
9	48
10	62
11	78
12	94
13	107
14	118
15	127

Deck Setup

The deck setup is shown in Figure 41.

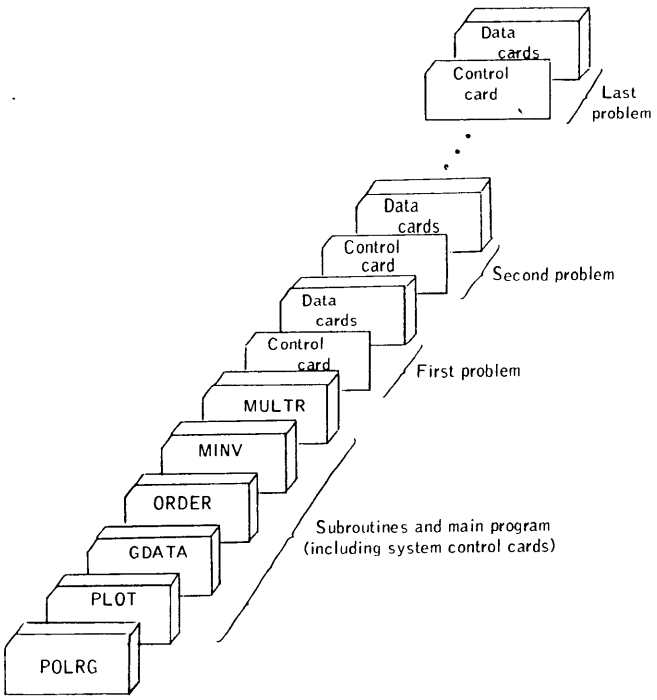

Figure 41. Deck setup (polynomial regression)

Sample

The listing of input cards for the sample problem is presented in Figure 42.

Output

Description

The output of the sample program for polynomial regression includes:

1. Regression coefficients for successive degree polynomials
2. Analysis-of-variance table for successive degree polynomials
3. Table of residuals for the final degree polynomial (optional)
4. Plot of Y values and Y estimates (optional)

Figure 42. Input card listing (polynomial regression)

Sample

The output listing for the sample problem is shown in Figure 43.

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize the user with the program modification, the following general rules are supplied in terms of the sample problem.

1. Changes in the dimension statements of the main program, POLRG:
   a. The dimension of array X must be greater than or equal to the product of n (m + 1), where n is the number of observations and m is the highest degree polynomial to be fitted. Since there are 15 observations and the highest degree polynomial specified is 4, the product is 75 = 15 (4 + 1).
   b. The dimension of array DI must be greater than or equal to the product of m x m. For the sample problem this product is 16 = 4 x 4.
   c. The dimension of array D must be greater than or equal to (m + 2) (m + 1)/2. For the sample problem this number is 15 = (4 + 2) (4 + 1)/2.
   d. The dimension of arrays B, E, SB, and T must be greater than or equal to the highest degree polynomial to be fitted, m. For the sample problem the value of m is 4.
   e. The dimension of arrays XBAR, STD, COE, SUMSQ, and ISAVE must be greater than or equal to (m + 1). For the sample problem this value is 5 = (4 + 1).
   f. The dimension of array P must be greater than or equal to 3(n). For the sample problem this value is 45 = 3(15). The array P is used when a plot of Y values and Y estimates is desired.

2. Changes in the input format statement of the main program, POLRG:

   Only the format statement for input data may be changed. Since sample data are either one-, two-, or three-digit numbers, rather than using six-column fields as in the sample problem, each row of data may be keypunched in two 3-column fields, and if so the format is changed to (2F3.0).

Figure 43. Output listing (polynomial regression)

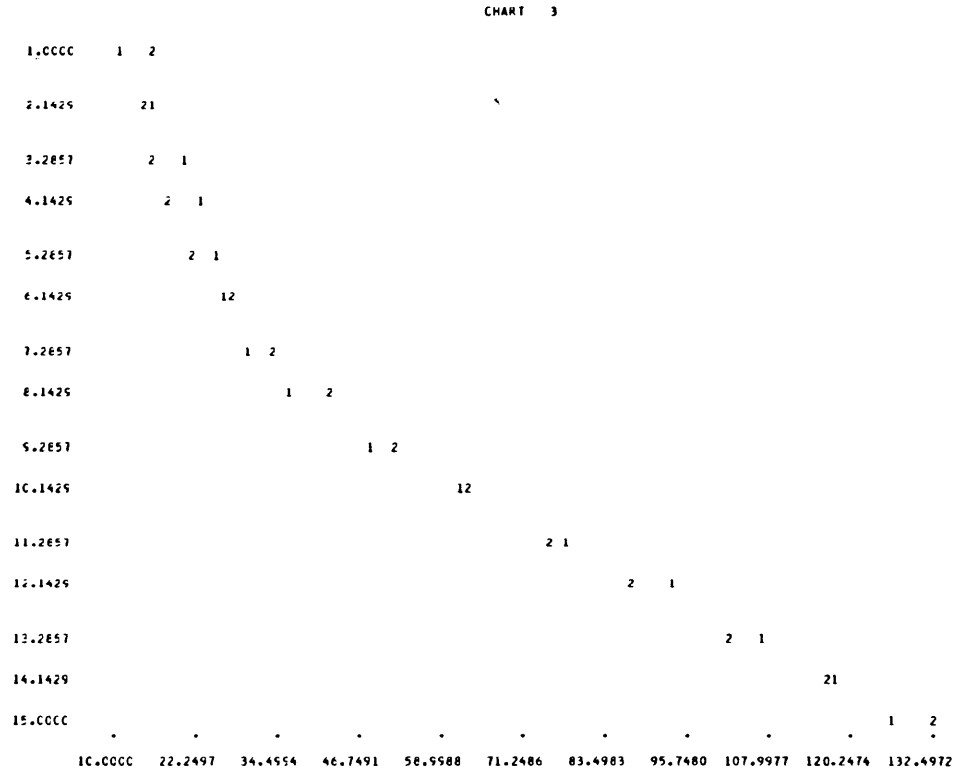

Figure 43. Output listing (polynomial regression) (Continued)

Operating Instructions

The sample program for polynomial regression is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output. A scratch tape (data set 13) is used as intermediate storage when Y values and Y estimates are plotted.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 35 seconds.

STEPWISE MULTIPLE REGRESSION

Problem Description

Stepwise multiple regression is a statistical technique for analyzing a relationship between a dependent variable (y) and a set of independent variables ($x_1, x_2, \ldots, x_m$) and for selecting the independent variables in the order of their importance. The criterion of importance is based on the reduction of sums of squares, and the independent variable most important in this reduction in a given step is entered in the regression. Any variable in the original set can be named as the dependent variable. A set of variables can be forced to enter in the regression, and another set of variables can be deleted.

The sample problem for stepwise multiple regression consists of 30 observations on six variables as presented in Table 4. The first five variables are independent variables (predictors), and the last variable is the dependent variable (criterion). All five independent variables are available for selection in the first analysis. In the second analysis, the third variable is forced to enter in the regression, the fourth variable is deleted, and the remaining three independent variables are available for selection. Note that the same sample problem has been used for multiple linear regression and that the results of these two programs may be compared.

Program

Description

The stepwise multiple regression program consists of the main routine named STEPR, a special input subroutine named DATA, a special output subroutine named STOUT, and four subroutines from the Scientific Subroutine Package: CORRE, MSTR, LOC, and STPRG.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to 35 variables, including both dependent and independent variables
2. Up to 99,999 observations, if observations are read into the computer one at a time by the special input subroutine named DATA. If all data are to be stored in core prior to the calculation of correlation coefficients, the limitation on the number of observations depends on the size of core storage available for input data.
3. (12F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions, it is not necessary to modify the sample program. However, if there are more than 35 variables, dimension statements in the sample main program must be modified to handle this particular problem. Similarly, if input data cards are prepared using a different format, the format in the input subroutine, DATA, must be modified. The general rules for program modification are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, STEPR. This card is prepared as follows:

Columns	Contents	For Sample Problem
1-6	Problem code (may be alphameric)	SAMPLE
7-11	Number of observations	00030
12-13	Number of variables	06
14-15	Number of selection cards (see below)	02
16-21	This constant is the proportion of the sum of squares which will be used to limit the entering of variables into the regression. Unless the proportion of the sum of squares attributable to an entering variable is greater than this value, the variable will not be entered. The keypunched value should have a decimal point.*	0.0
22	Option code for table of residuals 0--if it is not desired 1--if it is desired	1

*The choice of value depends upon the purpose of analysis. A suggested trial value is 0.01 (one percent). If all variables are to be included in the regression, use 0.0.

Leading zeros are not required to be keypunched.

Data Cards

Since input data can be read into the computer one observation at a time, each row of data in Table 4 is keypunched on a separate card using the format (12F6.0). This format assumes twelve 6-column fields per card.

If there are more than twelve variables in a problem, each row of data is continued on the second and third cards until the last data point is keypunched. However, each row of data must begin on a new card.

Selection Card

The selection card is used to specify a dependent variable, independent variables to be forced to enter in the regression, variables to be deleted, and independent variables to be chosen by the program to enter in the regression. Any one variable in the set of original variables can be designated as a dependent variable, and any number of variables can be specified as forcing variables, deleting variables, and unrestricted variables to be chosen by the program. The specification of the variables can be performed over and over again using the same set of original variables.

In a selection card, each variable is specified using one of the following codes:

Code	Specification
0 or blank	Independent variable to be chosen by the program to enter in the regression
1	Independent variable forced by the user to enter in the regression
2	Variable to be deleted
3	Dependent variable

The selection card itself is prepared as follows:

Columns	Contents	For Sample Problem Selections 1	2
1	Code for 1st variable	0	0
2	Code for 2nd variable	0	0
3	Code for 3rd variable	0	1
4	Code for 4th variable	0	2
5	Code for 5th variable	0	0
6	Code for 6th variable	3	3
etc.			

The input format of (72I1) is used for the selection card.

Deck Setup

The deck setup is shown in Figure 44.

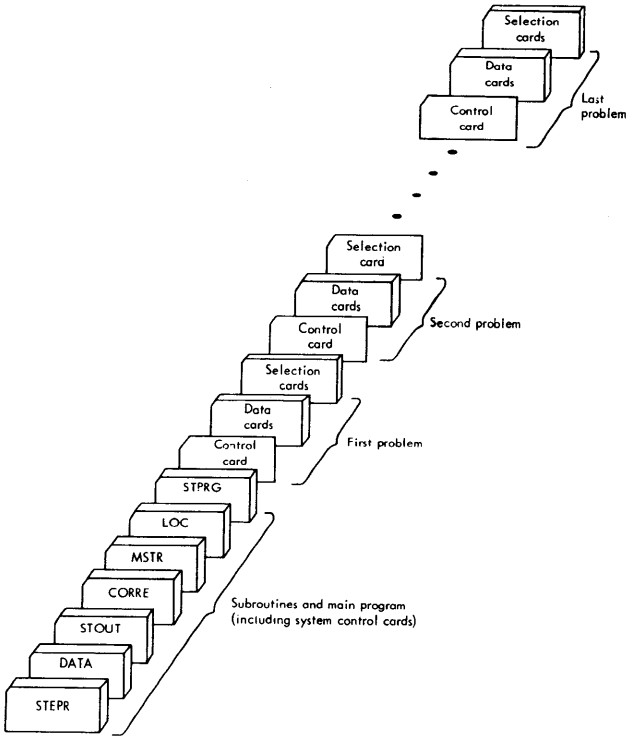

Figure 44. Deck setup (stepwise multiple regression)

Sample

The listing of input cards for the sample problem is presented in Figure 45.

Output

Description

The output of the sample program for stepwise multiple regression includes:

1. For all variables --
   a. Means
   b. Standard deviations
   c. Correlation coefficient matrix
2. For each step of multiple regression --
   a. Sum of squares reduced
   b. Proportion reduced
   c. Cumulative sum of squares reduced
   d. Cumulative proportion reduced
   e. Multiple correlation coefficient (adjusted and unadj.)
   f. F-value for analysis of variance
   g. Standard error of estimate (adjusted and unadj.)
   h. Regression coefficients
   i. Standard errors of regression coefficients
   j. Computed t-values
3. Tables of residuals (optional)

Sample

The output listing for the sample problem is shown in Figure 46.

Figure 46. (Continued)

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a different format statement. If the user encounters problems with large or small numbers in his output, he may wish to change output format statements from F to E notation. In order to familiarize the user with the program modification, the following general rules are supplied in terms of the sample problem.

1. Changes in the dimension statements of the main program, STEPR:

a. The dimension of arrays XBAR, STD, D, B, T, IDX, and L must each be greater than or equal to the number of variables, m. Since there are six variables in the sample problem, the value of m is 6.

b. The dimension of array RX must be greater than or equal to the product of m x m. For the sample problem this product is 36 = 6 x 6.

c. The dimension of array R must be greater than or equal to (m+1)m/2. For the sample problem this number is 21 = (6+1)6/2.

2. Changes in the input format statement of the special input subroutine, DATA:

Only the format statement for input data may be changed. If sample data are either one-, two-, or three-digit numbers, each row of data may be keypunched in six 3-column fields rather than using six-column fields as in the sample problem; in such case the format is changed to (6F3.0).

The special input subroutine, DATA, is normally written by the user to handle different formats for different problems. The user may modify this subroutine to perform testing of input data, transformation of data, and so on.

Operating Instructions

The sample program for stepwise multiple regression is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output. A scratch tape (data set 13) written in binary mode is used as intermediate storage.

Error Messages

The following error conditions will result in messages:

1. The number of selection cards is not specified on the control card--NUMBER OF SELECTIONS NOT SPECIFIED. JOB TERMINATED. This error terminates execution of the job.

2. More than one dependent variable is specified on a selection card--SELECTION CARD (N) DOES NOT NAME ONE AND ONLY ONE DEPENDENT VARIABLE. SELECTION IGNORED.

3. A control digit is not 0, 1, 2, or 3 on a selection card--COLUMN (K) OF SELECTION CARD (N) IS IN ERROR. IT IS POSSIBLE THAT COLUMNS SUCCEEDING THAT COLUMN ARE ALSO INCORRECT. THE SELECTION IS IGNORED.

4. There are too few observations for estimation to take place--(N) OBSERVATIONS ARE TOO FEW TO ALLOW PARAMETER ESTIMATION FOR (M) VARIABLES. JOB TERMINATED.

5. The correlation matrix is singular or badly conditioned--EITHER THE MATRIX IS SINGULAR, OR THE RESIDUAL SUM OF SQUARES IS NEGATIVE IMPLYING EXTREME ILL-CONDITION. SELECTION IGNORED.

Two other error types are not detected:

1. If the number of observations is incorrect, the job deck will be such that results on that selection and on succeeding jobs will be incorrect. The user should take care in preparing his job deck according to instructions given above.

2. If some variable is constant over all observations, a zero standard deviation will occur, and results for that selection will be incorrect or not forthcoming.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 45 seconds.

CANONICAL CORRELATION

Problem Description

An analysis of the interrelations between two sets of variables measured on the same subjects is performed by this program. These variables are predictors in one set and criteria in the other set, but it is irrelevant whether the variables in the first set or in the second set are considered as the prediction variables. The canonical correlation, which gives the maximum correlation between linear functions of the two sets of variables, is calculated. χ^2 is also computed to test the significance of canonical correlation.

The sample problem for canonical correlation consists of four variables in the first set (left-hand side) and three variables in the second set (right-hand side) as presented in Table 6. These two sets of measurements have been made on 23 subjects.

Table 6. Sample Data for Canonical Correlation

	First set				Second set

Program

Description

The canonical correlation program consists of the main routine named MCANO, a special input subroutine named DATA, and five subroutines from the Scientific Subroutine Package: CORRE, CANOR, MINV, NROOT, and EIGEN.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to 20 variables, including both the first set of variables (that is, left-hand variables) and the second set of variables (that is, right-hand variables) The number of variables in the first set must be greater than or equal to the number of variables in the second set.
2. Up to 99,999 observations
3. (12F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions it is not necessary to modify the sample program. However, if there are more than 20 variables, dimension statements in the sample main program must be modified to handle the particular problem. Similarly, if input data cards are prepared using a different format, the input format in the input subroutine, DATA, must be modified. The general rules for program modification are desc ibed later.

Input

Control Card

One control card is required for each problem and is read by the main program, MCANO. This card is prepared as follows:

Columns	Contents	For Sample Problem
1 - 6	Problem number (may be alphameric)	SAMPLE
7 - 11	Number of observations	00023
12 - 13	Number of variables in the first set (that is, left-hand variables)*	04
14 - 15	Number of variables in the second set (that is, right-hand variables)	03

*The number of variables in the first set must be greater than or equal to the number of variables in the second set.

Leading zeros are not required to be keypunched.

Data Cards

Since input data are read into the computer one observation at a time, each row of data in Table 6 is keypunched on a separate card using the format (12F6.0). This format assumes twelve 6-column fields per card.

If there are more than twelve variables in a problem, each row of data is continued on the second card until the last data point is keypunched. However, each row of data must begin on a new card.

Deck Setup

The deck setup is shown in Figure 47.

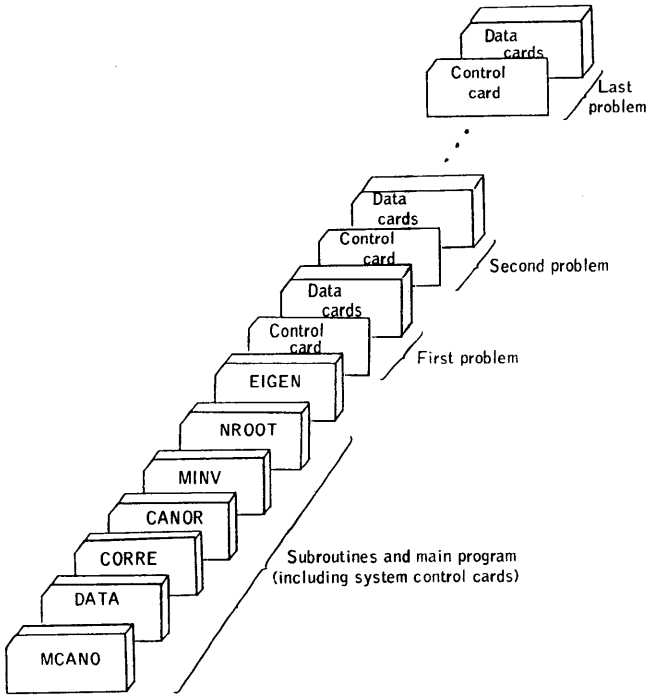

Figure 47. Deck setup (canonical correlation)

Sample

The listing of input cards for the sample problem is presented in Figure 48.

Output

Description

The output of the sample program for canonical correlation includes:

1. Means
2. Standard deviations
3. Correlation coefficients
4. Eigenvalues and corresponding canonical correlation
5. Lambda
6. Chi-square and degrees of freedom
7. Coefficients for left- and right-hand variables

Sample

The output listing for the sample problem is shown in Figure 49 of this sample problem.

```

Figure 48. Input card listing (canonical correlation)

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize the user with the program modification, the following general rules are supplied in terms of the sample problem.

1. Changes in the dimension statements of the main program, MCANO:
   a. The dimension of arrays XBAR, STD, CANR, CHISQ, and NDF must be greater than or equal to the total number of variables m (m = p + q, where p is the number of left-hand variables and q is the number of right-hand variables). Since there are seven variables, four on left and three on right, the value of m is 7.

Figure 49. Output listing (canonical correlation)

b. The dimension of array RX must be greater than or equal to the product of m x m. For the sample problem this product is 49 = 7 x 7.

c. The dimension of array R must be greater than or equal to (m + 1) m/2. For the sample problem this number is 28 = (7 + 1)7/2.

d. The dimension of array COEFL must be greater than or equal to the product of p x q. For the sample problem this product is 12 = 4 x 3.

e. The dimension of array COEFR must be greater than or equal to the product of q x q. For the sample problem this product is 9 = 3 x 3.

2. Changes in the input format statement of the special input subroutine, DATA:

Only the format statement for input data may be changed. Since sample data are either two- or three-digit numbers, rather than using six-column fields as in the sample problem, each row of data may be keypunched in seven 3-column fields, and, if so, the format is changed to (7F3.0).

The special input subroutine, DATA, is normally written by the user to handle different formats for different problems. The user may modify this subroutine to perform testing of input data, transformation of data, and so on.

Operating Instructions

The sample program for canonical correlation is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 19 seconds.

ANALYSIS OF VARIANCE

Problem Description

An analysis of variance is performed for a factorial design by use of three special operators suggested by H. O. Hartley.* The analysis of many other designs can be derived by reducing them first to factorial designs, and then pooling certain components of the analysis-of-variance table.

Consider a three-factor factorial experiment in a randomized complete block design as presented in Table 7. In this experiment, factor A has four levels, factors B and C have three levels, and the entire experiment is replicated twice. The replicates are completely unrelated and do not constitute a factor. Nevertheless, for the purpose of this program a four-factor experiment (with factors A, B, C, and R) is assumed. Thus, each element of the data in Table 5 may be represented in the form:

x_{abcr} where $a = 1, 2, 3, 4$; $b = 1, 2, 3$; $c = 1, 2, 3$; $r = 1, 2$

The general principle of the analysis-of-variance procedure used in the program is first to perform a formal factorial analysis and then to pool certain components in accordance with summary instructions that specifically apply to the particular design. The summary instructions for four different designs are presented in the output section.

Program

Description

The analysis-of-variance program consists of the main routine named ANOVA, and three subroutines from the Scientific Subroutine Package: AVDAT, AVCAL, and MEANQ.

*H. O. Hartley, "Analysis of Variance", Mathematical Methods for Digital Computers, edited by A. Ralston and H. Wilf, John Wiley and Sons, 1962, Chapter 20.

Table 7. Sample Data for Analysis of Variance

Replicate (Block)		b_1				b_2				b_3			
		a_1	a_2	a_3	a_4	a_1	a_2	a_3	a_4	a_1	a_2	a_3	a_4
r_1	c_1	3	10	9	8	24	8	9	3	2	8	9	8
	c_2	4	12	3	9	22	7	16	2	2	2	7	2
	c_3	5	10	5	8	23	9	17	3	2	8	6	3
r_2	c_1	2	14	9	13	29	16	11	3	2	7	5	3
	c_2	7	11	5	8	28	18	10	6	6	6	5	9
	c_3	9	10	27	8	28	16	11	7	8	9	8	15

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to six-factor factorial experiment
2. Up to a total of 3000 data points. The total number of data points in a problem is calculated by the formula:

$$T = \prod_{i=1}^{k} (LEVEL_i + 1)$$

where $LEVEL_i$ = number of levels of i^{th} factor
k = number of factors
Π = notation for cumulative multiplication

3. (12F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions it is not necessary to modify the sample program. However, if there are more than six factors or if the total number of data points is more than 3000, dimension statements in the sample main program must be modified. Similarly, if input data cards are prepared using a different format, the input format statement in the sample main program must be modified. The general rules for program modifications are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, ANOVA. This card is prepared as follows:

Columns	Contents	For Sample Problem
1- 6	Problem number (may be alphameric)	SAMPLE
7- 8	Number of factors	04
9-15	Blank	
16	Label for the first factor	A
17-20	Number of levels of the first factor	0004
21	Label for the second factor	B
22-25	Number of levels of the second factor	0003
26	Label for the third factor	C
27-30	Number of levels of the third factor	0003
31	Label for the fourth factor	R
32-35	Number of levels of the fourth factor	0002
.		
.		
.		
66	Label for the eleventh factor (if present)	
67-70	Number of levels of the eleventh factor	

If there are more than eleven factors, continue to the second card in the same manner.

Columns	Contents
1	Label for the twelfth factor
2 - 5	Number of levels of the twelfth factor
.	
.	
.	
etc.	

Leading zeros are not required to be keypunched.

Data Cards

Data are keypunched in the following order: X_{1111}, X_{2111}, X_{3111}, X_{4111}, X_{1211}, X_{2211}, X_{3211}, ..., X_{4332}. In other words, the innermost subscript is changed first -- namely, the first factor -- and then the second, third, and fourth subscripts. In the sample problem, the first subscript corresponds to factor A, and the second, third, and fourth subscripts to factors B, C, and R. Since the number of data fields per card is twelve, implied by the format (12F6.0), each row in Table 7 is keypunched on a separate card.

Deck Setup

The deck setup is shown in Figure 50.

Sample

The listing of input cards for the sample problem is presented in Figure 51.

Output

Description

The output of the sample analysis-of-variance program includes the numbers of levels of factors as input, the mean of all data, and the table of analysis of variance. In order to complete the analysis of variance properly, however, certain components in the table may need to be pooled. This is accomplished by means of summary instructions that specifically apply to the particular experiment. These are presented in Table 8.

As mentioned earlier, the sample problem is a randomized complete block design with three factors replicated twice. Therefore, it is necessary to pool certain components in the table of analysis of variance shown in Figure 52. Specifically, the components AR, BR, ABR, CR, ACR, BCR, and ABCR are combined into one value called the error term. The result is indicated in Figure 52. Since these data are purely hypothetical, interpretations of the various effects are not made.

Sample

The output listing for the sample problem is shown in Figure 52.

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize the user with the program modification, the following general rules are supplied in terms of the sample problem.

1. Changes in the dimension statements of the main program, ANOVA:
   a. The dimension of array X must be greater than or equal to the total number of data points as calculated by the formula in the program capacity section above. For the sample problem, the total number of data points is 240 = (4+1)(3+1)(3+1)(2+1).
   b. The dimension of arrays HEAD, LEVEL, ISTEP, KOUNT, and LASTS must be greater than or equal to the number of factors, k. Since there are four factors in the sample problem (4 = 3 original factors + 1 pseudo factor), the value of k is 4.
   c. The dimension of arrays SUMSQ, NDF, and SMEAN must be greater than or equal to $n = 2^k-1$, where k is the number of factors. For the sample problem, the value of n is $15 = 2^4-1$.
2. Change in the input format statement of the main program, ANOVA:
   Only the format statement for input data may be changed. Since sample data are either one- or two-digit numbers, rather than using six-column fields as in the sample problem, each data may be keypunched in a two-column field, and, if so, the format is changed to (12F2.0). This format assumes twelve 2-column fields per card, beginning in column 1.

Operating Instructions

The sample analysis-of-variance program is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 11 seconds.

DISCRIMINANT ANALYSIS

Problem Description

A set of linear functions is calculated from data on many groups for the purpose of classifying new individuals into one of several groups. The classification of an individual into a group is performed by evaluating each of the calculated linear functions, then finding the group for which the value is the largest.

The sample problem for discriminant analysis consists of four groups of observations as presented in Table 9. The number of observations in the first group is eight; the second group, seven; the third group, seven; and the fourth group, eight. The number of variables is six in all groups.

Program

Description

The discriminant analysis program consists of the main routine named MDISC, and three subroutines from the Scientific Subroutine Package: DMATX, MINV, and DISCR.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to five groups
2. Up to ten variables
3. Up to a total number of 250 observations in all groups combined
4. (12F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions it is not necessary to modify the sample program. However, if there are more than five groups, more than ten variables, or more than 250 observations, dimension statements in the sample

Table 9. Sample Data for Discriminant Analysis

	Observation	X_1	X_2	X_3	X_4	X_5	X_6
Group 1	1	3	10	9	8	24	8

	6	8	9	2	8	26	16
	7	7	8	6	9	18	2
	8	7	10	5	8	26	16

main program must be modified to handle this particular problem. Similarly, if input data cards are prepared using a different format, the input format statement in the sample main program must be modified. The general rules for program modification are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, MDISC. This card is prepared as follows:

Columns	Contents	For Sample Problem
1- 6	Problem number (may be alphameric)	SAMPLE
7- 8	Number of groups	04
9-10	Number of variables	06
11-15	Number of observations in first group	00008
16-20	Number of observations in second group	00007
21-25	Number of observations in third group	00007
26-30	Number of observations in fourth group	00008
⋮		
65-70	Number of observations in twelfth group (if present)	

If there are more than twelve groups in the problem, continue to the second card in the same manner.

Columns	Contents
1- 5	Number of observations in thirteenth group
6-10	Number of observations in fourteenth group

Leading zeros are not required to be keypunched.

Data Cards

Since input data are read into the computer one observation at a time, each row of data in Table 9 is keypunched on a separate card using the format (12F6.0). This format assumes twelve 6-column fields per card.

If there are more than twelve variables in a problem, each row of data is continued on the second and third cards until the last data point is keypunched. However, each row of data must begin on a new card.

Deck Setup

The deck setup is shown in Figure 53.

Sample

The listing of input cards for the sample problem is presented in Figure 54.

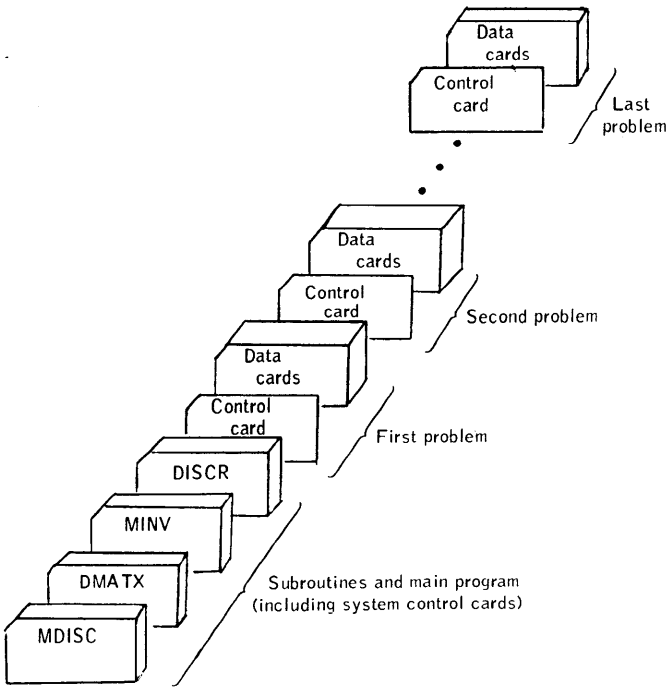

Figure 53. Deck setup (discriminant analysis)

Output

Description

The output of the sample program for discriminant analysis includes:

1. Means of variables in each group
2. Pooled dispersion matrix
3. Common means
4. Generalized Mahalanobis D-square
5. Constant and coefficients of each discriminant function
6. Probability associated with the largest discriminant function evaluated for each observation.

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize the user with the program modification, the following general rules are supplied in terms of the sample problem.

1. Changes in the dimension statements of the main program, MDISC:
   a. The dimension of array N must be greater than or equal to the number of groups, k. Since there are four groups in the sample problem, the value of k is 4.
   b. The dimension of array CMEAN must be greater than or equal to the number of variables, m. Since there are six variables in the sample problem, the value of m is 6.
   c. The dimension of array XBAR must be greater than or equal to the product of m times k. For the sample problem this product is 24 = 6 x 4.
   d. The dimension of array C must be greater than or equal to the product of (m+1)k. For the sample problem this product is 28 = (6+1)4.
   e. The dimension of array D must be greater than or equal to the product of m times m. For the sample problem this product is 36 = 6 x 6.
   f. The dimension of arrays P and LG must be greater than or equal to the total number of observations in all groups combined, t. For the sample problem this total is 30 = 8 + 7 + 7 + 8.

Figure 55. Output listing (discriminant analysis) (Continued)

g. The dimension of array X must be greater than or equal to the total number of data points that is equal to the product of t times m. For the sample this product is 180 = 30 x 6.

2. Changes in the input format statement of the main program, MDISC:

Only the format statement for input data may be changed. Since sample data are either one- or two-digit numbers, rather than using six-column fields as in the sample problem, each row of data may be keypunched in two-column fields, and, if so, the format is changed to (6F2.0). This format assumes six 2-column fields per card, beginning in column 1.

Operating Instructions

The sample program for discriminant analysis is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 30 seconds.

FACTOR ANALYSIS

Problem Description

A principal component solution and the varimax rotation of the factor matrix are performed. Principal component analysis is used to determine the minimum number of independent dimensions needed to account for most of the variance in the original set of variables. The varimax rotation is used to simplify columns (factors) rather than rows (variables) of the factor matrix.

The sample problem for factor analysis consists of 23 observations with nine variables as presented in Table 10. In order to keep the number of independent dimensions as small as possible, only those eigenvalues (of correlation coefficients) greater than or equal to 1.0 are retained in the analysis.

Table 10. Sample Data for Factor Analysis

Program

Description

The factor analysis program consists of the main routine named FACTO, a special input subroutine named DATA, and five subroutines from the Scientific Subroutine Package: CORRE, EIGEN, TRACE, LOAD, and VARMX.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to 35 variables
2. Up to 99,999 observations
3. (12F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions it is not necessary to modify the sample program. However, if there are more than 35 variables, dimension statements in the sample main program must be modified to handle this particular problem. Similarly, if input data cards are prepared using a different format, the input format statement in the input subroutine, DATA, must be modified. The general rules for program modification are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, FACTO. This card is prepared as follows:

Columns	Contents	For Sample Problem
1- 6	Problem number (may be alphameric)	SAMPLE
7-11	Number of observations	00023
12-13	Number of variables	09
14-19	Value used to limit the number of eigenvalues of correlation coefficients. Only those eigenvalues greater than or equal to this value are retained in the analysis. (A decimal point must be specified.)	0001.0

Leading zeros are not required to be keypunched.

Data Cards

Since input data are read into the computer one observation at a time, each row of data in Table 10 is keypunched on a separate card using the format (12F6.0). This format assumes twelve 6-column fields per card.

If there are more than twelve variables in a problem, each row of data is continued on the second and third cards until the last data point is keypunched. However, each row of data must begin on a new card.

Deck Setup

The deck setup is shown in Figure 56.

Sample

The listing of input cards for the sample problem is presented in Figure 57.

Output

Description

The output of the sample program for factor analysis includes:

1. Means
2. Standard deviations
3. Correlation coefficients
4. Eigenvalues
5. Cumulative percentage of eigenvalues
6. Eigenvectors
7. Factor matrix
8. Variance of the factor matrix for each iteration cycle

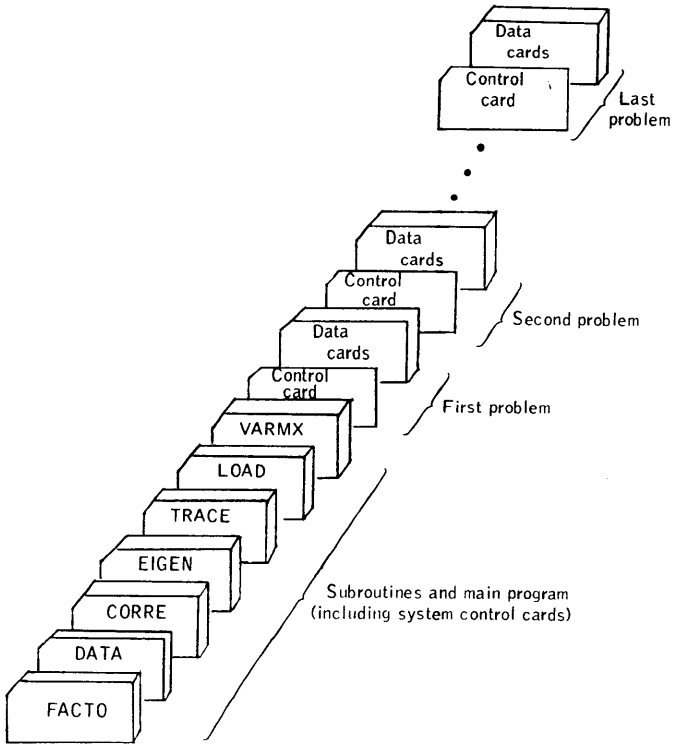

Figure 56. Deck setup (factor analysis)

9. Rotated factor matrix
10. Check on communalities

Sample

The output listing for the sample problem is shown in Figure 58.

Program Modification

Program capacity can be increased or decreased by making changes in dimension statements. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize the user with the program modification, the

Figure 58. Output listing (factor analysis) (Continued)

following general rules are supplied in terms of the sample problem.

1. Changes in the dimension statements of the main program, FACTO:

   a. The dimension of arrays B, D, S, T, and XBAR must be greater than or equal to the number of variables, m. Since there are nine variables in the sample problem, the value of m is 9.

   b. The dimension of array V must be greater than or equal to the product of m times m. For the sample problem this product is 81 = 9 x 9.

   c. The dimension of array R must be greater than $\frac{(m+1)m}{2}$. For the sample problem, this number is $45 = \frac{(9+1)9}{2}$.

2. Changes in the input format statement of the special input subroutine, DATA:

   Only the format statement for input data may be changed. Since sample data are either one- or two-digit numbers, rather than using six-column fields as in the sample problem, each row of data may be keypunched in two-column fields, and, if so, the format is changed to (9F2.0). This format assumes nine 2-column fields per card, beginning in column 1.

   The special input subroutine, DATA, is normally written by the user to handle different formats for different problems. The user may modify this subroutine to perform testing of input data, transformation of data, and so on.

Operating Instructions

The sample program for factor analysis is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Error Messages

If the number of factors to be rotated is one or zero, the following message will be printed:

ONLY____FACTOR RETAINED. NO ROTATION.

The program skips rotation and goes to the next problem if it is present.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 50 seconds.

KOLMOGOROV - SMIRNOV TEST

Problem Description

This program is concerned with the problem of determining (a) from what probability density function a particular sample is drawn, or (b) whether two different samples were drawn from the same population. In other words, in the one sample case, the actual distribution function of the sample is compared with one or more theoretical distribution functions, which may be normal, and/or exponential, and/or Cauchy, and/or uniform, and/or a user-specified distribution. In the two-sample case, the pair of sample (actual) distribution functions are compared with one another.

From the above comparisons, a statistic is derived. In the one sample case, this statistic evaluates the probability that the statistic will be as great as or greater than its current value, if the hypothesis that the actual (sample) and the theoretical distribution functions are equal is correct. In other words, if the probability is determined to be 0.40, for example, rejecting the hypothesis of equality of the distribution functions will be an incorrect action 40 times out of 100. Similarly, in the two-sample case, the hypothesis being tested is the equality of the two actual (sample) distribution functions.

This probability is calculated using asymptotic formulas. This means that the sample sizes involved should be large. Sizes greater than 100 are suggested by the literature. In this connection, the remarks given under the topic "Subroutine SMIRN" should be considered.

Note also that added problems arise when, in the one sample case, the parameters of the continuous distribution in question are estimated from the sample. Lilliefors discusses these problems (see reference given in KOLMO description).

Program

Description

This program consists of the main routine KOLM, and four subroutines from the Scientific Subroutine Package: KOLMO, KOLM2, SMIRN, and NDTR.

Capacity

This program allows up to two samples each with 500 or fewer observations to be examined. If the user desires to modify this program to handle more observations, the instructions given below under "Program Modification" should be followed.

Input

After two initializing cards (1, 2 below) each job consists of two control cards and the data cards (3-5 below).

1. Initializing card (minus signs in cc 1-4)
2. Names of distribution functions (as supplied, these are the normal, exponential, Cauchy, uniform, and user's pdf). These names are punched in the order given, centrally located in 16 digit fields on one card; that is, "normal" is punched in cc 1-16, "exponential" in cc 17-32, and so on.
3. Job control card (minus signs in cc 1-4)
4. Program control card

Each job requires one program control card, defined below:

Columns	Contents	For Sample Problems
1 - 20	Title (alphameric)	Uniform test (Job 1) Uniform-Gauss Test (job 2)
21	1 -- one-sample test	1 (job 1)
	2 -- two-sample test	2 (job 2)
22	Leave blank for one-sample test.	0 (job 1) 1 (job 2)
	0 -- Read both samples (two-sample tests).	
	1 -- Read only one sample and compare it with the first sample read on preceding job.	
23	0 -- Do not print the sample(s).	0 (job 1)
	1 -- Print the sorted sample(s).	1 (job 2)
	(F10.3, ten per line)	
(The rest of this control card pertains to a one-sample test.)		
24	0 -- Do not compare with normal pdf.	1 (job 1)
	1 -- Compare with normal pdf.	
25 - 29	u -- mean of the normal pdf	0.5 (job 1)
30 - 34	s -- standard deviation of the normal pdf	0.5 (job 1)
35	0 -- Do not compare with exponential pdf.	
	1 -- Compare with exponential pdf.	1 (job 1)
36 - 40	u -- mean of the exponential pdf	0.5 (job 1)
41 - 45	s -- standard deviation of the exponential pdf	1.0 (job 1)
46	0 -- Do not compare with Cauchy pdf.	
	1 -- Compare with Cauchy pdf.	1 (job 1)
47 - 51	u -- median of the Cauchy pdf	0.5 (job 1)
52 - 56	s -- u-s is the first quartile of the Cauchy pdf	1.0 (job 1)
57	0 -- Do not compare with uniform pdf.	
	1 -- Compare with uniform pdf.	1 (job 1)
58 - 62	u -- left endpoint of the uniform pdf	0 (job 1)
63 - 67	s -- right endpoint of uniform pdf	1.0 (job 1)
68	0 -- Do not compare with user's pdf.	0 (job 1)
	1 -- Compare with user-specified pdf.	
69 - 73	u } -- Parameters for	0 (job 1)
74 - 78	s } -- user-specified pdf	0 (job 1)
	u and s are described fully in "Description of Parameters" under subroutine KOLMO, and are read using Format F 5.0; decimal points will override the format specification.	

5. Data is read into the computer one sample at a time. The reading of a sample is terminated by a data element of 999999. New samples must begin on a new card. Data elements are punched on cards using format F6.0, which assumes twelve 6-column fields per card; decimal points on the card override the format specification. Since the routines KOLMO and KOLM2 sort the samples, no particular order within a sample is necessary.

Deck Setup

See figure 59.

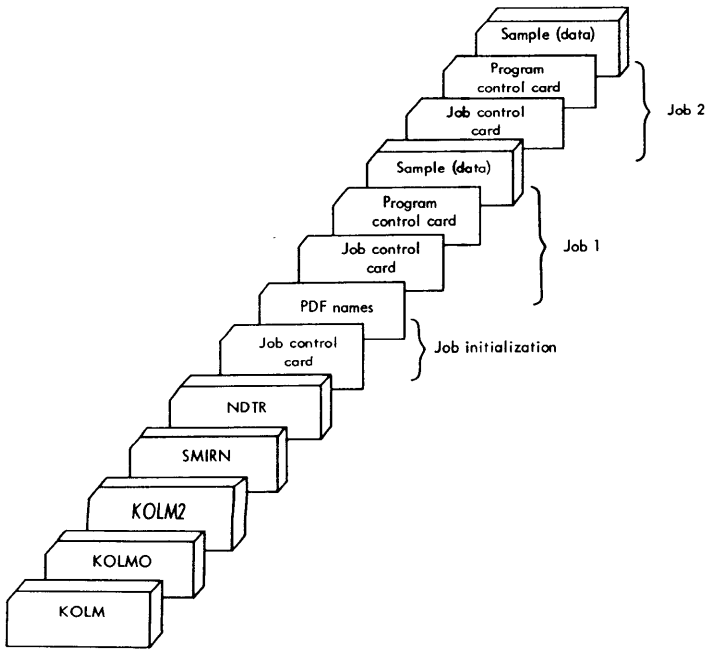

Figure 59. Deck setup (Kolmogorov - Smirnov test)

Sample Data

See Figure 60.

Figure 60.

Output

Description

The output from the program KOLM gives the statistics and probability statements described below, and in addition identifies the distribution functions being considered. Sorted samples are printed on option.

The following items are produced as output:

1. Z score, where $z = \sqrt{n}\, D_n$ for the one-sample test; n is the sample size, and D_n is the maximum difference between the empirical distribution function and the theoretical distribution function.

   $z = \sqrt{\frac{mn}{m+n}}\, D_{m,n}$ for the two-sample test, m is the size of the second sample; n is the size of the first sample; $D_{m,n}$ is the maximum difference between the two empirical distribution functions.

2. The probability of incorrectly rejecting the hypothesis of equality of distribution functions.

Sample

See Figure 61.

Program Modification

1. Program capacity may be increased or decreased by making changes in the dimension statements. If this is done, the statements DO 111 I = 1, 50 and DO 117 I = 1, 50 may require modification (under READ SAMPLE comments card in listing of program). This will also be true if data formats require changing. The "read sample" sections of the program use FORMAT statement 3, and the user may wish to change these sections.

2. Any modifications to the subroutine KOLMO in terms of added continuous pdf's should be reflected in the program KOLM. It may be necessary to:

   a. Modify the dimensions of DIST (5, 3), which contains the switches calling on pdf's and also contains the parameters u and s used by KOLMO
   b. Modify the pdf titling card, statement 6 (FORMAT), the READ (5, 6)TIT1 card which reads titles, and the dimension of TIT1 (now 20, to hold five 16-digit titles)
   c. Modify the section of the program from statement 121 through 132 to reflect changes a and b above. These statements call KOLMO to perform tests and output results.

3. List of names in KOLM, and their usage:

D -- Temporary vector used in reading samples
DAS2 -- Initializing card name (----)
DASH -- Job control card name (----)
DIST -- 5 by 3 matrix. The five elements in column 1 are switches that allow the (5) pdf's to be used in one-sample tests. Columns 2 and 3 contain the parameters u and s for the associated test.
IFL -- Error indicator (job deck error)
IER -- Error (in KOLMO, used for skipping the test concerned)
IES -- Error (in KOLMO , used for error message)

```
UNIFORM TEST

A 1 SAMPLE TEST WAS REQUESTED

THE SIZE OF SAMPLE  1 IS 498.

THE HYPOTHESIS THAT THE SAMPLE IS FROM A(N)      NORMAL      DISTRIBUTION
 WITH MEAN       0.5000 AND VARIANCE       0.2500
 CAN BE REJECTED WITH PROBABILITY 0.0   OF BEING INCORRECT.  THE STATISTIC Z
 IS  0.3504E 01 FOR THIS SAMPLE.

THE HYPOTHESIS THAT THE SAMPLE IS FROM A(N)   EXPONENTIAL    DISTRIBUTION
 WITH MEAN       0.5000 AND VARIANCE       1.0000
 CAN BE REJECTED WITH PROBABILITY 0.0   OF BEING INCORRECT.  THE STATISTIC Z
 IS  0.8803E 01 FOR THIS SAMPLE.

THE HYPOTHESIS THAT THE SAMPLE IS FROM A(N)      CAUCHY      DISTRIBUTION
 WITH MEDIAN       0.5000 AND FIRST QUARTILE      -0.5000
 CAN BE REJECTED WITH PROBABILITY 0.0   OF BEING INCORRECT.  THE STATISTIC Z
 IS  0.7887E 01 FOR THIS SAMPLE.

THE HYPOTHESIS THAT THE SAMPLE IS FROM A(N)     UNIFORM      DISTRIBUTION
 IN THE INTERVAL       0.0    TO       1.0000 INCLUSIVE
 CAN BE REJECTED WITH PROBABILITY 0.989 OF BEING INCORRECT.  THE STATISTIC Z
 IS  0.4444E 00 FOR THIS SAMPLE.

THE JOB WITH TITLE UNIFORM TEST          WAS COMPLETED.

UNIFORM-GAUSS TEST

A 2 SAMPLE TEST WAS REQUESTED

THE SIZE OF SAMPLE  2 IS 492.

THE HYPOTHESIS THAT THE TWO SAMPLES ARE FROM THE SAME POPULATION CAN BE REJECTED WITH (ASYMPTOTIC)
PROBABILITY OF BEING INCORRECT OF  0.000.  THE STATISTIC Z IS   0.2590E 01 FOR THESE SAMPLES.

 THE JOB WITH TITLE UNIFORM-GAUSS TEST   WAS COMPLETED.
```

Figure 61. (Continued)

IO -- Switch (used for printing samples)
IR -- Number of samples to be read in current job
IS -- Number of samples to be used in current job (1 or 2)
K -- Counter used to print correct pdf name for pdf used in the test
M -- Size of second sample
N -- Size of first sample
N1 -- 1 or 2, for number of samples tested
P -- Probability of being incorrect if hypothesis is rejected
S2 -- Temporary storage for u and s output
TIT1 -- Current pdf names
TITLE -- Job title
X -- Sample 1
Y -- Sample 2
Z -- Z statistic, from KOLMO or KOLM2

Operating Instructions

This sample program is a standard FORTRAN program and needs no special operating instructions. Data set 5 is used for input, and 6 for output.

Error Messages

The following error conditions will result in messages, followed by the action specified:

1. Neither a one- nor two-sample test is requested, or the size of either sample is larger than 500 -- CC.21, CONTROL CARD, INCORRECT, OR SAMPLE SIZE TOO LARGE. JOB IGNORED. Action: Cards are read until a new job control card is found, or until the hopper is empty.

2. Sample size is less than 100 (not an error) -- NOTE THE REMARKS CONCERNING ASYMPTOTIC RESULTS AND SAMPLE SIZE IN SUBROUTINE SMIRN. Action: None - job continues.

3. The requirement of subroutine KOLMO that certain parameters be nonzero or positive is violated -- AT LEAST ONE (S) ENTRY PARAMETER FOR THE SUBROUTINE KOLMO WAS INCORRECT. THE TEST FOR THE ASSOCIATED CONTINUOUS PDF WAS IGNORED. Action: All tests are made for cases where the parameter s was correct.

4. A case in which an error requires aborting the job, and the succeeding job in the job stack requests a two-sample test where the second sample is to be

compared with a (first) sample which was read on the previous job -- THIS JOB CALLS FOR THE USE OF A PREVIOUSLY READ SAMPLE, AND THE PREVIOUS JOB WAS IGNORED BECAUSE OF ERRORS. JOB IGNORED. Action: Cards are read until a new job control card is found, or until the hopper is empty.

5. The job control card preceding a job is not there or is incorrect -- FIRST CARD IN JOB DECK (JOB CONTROL CARD) IS INCORRECT. Action: Cards are read until a new job control card is found, or until the hopper is empty.

Timing

The execution time of this program on a System/360, Model 40, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 Printer as output, is:

33 seconds for job 1

50 seconds for job 2

TRIPLE EXPONENTIAL SMOOTHING

Problem Description

Given a time series X, a smoothing constant, and three coefficients of the prediction equation, this sample program finds the triple exponentially smoothed series S of the time series X.

Program

Description

The sample program for triple exponential smoothing consists of the main program named EXPON, and one subroutine, EXSMO, from the Scientific Subroutine Package.

Capacity

The capacity of the sample program and the format required for data input have been set up as follows:

1. Up to 1000 data points in a given time series
2. (12F6.0) format for input data cards

Therefore, if a problem satisfies the above conditions, the sample program need not be modified. However, if there are more than 1000 data points, the dimension statement in the sample main program must be modified to handle this particular problem. Similarly, if input data cards are prepared using a different format, the input format in the sample main program must be modified. The general rules for program modification are described later.

Input

Control Card

One control card is required for each problem and is read by the main program, EXPON. This card is prepared as follows:

Columns	Contents	For Sample Problem
1- 6	Problem number (may be alphameric)	SAMPLE
7-10	Number of data points in a given time series	0038
11-15	Smoothing constant, α $(0.0 < \alpha < 1.0)$	0.1
16-25	First coefficient (A) of the prediction equation	0.0
26-35	Second coefficient (B) of the prediction equation	0.0
36-45	Third coefficient (C) of the prediction equation	0.0

Smoothing constant and three coefficients must be keypunched with decimal points.

Leading zeros are not required to be keypunched.

Data Card

Time series data are keypunched using the format (12F6.0). This format assumes that each data point is keypunched in a six-column field and twelve fields per card.

Deck Setup

The deck setup is shown in Figure 62.

Sample

The listing of input cards for the sample problem is presented in Figure 63.

Output

Description

The output of the sample program for triple exponential smoothing includes:

```

Figure 63. Input listing (triple exponential smoothing)

1. Original and updated coefficients
2. Time series as input and triple exponentially smoothed time series

Sample

The output listing for the sample problem is shown in Figure 64.

Program Modification

Program capacity can be increased or decreased by making changes in the dimension statement. Input data in a different format can also be handled by providing a specific format statement. In order to familiarize the user with the program modification, the following general rules are supplied in terms of the sample problem.

```

Figure 64. Output listing (triple exponential smoothing)

1. Changes in the dimension statement of the main program, EXPON:

The dimension of arrays X and S must be greater than or equal to the number of data points in time series, NX. Since there are 38 data points in the sample problem, the value of NX is 38.

2. Changes in the input format statement of the main program, EXPON:

Only the format statement for input data may be changed. Since sample data are three-digit numbers, rather than using six-column fields as in the sample problem, each data point may be keypunched in a three-column field and 24 fields per card. If so, the format is changed to (24F3.0).

Operating Instructions

The sample program for triple exponential smoothing is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is twelve seconds.

MATRIX ADDITION

Problem Description

An input matrix is added to another input matrix to form a resultant matrix. Each set of input matrices and the corresponding output matrix is printed. This procedure is repeated until all sets of input matrices have been processed.

Program

Description

The matrix addition program consists of a main routine, ADSAM, and four subroutines, MATIN, MADD, MXOUT, and LOC. MADD and LOC are from the Scientific Subroutine Package. MATIN and MXOUT are sample subroutines for matrix input and output (see program listings).

Capacity

Matrix size has arbitrarily been set at 1000 data elements.

Input

Control Cards

Each input matrix must be preceded by a parameter card with the following format:

Columns	Contents	For Sample Problem
1-2	Blank	
3-6	Up to four-digit identification code	0001
7-10	Number of rows in matrix	0008
11-14	Number of columns in matrix	0011
15-16	Storage mode of matrix 0 for general matrix 1 for symmetric matrix 2 for diagonal matrix	0

Each input matrix must be followed by a card with a 9-punch in column 1.

A blank card after the last pair of input matrices terminates the run.

Data Cards

Data cards are assumed to have seven fields of ten columns each. The decimal point may appear anywhere in a field. If no decimal point is included, it is assumed that the decimal point is to the right of the last digit. The number in each field may be preceded by blanks. Data elements must be punched by row. A row may continue from card to card. However, each new row must start in the first field of the next card. Only the upper triangular portion of a symmetric matrix or the diagonal elements of a diagonal matrix are contained on data cards. The first element of each new row will be the diagonal element for a matrix with symmetric or diagonal storage mode. Columns 71-80 of data cards may be used for identification, sequence numbering, and so on.

Deck Setup

The deck setup is shown in Figure 65.

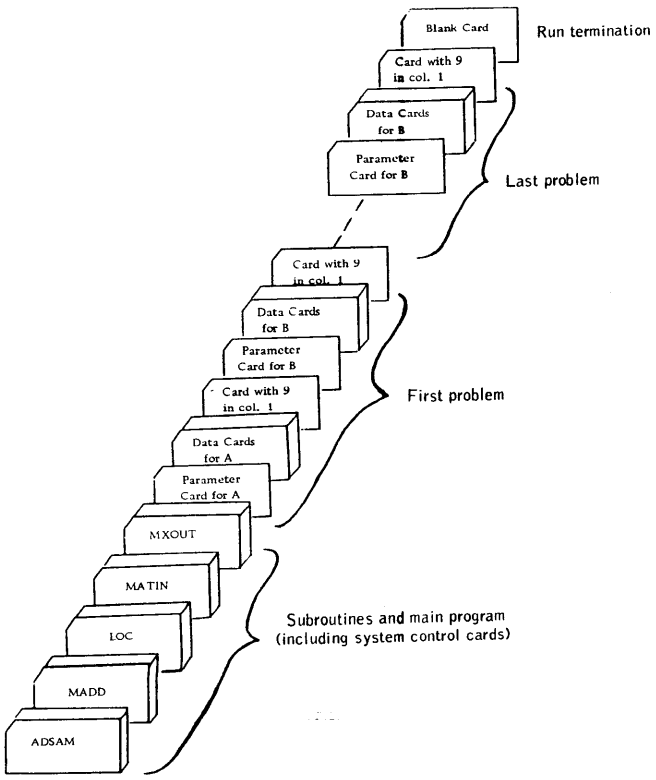

Figure 65. Deck setup (matrix addition)

Sample

A listing of input cards for the sample problem is presented in Figure 66.

Figure 66. Input listing (matrix addition)

Output

Description

The resultant matrix is printed for any size array as a general matrix regardless of the storage mode. Each page is headed with the matrix code number, dimensions, and storage mode. Columns and rows are headed with their respective number. The code number for the output matrix is derived by adding the code numbers for the input matrices.

Sample

The output listing for the sample problem is shown in Figure 67.

Program Modification

Matrix size can be increased or reduced by making the following changes in ADSAM:

1. Modify the DIMENSION statement to reflect the number of elements for A, B, and R.

2. Insert the same number in the third parameter of the two CALL MATIN statements (20 and 45).

```

END OF CASE
```

Figure 67. Output listing (matrix addition)

The output listing is set for 60 print lines per page, 132 print positions across the page, and double spacing. This can be changed by means of the last three parameters in the three-call MXOUT statements in ADSAM (statements 40, 80, 90).

Operating Instructions

The matrix addition sample program is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Error Messages

The following error conditions will result in messages:

1. Reserved storage area is too small for matrix -- DIMENSIONED AREA TOO SMALL FOR INPUT MATRIX (matrix code no.). GO ON TO NEXT CASE.

2. Input matrices do not have the same dimensions -- MATRIX DIMENSIONS NOT CONSISTENT. GO ON TO NEXT CASE.

3. Number of data cards does not correspond to that required by parameter card -- INCORRECT NUMBER OF DATA CARDS FOR MATRIX (matrix code no.). EXECUTION TERMINATED.

Error conditions 1 and 2 allow the computer run to continue. Error condition 3, however, terminates execution and requires another run to process succeeding cases.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 36 seconds.

NUMERICAL QUADRATURE INTEGRATION

Problem Description

The tabulated values of a function for a given spacing are integrated. Multiple sets of tabulated values may be processed.

Program

Description

The numerical quadrature integration program consists of a main routine, QDINT, and one subroutine, QSF, from the Scientific Subroutine Package.

Capacity

Up to 500 tabulated values of a function may be integrated.

Input

Control Cards

Each integration requires a parameter card with the following format:

Columns	Contents	For Sample Problem
1- 5	Up to 5-digit numeric identification code	12345
6-10	Number of tabulated values for this function	0020
11-20	Interval between tabulated values	1.0

The first two parameters consist of up to five digits with no decimal point (FORMAT (2I5)). Note that the second parameter may not exceed 500. The third parameter consists of up to ten digits with decimal point. If no decimal point is included, it is assumed that the decimal point is to the right of the field (FORMAT (F10.0)). A blank card following the last set of data terminates the run.

Data Cards

Data cards are assumed to be seven fields of ten columns each. The decimal point may appear anywhere in the field. The number in each field may be preceded by blanks. Columns 71 through 80 of the data cards may be used for identification, sequence numbering, and so on. If there are more than seven tabulated values, the values should continue from card to card with seven values per card until the number of values specified in the parameter card has been reached.

Deck Setup

The deck setup is shown in Figure 68.

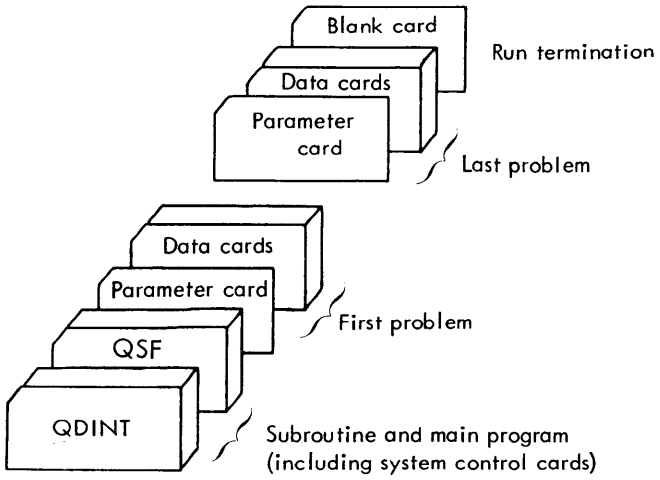

Figure 68 Deck setup (numerical quadrature integration)

Sample

A listing of input cards for the sample program is presented in Figure 69.

```

Figure 69. Input listing (numerical quadrature integration)

Output

Description

The identification code number, number of tabulated input values, the interval for the tabulated values, and the resultant integral values at each step are printed.

Sample

The output listing for the sample program is shown in Figure 70.

```

```

Figure 70. Output listing (numerical quadrature integration)

Program Modification

The maximum number of tabulated values acceptable to the sample program may be changed by modifying the dimension statement in QDINT. The format of the parameter cards and data cards may be changed by modifying statements 10 and 40, respectively, in QDINT.

Operating Instructions

The numerical quadrature integration sample program is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Error Messages

The following conditions will result in error messages:

1. The number of tabulated values specified in the parameter card is less than or equal to one -- ILLEGAL CONDITION. NUMBER OF TABULATED VALUES IS LESS THAN THREE. The program will go on to the next set of data.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is six seconds.

RUNGE-KUTTA INTEGRATION

Problem Description

A differential equation of the form:

$$\frac{dy}{dx} = f(x, y)$$

is integrated with initial conditions as specified in a parameter card. The differential equation is defined in the form of a function subprogram that is provided by the user.

Program

Description

The Runge-Kutta integration program consists of a main routine RKINT, one subroutine RK2 from the Scientific Subroutine Package, and one user-supplied function subprogram FUN, which defines the differential equation to be integrated.

Capacity

Up to 500 values of the integral may be tabulated.

Input

Control Cards

Each integration requires a parameter card with the following format:

Columns	Contents	For Sample Problem
1-10	Initial value of $X = X_0$	1.0
11-20	Initial value of $Y = Y(X_0)$	0.0
21-30	Step size	0.01
31-35	Number of steps required between tabulated values	10
36-40	Total number of tabulated values required	30

The first three parameters consist of up to ten digits with decimal point. If no decimal point is included, it is assumed that the decimal point is to the right of the field.

(FORMAT (F10.0))

The last two parameters consist of up to four digits plus a blank with no decimal point.

(FORMAT (15))

Multiple parameter cards may be used. A blank card terminates the run.

Data Cards

None.

Deck Setup

The deck setup is shown in Figure 71.

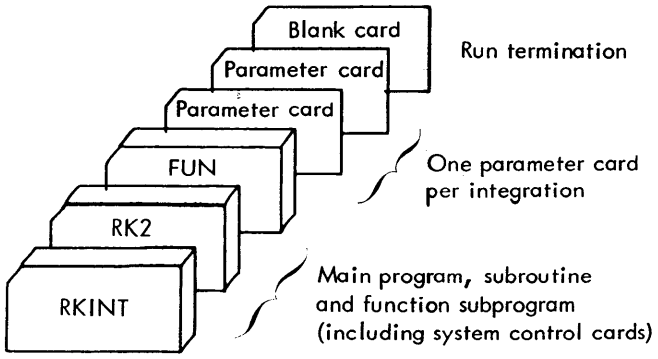

Figure 71. Deck setup (Runge-Kutta integration)

Sample

A listing of the input cards for the sample problem is presented in Figure 72.

```
/DATA
      1.0        0.0        .01    10    30                    10
                                                               20
                                                               30
```

Figure 72. Input listing (Runge-Kutta integration)

Output

Description

The values for the initial conditions and the tabulated values of the integral are printed.

Sample

The output listing for the sample problem is shown in Figure 73.

```

Figure 73. Output listing (Runge-Kutta integration)

Program Modification

The function subprogram FUN may be replaced by any function subprogram having the same name and parameter list. In this way, the user may define any desired first-order differential equation. The maximum number of tabulated values may be changed by altering the dimension statement in the sample program RKINT.

Operating Instructions

The sample program for Runge-Kutta integration is a standard FORTRAN program. Special operating instructions are not required. Data set reference 5 is used for input, and data set reference 6 is used for output.

Error Messages

None.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is twelve seconds.

POLYNOMIAL ROOTS

Problem Description

The real and complex roots are computed for a real polynomial with given coefficients. Multiple sets of coefficients may be processed.

Program

Description

The polynomial roots sample program consists of a main routine, SMPRT, and one subroutine POLRT from the Scientific Subroutine Package.

Capacity

Roots for polynomials of order 36 or less may be computed.

Input

Control Cards

Each set of data requires a control card with the following format:

Columns	Contents	For Sample Problem
1	Blank	
2-5	Up to four-digit identification code	360
6-8	Blank	
9-10	Order of polynomial	9

The first parameter consists of up to four digits without decimal point. The second parameter consists of up to two digits with no decimal point. The order of the polynomial must be less than or equal to 36.

Data Cards

Data cards are assumed to have seven fields of ten columns each. The decimal point may appear anywhere in the field. If no decimal point is included, it is assumed to be to the right of the field. The number in each field may be preceded by blanks. Columns 71 to 80 of the data cards may be used for identification, sequence numbering, and so on. If there are more than seven coefficients, the values should continue from card to card with seven values per card until the number of values has been reached that is one greater than the order of the polynomial.

The first coefficient is for the constant term of the polynomial and the last coefficient for the highest order term. Fields with zero coefficients may be left blank.

Deck Setup

The deck setup is shown in Figure 74.

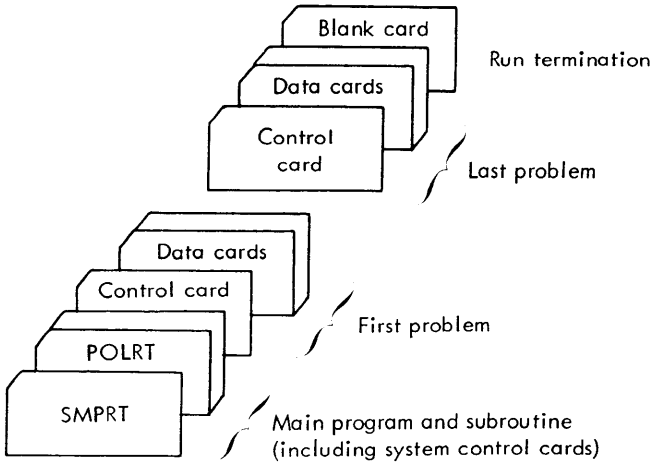

Figure 74. Deck setup (polynomial roots)

Sample

A listing of the input cards for the sample program is shown in Figure 75.

Program Modification

The maximum order of the polynomial is fixed by the subroutine POLRT. The sample program can accept polynomials up to the maximum of 36th order, which is allowed by the subroutine. The format of the control card and data cards may be changed by modifying statements 10 and 40, respectively, in SMPRT.

Operating Instructions

The polynomial roots sample program is a standard FORTRAN program. Special operating instructions are not required. Data set 5 is used for input, and data set 6 is used for output.

Error Messages

The following conditions will result in error messages:

1. The order of the polynomial specified in the control card is less than one -- ORDER OF POLYNOMIAL LESS THAN ONE.

   The program will go on to the next set of data.

2. The order of the polynomial specified in the control card is greater than 36 -- ORDER OF POLYNOMIAL GREATER THAN 36.

   The program will go on to the next set of data.

3. The subroutine POLRT is unable to determine a root after 500 iterations on eight different starting values -- UNABLE TO DETERMINE ROOT. THOSE ALREADY FOUND ARE....

   The program will print all the roots that were computed and then go on to the next set of data.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is eleven seconds.

SOLUTION OF SIMULTANEOUS EQUATIONS

Problem Description

A solution is obtained for a set of simultaneous equations by the method of elimination using largest pivotal divisor. Both the input data and the solution values are printed. This procedure is repeated until all sets of input data have been processed.

Program

Description

The solution of the simultaneous equations program consists of a main routine, SOLN, and four subroutines, MATIN, SIMQ, MXOUT, and LOC. SIMQ and LOC are from the Scientific Subroutine Package. MATIN and MXOUT are sample subroutines for matrix input and output (see program listings).

Capacity

The program will solve up to 50 equations. This can easily be changed as described under "Program Modification" below.

Input

Control Cards

A parameter card with the following format must precede each matrix of coefficients:

Columns	Contents	For Sample Problem
1-2	Blank	
3-6	Up to four-digit identification code (numeric only)	1
7-10	Number of rows in matrix	10
11-14	Number of columns in matrix (same as number of rows)	10

Each matrix must be followed by a card with a 9-punch in column 1. This, in turn, is followed by the constant vector.

A blank card after the last set of input data terminates the run.

Data Cards

Data Cards are assumed to have seven fields of ten columns each. The decimal point may appear anywhere in a field. If no decimal point is included, it is assumed that the decimal point is to the right of the last digit. The number in each field may be preceded by blanks. Equation coefficients must be punched by row. A row may continue from card to card. However, each new row must start in the first field of the next card. The vector of constants is punched in continuous data fields following the 9 card. Columns 71-80 of data cards may be used for identification, sequence numbering, and so on.

Deck Setup

The deck setup is shown in Figure 77.

Sample

A listing of input cards for the sample problem is presented in Figure 78.

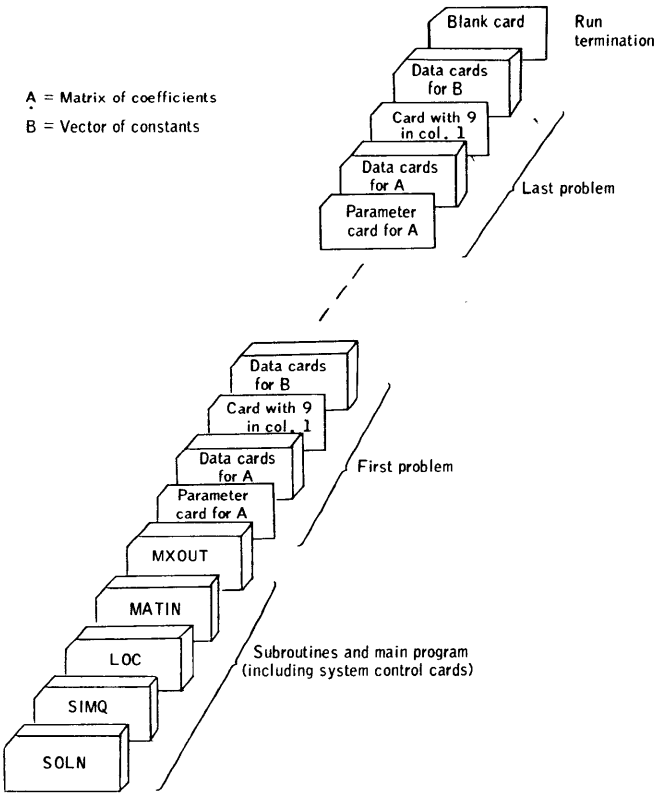

Figure 77. Deck setup (solution of simultaneous equations)

Figure 78. Input listing (solution of simultaneous equations)

Output

Description

The original matrix is printed for any size array. Each page is headed with the matrix code number, dimensions, and storage mode (always 0 in this sample program). Columns and rows are headed with their respective number. The original vector of constants is also printed. The solution values are then listed. This output is given for each case to be processed.

Sample

The output listing for the sample problem is shown in Figure 79.

```

Figure 79. Output listing (solution of simultaneous equations)

Program Modification

The size of the maximum problem to be solved can be increased or decreased by making the following changes in SOLN:

1. Modify the DIMENSION statement to reflect the maximum number of elements for matrix A (= N x N) and the maximum number of equations (N) for B.

2. Insert the dimension size for A in the third argument of the CALL MATIN statement (statement 25).

The matrix listing is set for 60 print lines per page, 120 print positions across the page, and double spacing. This can be changed by means of the last three arguments in the CALL MXOUT statement in SOLN (statement 65). The format of solution values can be altered by changing statement 21 in SOLN.

Operating Instructions

The sample program for the solution of simultaneous equations is a standard FORTRAN program. Special operating instructions are not required. Data set reference 5 is used for input, and data set reference 6 is used for output.

Error Messages

The following error conditions will result in messages:

1. Reserved storage area is too small for matrix -- DIMENSIONED AREA TOO SMALL FOR INPUT MATRIX (matrix code no.). GO ON TO NEXT CASE.
2. Matrix of coefficients is not square -- ROW AND COLUMN DIMENSIONS NOT EQUAL FOR MATRIX (matrix code no.). GO ON TO NEXT CASE.
3. Number of data cards does not correspond to that required by parameter card -- INCORRECT NUMBER OF DATA CARDS FOR MATRIX (matrix code no.). EXECUTION TERMINATED.
4. Singular input matrix -- MATRIX IS SINGULAR. GO ON TO NEXT CASE.

Error conditions 1, 2, and 4 allow the computer run to continue. Error condition 3, however, terminates execution and requires another run to process succeeding cases.

Timing

The execution time of this sample program on a System/360, Model 30, using an IBM 2540 Card Reader as input and an IBM 1403, Model 3 as output, is 21 seconds.
