System/360 Scientific Subroutine Package

Version III

Programmer's Manual

Program Number 360A-CM-03X

The Scientific Subroutine Package (SSP) is a collection of over 250 FORTRAN subroutines divided, for the sake of presentation, into two groups: statistics and mathematics. Also, over 200 subroutines are presented in both single and double precision mode. SSP is a collection of input/output-free computational building blocks that can be combined with a user's input, output, or computational routines to meet his needs. The package can be applied to the solution of many problems in industry, science, and engineering.

Version 3 of the Scientific Subroutine Package for System/360 incorporates and extends the capabilities of the original SSP/360. This version provides over 40 new mathematical and statistical subroutines 24 of which are in both single- and double-precision FORTRAN. Examples of the new capabilities are the use of the QR iteration for obtaining eigenvalues of a matrix, and the nonparametric test of Kolmogorov-Smirnov.

This manual contains sufficient information to permit the reader to understand and use all of the subroutines of the Scientific Subroutine Package.

Fifth Edition (August 1970)

This edition, GH20-0205-4, is a reprint of GH20-0205-3 incorporating TNL GN20-1994. It does not obsolete GH20-0205-3 as updated by that TNL.

This edition applies to Version 3, Modification Level 1, of System/360 Scientific Subroutine Package (360A-CM-03X) and to all subsequent versions and modifications until otherwise indicated in new editions or Technical Newsletters.

Changes are continually made to the information herein. Therefore, before using this publication, consult the latest System/360 SRL Newsletter (GN20-0360) for the editions that are applicable and current.

Copies of this and other IBM publications can be obtained through IBM branch offices.

A form has been provided at the back of this publication for readers' comments. If this form has been removed, address comments to: IBM Corporation, Technical Publications Department, 112 East Post Road, White Plains, New York 10601.

CONTENTS

This programming package has been developed with the cooperation and assistance of IBM Germany and IBM France.

PURPOSE AND OBJECTIVES OF THE PACKAGE

The Scientific Subroutine Package is a set of basic computational subroutines intended to aid the user in the development of his own FORTRAN subroutine library. While this package may provide many of the tools necessary to solve the more commonly encountered problems in engineering and science, there is no intent to imply that these subroutines represent the current state of the art in statistics or numerical analysis. As with all tools, the user should understand their capabilities and their application to his functional requirements before deciding to use them.

AREAS OF APPLICATION

Individual subroutines, or a combination of them, can be used to carry out the listed functions in the following areas:

Statistics

- Probit analysis
- Analysis of variance (factorial design)
- Correlation analysis
- Multiple linear regression
- Stepwise regression
- Polynomial regression
- Canonical correlation
- Factor analysis (principal components, varimax)
- Discriminant analysis (many groups)
- Time series analysis
- Data screening and analysis
- Nonparametric tests
- Random number generation (uniform, normal)
- Distribution functions

Mathematics

- Inversion
- Eigenvalues and eigenvectors
- Simultaneous linear algebraic equations
- Transpositions
- Matrix arithmetic (addition, product, etc.)
- Matrix partitioning
- Matrix tabulation and sorting of rows or columns
- Elementary operations on rows or columns of matrices
- Matrix factorization
- Integration and differentiation of given or tabulated functions
- Solution of systems of first-order differential equations
- Fourier analysis of given or tabulated functions
- Bessel and modified Bessel function evaluation
- Gamma function evaluation
- Jacobian elliptic functions
- Elliptic, exponential, sine cosine, Fresnel integrals
- Finding real roots of a given function
- Finding real and complex roots of a real polynomial
- Polynomial arithmetic (addition, division, etc.)
- Polynomial evaluation, integration, differentiation
- Chebyshev, Hermite, Laguerre, Legendre polynomials
- Minimum of a function
- Approximation, interpolation, and table construction

CHARACTERISTICS

Some of the characteristics of the Scientific Subroutine Package are:

- All subroutines are free of input/output statements.
- Subroutines do not contain fixed maximum dimensions for the data arrays named in their calling sequences.
- All subroutines are written in FORTRAN.
- Many matrix manipulation subroutines handle symmetric and diagonal matrices (stored in economical, compressed formats) as well as general matrices. This can result in considerable saving in data storage for large arrays.
- The use of the more complex subroutines (or groups of them) is illustrated in the program documentation by sample main programs with input/output.
- All subroutines are documented uniformly.

The subroutines in SSP have been programmed in the subset of the FORTRAN IV language, which is compatible with all of the FORTRAN processors announced for System/360. Many of the larger functions such as those in statistics have been programmed as a series or sequence of subroutines.

An example of the use of sequences of subroutines is the statistical function called factor analysis. Factor analysis is a method of analyzing the intercorrelations within a set of variables. It determines whether the variance in the original set of variables can be accounted for adequately by a

smaller number of basic categories; namely, factors. In the Scientific Subroutine Package, factor analysis is normally performed by calling the following five subroutines in sequence:

1. CORRE - to find means, standard deviations, and correlation matrix
2. EIGEN - to compute eigenvalues and associated eigenvectors of the correlation matrix
3. TRACE - to select the eigenvalues that are greater than or equal to the control value specified by the user
4. LOAD - to compute a factor matrix
5. VARMX - to perform varimax rotation of the factor matrix

The multiple use of subroutines is illustrated by the fact that subroutine CORRE is also utilized in the multiple linear regression and canonical correlation. Subroutine EIGEN is used in canonical correlation as a third-level subroutine.

OVERALL RULES OF USAGE

GENERAL RULES

All subroutines in the Scientific Subroutine Package (SSP) are entered by means of the standard FORTRAN CALL statement. These subroutines are purely computational in nature and do not contain any references to input/output devices. The user must therefore furnish, as part of his program, whatever input/output and other operations are necessary for the total solution of his problem. In addition, the user must define by DIMENSION statements all matrices to be operated on by SSP subroutines as well as those matrices utilized in his program. The subroutines contained in SSP are no different from any user-supplied subroutine. All of the normal rules of FORTRAN concerning subroutines must therefore be adhered to, with the exception that the dimensioned areas in the SSP subroutine are not required to be the same as those in the calling program.

The CALL statement transfers control to the subroutine and replaces the dummy variables in that subroutine with the value of the actual arguments that appear in the CALL statement if the argument is a constant or a variable. When the argument is an array or function subprogram name, the address of the array or subprogram is transmitted to the called subroutine.

The arguments in a CALL statement must agree in order, number, and type with the corresponding arguments in the subroutine. A number may be passed to a subroutine either as a variable name in the argument list or as a constant in the argument list. For example, if the programmer wishes to add matrix AR1 to matrix AR2 in order to form matrix AR3 using the SSP subroutine GMADD, and if AR1 and AR2 are both matrices with ten rows and twenty columns, either of the two following methods can be used:

Method 1

```
CALL GMADD(AR1, AR2, AR3, 10, 20)
```

Method 2

```
N = 10
M= 20
CALL GMADD(AR1, AR2, AR3, N, M)
```

Many of the subroutines in SSP require the name of a user function subprogram or a FORTRAN-supplied function name as part of the argument list in the CALL statement. If the user's program contains such a CALL, the function name appearing in the argument list must also appear in an EXTERNAL statement at the beginning of that program.

For example, the SSP subroutine RK2 integrates a function furnished by the user. The user must therefore program the function and give the name of the function to RK2 as a parameter in the CALL statement. If the user wishes to integrate the function $\frac{dy}{dx} = 3.0x + 2.0Y$, his main program may appear as:

```
EXTERNAL DERY
      .
      .
CALL RK2(DERY, .....)
      .
      .
RETURN
END
```

His function subprogram can be:

```
FUNCTION DERY (X, Y)
DERY= 3.0*X+2.0* Y
RETURN
END
```

The user's main program gives the name of the programmed function to RK2 by including that name in the CALL statement and in an EXTERNAL statement. RK2, in turn, goes to the function DERY each time it requires a value for the derivative. The subroutine RK2 is not modified by the programmer. The dummy function name FUN in subroutine RK2 is, in effect, replaced by the name appearing in the user's CALL statement during execution of the subroutine.

MATRIX OPERATIONS

Special consideration must be given to the subroutines that perform matrix operations. These subroutines have two characteristics that affect the format of the data in storage--variable dimensioning and data storage compression.

Variable Dimensioning

Those subroutines that deal with matrices can operate on any size array, limited in most cases only by the available core storage and numerical analysis considerations. The subroutines do not contain fixed maximum dimensions for data arrays named in their calling sequence. The variable dimension capability

has been implemented in SSP by using a vector storage approach. Under this approach, each column of a matrix is immediately followed in storage by the next column. Vector storage and two-dimensional storage result in the same layout of data in core, so long as the number of rows and columns in the matrix are the same as those in the user's dimension statement. If, however, the matrix is smaller than the dimensioned area, the two forms of storage are not compatible.

Consider the layout of data storage when operating on a 5 by 5 array of numbers in an area dimensioned as 10 by 10. If the programmer has been using double-subscripted variables in the normal FORTRAN sense, the 25 elements of data will appear as shown in Figure 1. FORTRAN stores double-subscripted data by column based on the column length specified in the DIMENSION statement. Thus, in the example, sequential core locations will contain data elements 1 to 5, five blank locations, data elements 6 to 10, five blank locations, and so on. The matrix subroutines take a vector approach in storing arrays by column, which means that they assume the data is stored as shown in Figure 2.

	Column									
	1	2	3	4	5	6	7	8	9	10
1	(1)	(6)	(11)	(16)	(21)					
2	(2)	(7)	(12)	(17)	(22)					
3	(3)	(8)	(13)	(18)	(23)					
4	(4)	(9)	(14)	(19)	(24)					
Row 5	(5)	(10)	(15)	(20)	(25)					
6										
7										
8										
9										
10

(7)	(17)	
(8)	(18)	
(9)	(19)	
(10)	(20)	

Figure 2. Vector storage

As stated previously, if the dimensioned area is the same as the matrix size, the two approaches will have the same data storage layout, and the user can proceed in a regular double-subscripted fashion. If, however, he is operating in a mode where the dimensioned area is larger than the arrays, and if he wishes to use the SSP subroutines, he must be certain that his data is stored in the vector fashion illustrated by Figure 2. A subroutine called ARRAY is available in SSP to change from one form of storage to the other. In addition, a subroutine called LOC is available to assist in referencing elements in an array stored in the vector fashion.

Storage Compression

Many subroutines in SSP can operate on compressed forms of matrices as well as on the normal form. By using this capability, which is called "storage mode", considerable savings in data storage can be obtained for special forms of large arrays. The three modes of storage are termed general, symmetric, and diagonal. In this context, general mode is one in which all elements of the matrix are in storage. Symmetric mode is one in which only the upper triangular portion of the matrix is retained columnwise in sequential locations in storage. (The assumption is made that the corresponding elements in the lower triangle have the same value.) Diagonal mode is one in which only the diagonal elements of the matrix are retained in sequential locations in storage. (The off-diagonal elements are assumed to be zero.) This capability has been implemented using the vector storage approach.

Figure 3 illustrates the effect of the storage mode capability. A symmetric matrix is shown in Figure 3A. If this array is to be manipulated using the SSP matrix subroutines with storage mode capability, the array may be stored as shown in Figure 3B. This is the upper triangular portion of the array and corresponds to a storage mode code of 1. Symmetric matrices of order N may be stored in a vector of only N*(N+1)/2 locations rather than N*N locations. For larger matrices, this will be a saving of almost one half.

The effect of storage mode when dealing with diagonal matrices is even more pronounced. Diagonal matrices of order N may be stored in a vector only N locations long. Figure 3C shows a 3 by 3 diagonal matrix. If this array is to be manipulated using the SSP matrix subroutines with storage mode capability, only the diagonal elements of the array need be stored. This is shown in Figure 3D and corresponds to a storage mode code of 2.

General matrices of order N by M require a vector N*M long and use a storage mode code of 0.

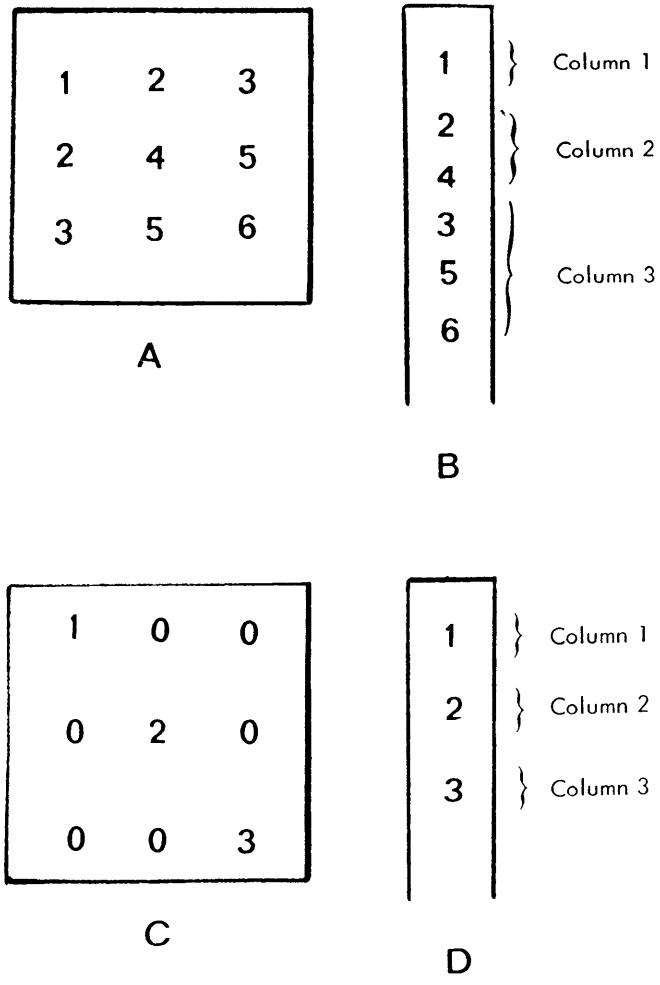

Figure 3. Storage mode

Thus, if the programmer wishes to use SSP subroutines on matrix A, which is general, matrix B, which is symmetric, and matrix C, which is diagonal, and all matrices are 10 by 10 or smaller, the dimension statement in his program can be:

```
DIMENSION A(100), B(55), C(10)
```

Matrix Element References

Subroutine LOC in the Scientific Subroutine Package may be used to reference elements within a matrix stored in a vector fashion, and may involve storage mode compression. The calling sequence for LOC is:

```
CALL LOC (I, J, IJ, N, M, MS)
```

The capabilities of subroutine LOC are as follows. If reference is required to the element at row I and column J of matrix A whose dimensions are N by M, and if the storage mode code is MS, a CALL to the LOC subroutine as shown above will result in the computation of the subscript IJ such that A(IJ) is the desired element. The parameters represented by I, J, N, M, MS can be either integer variables or integer constants. The parameter represented by IJ is an integer variable. Note that the user must dimension the array A as a single-subscripted variable to meet the restrictions of some FORTRAN systems. To illustrate the use of LOC, if reference is required to the element at row 2, column 2 of the 3 by 3 symmetric matrix illustrated in Figure 3A and stored as shown in Figure 3B (storage mode code 1), the sequence may be:

```
CALL LOC (2, 2, IJ, 3, 3, 1)
```

The value of IJ computed by LOC will be 3, meaning that the proper element is the third element in the specially stored symmetric matrix (Figure 3B). If the storage mode code is for a symmetric matrix where only the upper triangular portion is retained in storage, and if I and J refer to an element in the lower triangular portion, IJ will contain the subscript for the corresponding element in the retained upper triangle. Thus if the user wanted the element in row 3, column 1 of the matrix shown in Figure 3A, and the array was stored as in Figure 3B, the statement:

```
CALL LOC (3, 1, IJ, 3, 3, 1)
```

would result in IJ having the value of 4; that is, the fourth element in Figure 3B. If a matrix is stored as shown in Figure 3D (storage mode 2), and LOC is used to compute the subscript for an off-diagonal element (I not equal to J), the result in IJ will be zero. This is due to the fact that the element does not exist in storage. In this situation, the user must not utilize IJ as a subscript. Following is an illustration of how to take care of this condition and also handle the case where the current storage mode is unknown.

If the user wishes to set a variable X equal to the element in the third row and fourth column of a 10 by 10 array named A, for either a symmetric, diagonal, or general matrix, the required program can be implemented for any storage mode MS as follows:

```
      CALL LOC (3, 4, IJ, 10, 10, MS)
      X = 0.0
      IF(IJ)20, 30, 20
   20 X = A(IJ)
   30 --------
```

(MS is assumed to have been set at 0, 1, or 2 at some earlier point in the program.) This sequence will then set the proper value for X, given any storage mode that may be encountered. The second and third statements take care of the off-diagonal condition for a matrix with a storage mode of 2.

As a special case, LOC can be used to compute the total length of an array in storage with a statement such as:

```
CALL LOC (N, M, IJ, N, M, MS)
```

For example, if the user has a 3 by 3 matrix whose storage mode is 1 (Figure 3B), the statement:

```
CALL LOC (3, 3, IJ, 3, 3, 1)
```

will result in IJ being set to 6. This is not only the proper subscript to reference element 3, 3, but is also the actual length of the vector in storage.

The information contained in the fifth parameter (number of columns) in the calling sequence for LOC is not actually used in the calculations performed by LOC. It has been included in the calling sequence in case the user wishes to expand LOC to cover other forms of data storage.

ADVANCED FORTRAN FEATURES

The user may wish to take advantage of more advanced FORTRAN compiler features. For example, the larger FORTRAN systems include a subroutine multiple entry point capability. Some of the subroutines in SSP can be combined by using this feature. To illustrate this, GMADD and GMSUB (addition and subtraction of general matrices) can be combined as shown in Figure 4. This will in no way affect the programs using these subroutines but will reduce the total program storage requirements.

```
      SUBROUTINE GMADD (A,B,R,N,M)
      DIMENSION A(1),B(1),R(1)
      K=0
      GO TO 10
      ENTRY GMSUB (A,B,R,N,M)
      K=1
10    NM=N*M
      DO 40 I=1,NM
      IF(K) 20,20,30
20    R(I)=A(I)+B(I)
      GO TO 40
30    R(I)=A(I)-B(I)
40    CONTINUE
      RETURN
      END
```

Figure 4. Multiple entry point

OPTIMIZATION OF TIME

The subroutines in SSP are designed to conserve storage for data. If the user wishes to exchange space for time, there are several ways in which SSP may be modified to effect this end. For example, many of the subroutines in SSP make use of the LOC subroutine to handle vector storage and storage mode referencing. The execution time of these subroutines can be substantially reduced by implementing LOC in Assembler Language. (The distributed version of LOC is implemented in FORTRAN.) Another approach is to incorporate the function of LOC within each subroutine and thus avoid the "set-up" costs of repeated calls to LOC. This has the effect of reducing execution time but at some cost in subroutine storage and in the ease with which other modes of storage, such as triangular matrix storage or storage by row rather than by column, can be implemented. Figure 5 shows how matrix addition and the LOC capabilities can be implemented within the same subroutine.

```
      SUBROUTINE MACX(A,B,R,N,M,MSA,MSB)
      DIMENSION A(1),B(1),R(1)

   95 IF(KX) 40,45,50
      END
```

Figure 5. Inline LOC

DOUBLE PRECISION

The accuracy of the computations in many of the SSP subroutines is highly dependent upon the number of significant digits available for arithmetic operations. Matrix inversion, integration, and many of the statistical subroutines fall into this category. The user may, therefore, wish to use double-precision versions of these subroutines.

Many of the subroutines in SSP have been provided in both single- and double-precision versions. In others, instructions for converting to double precision are included as part of the subroutine description. FORTRAN double-precision statements have been included in each of these subroutines in the form of a comments card. In most cases, the double-precision version of the subroutine can be obtained merely by removing the C from column 1 of the double-precision statement card(s) before compilation. In a few cases, additional instructions are given for changing references to FORTRAN-furnished functions; for example, SQRT to DSQRT and ABS to DABS; in other cases, new constants are given.

The use of double-precision subroutines requires a detailed knowledge of the FORTRAN rules concerning double precision. A few of the more basic ones are as follows:

1. Any real variable, vector, or array name contained in the argument list of a CALL to a double-precision subroutine must be declared as double precision in the calling program. For example, if the SSP matrix inversion subroutine MINV has been modified for double precision, and if the user's program contains the statement:

```
CALL MINV (AR1, N, DET, MY1, MY2)
```

where:

AR1 is the array name (real, double-precision array)
N is the dimension (integer variable)
DET is the determinant (real, double-precision variable)
MY1 is a work vector (integer array)
MY2 is a work vector (integer array)

then the program must also have at its beginning the specification statement:

```
DOUBLE PRECISION AR1, DET
```

The other variables are integer variables and should not be included in the specification statement.

2. Any user-supplied function named in the CALL statement for a double-precision SSP subroutine must be programmed as a double-precision function. For example, the sample program for Runge-Kutta integration performs the integration on a sample function called FUN using subroutine RK2. This function is programmed as:

```
FUNCTION FUN (X, Y)

FUN = 1.1*X

RETURN

END
```

If a double-precision version of RK2 is used, the function must also be double precision. The sample function will then be:

```
DOUBLE PRECISION FUNCTION FUN (X, Y)

DOUBLE PRECISION X, Y

FUN = 1.1*X

RETURN

END
```

FORMAT OF THE DOCUMENTATION

The major portion of this manual consists of the documentation for the individual subroutines and the sample programs.

SUBROUTINE DESCRIPTIONS

Subroutine and sample program guides, both categorial and alphabetic, designed to aid in locating any particular subroutine are given in the pages that follow.

Each of the subroutine descriptions consists of a program listing and, in some cases, a mathematical description. The first part of the program listing is a set of comment cards containing the subroutine name, its calling sequence, description of parameters, remarks, names of other subroutines required, and method. References to books and periodicals will be found under the method section of the description. The mathematical description pages do not, in most cases, indicate the derivation of the mathematics. They are intended to indicate what mathematical operations are actually being performed in the subroutines. Some of the major statistical functions are performed by a sequence of SSP subroutines. An explanation of this sequence will be found just before the description of the first subroutine that is specific to this function.

SAMPLE PROGRAM DESCRIPTIONS

The sample program listings are given in Appendix B.

Each sample program consists of a detailed description including information on the problem, the program, input, output, program modification, operating instructions, error messages, timing and machine listings of the programs, input data and output results. The sample programs have been chosen to (1) illustrate a sequence of SSP subroutines, (2) illustrate the use of a complex subroutine, or (3) show the way in which one member (such as matrix addition) of a large set of simple subroutines might be used.

As part of the development of the sample programs, some special sample subroutines have been implemented that may prove useful to the programmer. These include:

HIST - print a histogram of frequencies

MATIN - read an input matrix into storage in vector form for use by SSP matrix subroutines

PLOT - plot several variables versus a base variable

MXOUT - print a matrix stored in the SSP vector format

Listings of the above subroutines are included after the sample program documentation in this manual. The source decks are part of the sample program source decks on the distributed magnetic tape.

The sample programs have been implemented for execution on a 32K byte (8K word) System/360 using Basic Programming Support FORTRAN (Tape). Instructions for modifying the sample programs for different data capacities are included in the documentation. In addition, those sample programs that illustrate potentially double-precision subroutines include double-precision statements in the form of comment cards. These comment cards are contained in the sample program source decks.

It is recommended that those SSP subroutines that will be frequently used in an installation be compiled and the relocatable decks placed on the FORTRAN system's residence device. In the case of Basic Programming Support FORTRAN (Tape), this will be the library portion of the system tape. Information on the method for updating the system to include user-supplied subroutines will be found in the appropriate FORTRAN programmer's guide. SSP subroutines are handled in the same manner as user-supplied subroutines. If the subroutines are not placed on the FORTRAN system's residence device. those required by a particular program will have to be included in that program each time it is run.

CATEGORIAL GUIDE TO SUBROUTINES AND SAMPLE PROGRAMS

(Subroutines added in Version III are marked with an asterisk)

STATISTICS

ALPHABETIC GUIDE TO SUBROUTINES WITH STORAGE REQUIREMENTS

The following table lists the number of characters of storage required by each of the subroutines in the Scientific Subroutine Package. The figures given were obtained by using Basic Programming Support FORTRAN (Tape), Version 3, Level 0. The use of other FORTRAN compilers on System/360 may cause deviations from these figures.

The double-precision version of the subroutines in the Scientific Subroutine Package are listed immediately following their alphabetized single-precision counterparts. Main line routines are asterisked.

Subroutine TAB1

This subroutine tabulates, for a selected variable in an observation matrix, the frequencies and percent frequencies over class intervals. Interval size is computed as follows:

$$k = \frac{UBO_3 - UBO_1}{UBO_2 - 2} \qquad (1)$$

where UBO_1 = given lower bound

UBO_2 = given number of intervals

UBO_3 = given upper bound

If $UBO_1 = UBO_3$, the subroutine finds and uses the minimum and maximum values of the variable.

A table lookup is used to obtain the frequency of the i^{th} class interval for the variable, where i = 1, 2, ..., UBO_2. Then each frequency is divided by the number of observations, n, to obtain the percent frequency:

$$P_i = \frac{100F_i}{n} \qquad (2)$$

In addition, the following statistics are calculated for the variable:

$$\text{Total: } T = \sum_{i=1}^{n} X_{ij} \qquad (3)$$

where j = selected variable

$$\text{Mean: } \overline{X} = \frac{T}{n} \qquad (4)$$

Standard deviation:

$$s = \sqrt{\frac{\sum_{i=1}^{n} X_{ij}^2 - \left(\sum_{i=1}^{n} X_{ij}\right)^2 \Big/ n}{n-1}} \qquad (5)$$

```

Subroutine TAB2

This subroutine performs a two-way classification of the frequency, percent frequency, and other statistics over given class intervals, for two selected variables in an observation matrix.

Interval size for each variable is computed as follows:

$$k_j = \frac{UBO_{3j} - UBO_{1j}}{UBO_{2j} - 2} \quad (1)$$

where UBO_{1j} = given lower bound

UBO_{2j} = given number of intervals

UBO_{3j} = given upper bound

$j = 1, 2$

If $UBO_{1j} = UBO_{3j}$, the subroutine finds and uses the minimum and maximum values of the j^{th} variable.

A frequency tabulation is then made for each pair of observations in a two-way table as shown in Figure 6.

Symbols $\geq$ and $<$ in Figure 6 indicate that a count is classified into a particular interval if the data point is greater than or equal to the lower limit of that interval but less than the upper limit of the same interval.

Then, each entry in the frequency matrix, F_{ij}, is divided by the number of observations, N, to obtain the percent frequency:

$$P_{ij} = \frac{100F_{ij}}{N} \quad (2)$$

where $i = 1, 2, \ldots, UBO_{21}$

$j = 1, 2, \ldots, UBO_{22}$

As data are classified into the frequency matrix, the following intermediate results are accumulated for each class interval of both variables:

1. Number of data points, n
2. Sum of data points, $\sum_{i=1}^{n} X_i$
3. Sum of data points squared, $\sum_{i=1}^{n} X_i^2$

From these, the following statistics are calculated for each class interval:

Mean: $$\overline{X} = \frac{\sum_{i=1}^{n} X_i}{n} \quad (3)$$

Standard deviation:

$$s = \sqrt{\frac{\sum_{i=1}^{n} X_i^2 - \left(\sum_{i=1}^{n} X_i\right)^2 / n}{n - 1}} \quad (4)$$

Correlation and Regression (see Smoothing, Factorization)

Subroutine CORRE

This subroutine calculates means, standard deviations, sums of cross-products of deviations from means, and product moment correlation coefficients from input data X_{ij}, where i = 1, 2, ..., n implies observations and j = 1, 2, ..., m implies variables.

The following equations are used to calculate these statistics.

Sums of cross-products of deviations:

$$S_{jk} = \sum_{i=1}^{n} \left(X_{ij} - T_j \right) \left(X_{ik} - T_k \right) - \frac{\sum_{i=1}^{n} \left(X_{ij} - T_j \right) \sum_{i=1}^{n} \left(X_{ik} - T_k \right)}{n} \quad (1)$$

where j = 1, 2, ..., m; k = 1, 2, ..., m

$$T_j = \frac{\sum_{i=1}^{m} X_{ij}}{m} \quad (2)$$

(These temporary means T_j are subtracted from the data in equation (1) to obtain computational accuracy.)

Means: $$\overline{X}_j = \frac{\sum_{i=1}^{n} X_{ij}}{n} \quad (3)$$

where j = 1, 2, ..., m

Correlation coefficients:

$$r_{jk} = \frac{S_{jk}}{\sqrt{S_{jj}} \sqrt{S_{kk}}} \quad (4)$$

where j = 1, 2, ..., m; k = 1, 2, ..., m

Standard deviations:

$$s_j = \frac{\sqrt{S_{jj}}}{\sqrt{n-1}} \quad (5)$$

Subroutine MISR

This subroutine computes means, standard deviations, third and fourth moments, correlation coefficients, regression coefficients, and standard errors of regression coefficients when there is missing data. Effective sample sizes are also provided. Missing observations or certain values of the data can be skipped at the user's option. The computational steps are as follows:

1. Compute means:

$$\bar{x}_j = \frac{\sum_{\alpha=1}^{n} x_{\alpha j}}{n} \qquad (1)$$

where j = 1, 2, . . . , m implies variables
n = number of nonmissing values for the jth variable

2. Compute sums of cross-products of deviations from means for complete sets of ith and jth variables:

$$S_{ij} = \sum_{\alpha=1}^{n'} (x_{\alpha i} - \bar{x}_i)(x_{\alpha j} - \bar{x}_j) - \frac{\sum_{\alpha=1}^{n'} (x_{\alpha i} - \bar{x}_i) \sum_{\alpha=1}^{n'} (x_{\alpha j} - \bar{x}_j)}{n'} \qquad (2)$$

where $\bar{x}_i$, $\bar{x}_j$ = means of ith and jth variables computed as above
n' = number of sets where the ith and jth variables are both present

3. Compute product-moment correlations:

$$r_{ij} = \frac{S_{ij}}{\sqrt{S_{ii}}\sqrt{S_{jj}}} \qquad (3)$$

4. Compute regression coefficients, intercepts, and standard errors of regression coefficients:

a. ith variable as independent and jth variable as dependent:

Regression coefficient: $b_{ij} = \frac{S_{ij}}{S_{ii}}$ (4)

Intercept: $a_{ij} = \bar{x}'_j - b_{ij}\bar{x}_i'$ (5)

Standard error regression coefficient:

$$s_{b_{ij}} = \frac{S_{jj} - r_{ij}^2 \, S_{jj}}{(n' - 2) \, S_{ii}} \qquad (6)$$

b. jth variable as independent and ith variable as dependent:

Regression coefficient: $b_{ji} = \frac{S_{ij}}{S_{jj}}$ (7)

Intercept: $a_{ji} = \bar{x}_i' - b_{ji} \bar{x}_j'$ (8)

Standard error of regression coefficient:

$$s_{b_{ji}} = \frac{S_{ii} - r_{ij}^2 \, S_{ii}}{(n' - 2) \, S_{jj}} \qquad (9)$$

5. Compute standard deviations:

$$s_j = \sqrt{\frac{S_{jj}}{n - 1}} \qquad (10)$$

where n = number of nonmissing values for jth variable

6. Compute skewness and kurtosis, s and k:

Let $\mu_{i_j} = \sum_{\alpha=1}^{n} (x_{\alpha_j} - \bar{x}_j)^{i} / n$

Then $s_j = \mu_{3_j} / (\mu_{2_j})^{3/2}$ (11)

and $k_j = (\mu_{4_j} / \mu_{2_j}^2) - 3$ (12)

Note: This subroutine cannot distinguish between a blank and a zero. Therefore, if a blank is specified as a missing data code in input cards, it will be treated as 0 (zero).

In the Scientific Subroutine Package, multiple linear regression is normally performed by calling four subroutines in sequence.

1. CORRE - to find means, standard deviations, and correlation matrix

2. ORDER - to choose a dependent variable and a subset of independent variables from a larger set of variables

3. MINV - to invert the correlation matrix of the subset selected by ORDER

4. MULTR - to compute the regression coefficients b_0, b_1, b_2, ..., b_m, and various confidence measures

The subroutine CORRE works in either of two ways: (1) it expects all observations in core, or (2) it triggers a user-provided input subroutine, DATA, to read one observation at a time into a work area. In either case, the user must provide a subroutine named DATA (see "Subroutines Required" in the comment cards description of subroutine CORRE).

Subroutine MULTR

This subroutine performs a multiple regression analysis for a dependent variable and a set of independent variables.

Beta weights are calculated using the following equation:

$$\beta_j = \sum_{i=1}^{k} r_{iy} \cdot r_{ij}^{-1} \quad (1)$$

where r_{iy} = intercorrelation of i^{th} independent variable with dependent variable

r_{ij}^{-1} = the inverse of intercorrelation r_{ij}

$i, j = 1, 2, \ldots, k$ imply independent variables

r_{iy} and r_{ij}^{-1} are input to this subroutine.

Then, the regression coefficients are calculated as follows:

$$b_j = \beta_j \cdot \frac{s_y}{s_j} \quad (2)$$

where s_y = standard deviation of dependent variable

s_j = standard deviation of j^{th} independent variable

$j = 1, 2, \ldots, k$

s_y and s_j are input to this subroutine.

The intercept is found by the following equation:

$$b_0 = \overline{Y} - \sum_{j=1}^{k} b_j \cdot \overline{X}_j \quad (3)$$

where $\overline{Y}$ = mean of dependent variable

$\overline{X}_j$ = mean of j^{th} independent variable

$\overline{Y}$ and $\overline{X}_j$ are input to this subroutine.

Multiple correlation coefficient, R, is found first by calculating the coefficient of determination by the following equation:

$$R^2 = \sum_{i=1}^{k} \beta_i r_{iy} \quad (4)$$

and taking the square root of R^2:

$$R = \sqrt{R^2} \quad (5)$$

The sum of squares attributable to the regression is found by:

$$SSAR = R^2 \cdot D_{yy} \quad (6)$$

where D_{yy} = sum of squares of deviations from mean for dependent variable

D_{yy} is input to this subroutine.

The sum of squares of deviations from the regression is obtained by:

$$SSDR = D_{yy} - SSAR \quad (7)$$

Then, the F-value for the analysis of variance is calculated as follows:

$$F = \frac{SSAR/k}{SSDR/(n-k-1)} = \frac{SSAR(n-k-1)}{SSDR(k)} \quad (8)$$

Certain other statistics are calculated as follows:

Variance and standard error of estimate:

$$S^2_{y.12\ldots k} = \frac{SSDR}{n-k-1} \quad (9)$$

where n = number of observations

$$S_{y.12\ldots k} = \sqrt{S^2_{y.12\ldots k}} \quad (10)$$

Standard deviations of regression coefficients:

$$S_{b_j} = \sqrt{\frac{r_{jj}^{-1}}{D_{jj}} \cdot S^2_{y.12\ldots k}} \quad (11)$$

where D_{jj} = sum of squares of deviations from mean for j^{th} independent variable. D_{jj} is input to this subroutine.

$j = 1, 2, \ldots, k$

Computed t:

$$t_j = \frac{b_j}{S_{b_j}} \quad (12)$$

$j = 1, 2, \ldots, k$

```

Polynomial Regression

In the Scientific Subroutine Package, polynomial regression is normally performed by calling the following four subroutines in sequence:

1. GDATA - to generate the powers of the independent variable and find means, standard deviations, and correlation matrix
2. ORDER - to choose a dependent variable and subset of independent variables from a larger set of variables
3. MINV - to invert the correlation coefficient matrix
4. MULTR - to compute the regression coefficients $b_0, b_1, b_2, \ldots, b_m$, and various confidence measures

Subroutine GDATA

This subroutine generates independent variables up to the m^{th} power (the highest degree polynomial specified) and calculates means, standard deviations, sums of cross-products of deviations from means, and product moment correlation coefficients.

X_{il} denotes the i^{th} case of the independent variable;

X_{ip} denotes the i^{th} case of the dependent variable,

where $i = 1, 2, \ldots, n$

n = number of cases (observations)

$p = m + 1$

m = highest degree polynomial specified

The subroutine GDATA generates powers of the independent variable as follows:

$$\begin{aligned} X_{i2} &= X_{i1} \cdot X_{i1} \\ X_{i3} &= X_{i2} \cdot X_{i1} \\ X_{i4} &= X_{i3} \cdot X_{i1} \\ &\vdots \\ X_{im} &= X_{i,m-1} \cdot X_{i1} \end{aligned} \qquad (1)$$

where i and m are as defined as above.

Then, the following are calculated.

Means:

$$\bar{X}_j = \frac{\sum_{i=1}^{n} X_{ij}}{n} \qquad (2)$$

where $j = 1, 2, \ldots, p$

Sums of cross-products of deviations from means:

$$D_{jk} = \sum_{i=1}^{n}\left(X_{ij} - \bar{X}_j\right)\left(X_{ik} - \bar{X}_k\right) - \frac{\sum_{i=1}^{n}\left(X_{ij} - \bar{X}_j\right)\sum_{i=1}^{n}\left(X_{ik} - \bar{X}_k\right)}{n} \qquad (3)$$

where $j = 1, 2, \ldots, p$; $k = 1, 2, \ldots, p$.

Correlation coefficients:

$$r_{ij} = \frac{D_{ij}}{\sqrt{D_{ii}}\ \sqrt{D_{jj}}} \qquad (4)$$

where $i = 1, 2, \ldots, p$; $j = 1, 2, \ldots, p$.

Standard deviations:

$$s_j = \frac{\sqrt{D_{jj}}}{\sqrt{n-1}} \qquad (5)$$

where $j = 1, 2, \ldots, p$

Stepwise Multiple Regression

In the Scientific Subroutine Package, stepwise multiple regression is normally performed by calling the following subroutines:

1. CORRE - to find means, standard deviations, sums of cross-products of deviation matrix, and correlation matrix
2. MSTR - to save the matrix of sums of cross-products of deviations and to copy it to a working matrix for the purpose of using the same data repeatedly
3. LOC - to compute a vector subscript for an element in general and symmetric matrices. This subroutine is called by the subroutine MSTR
4. STPRG - to compute regression coefficients and other statistics for each step of regression

The subroutine CORRE works in either of two ways: (1) it expects all observations in core, or (2) it triggers a user-provided input subroutine, DATA, to read one observation at a time into a work area. In either case, the user must provide a subroutine named DATA (see "Subroutines and Function Subprograms Required" in the comment cards description of the subroutine CORRE).

The subroutine STPRG calls an output subroutine, STOUT, in order to print various statistics computed for each step of regression. The subroutine STOUT must also be provided by the user.

Subroutine STPRG

This subroutine performs a stepwise multiple regression analysis for a dependent variable and a set of independent variables. In each step of the regression $i=1,2,\ldots,q$, where q is the number of independent variables, the abbreviated Doolittle method is used to calculate the following statistics:

The independent variable entering in the regression is selected, first, by computing the amount of reduction of sum of squares for each variable:

$$C_j = \frac{a_{jy}^2}{a_{jj}} \tag{1}$$

where a_{jj} is initially an element in the sums of cross-products of deviations matrix which will be modified in successive steps.

$j = 1,2,\ldots,q$ are independent variables ($j \neq$ variables deleted and variables entered before the i^{th} step)

$y =$ dependent variable

and, second, by finding the maximum (over j) of C.

Set $S_i = C_j$ to indicate the sum of squares that will be reduced in the i^{th} step.

The proportion of S_i to the total is obtained by:

$$p = \frac{S_i}{D} \tag{2}$$

where $D = \sum_{j=1}^{n} (y_j - \bar{y})^2$

n = number of observations

If p is less than the constant specified by the user to limit independent variables, the analysis will be terminated without entering the last variable selected; otherwise, the following calculations are continued:

The cumulative sum of squares reduced is obtained by

$$S_{cum} = S_{cum} + S_i \tag{3}$$

and the cumulative proportion reduced by

$$P_{cum} = P_{cum} + p \tag{4}$$

The multiple correlation coefficient is computed by

$$R = \sqrt{P_{cum}} \tag{5}$$

and adjusted for degrees of freedom by

$$R_c = \sqrt{1 - (1-R^2) \quad (n-1) / (n-k)}$$

where there are k independent variables in the regression.

The F-value for analysis of variance is given by

$$F = \frac{S_{cum} / k}{(D-S_{cum}) / (n-k-1)} \tag{6}$$

The standard error of the estimated y is obtained by the use of the formula

$$s_{y.12\ldots i} = \sqrt{\frac{D - S_{cum}}{n - k - 1}} \tag{7}$$

and adjusted by

$$s_c = s \sqrt{(n-1) / (n-k)}$$

Then, the following is computed:

$$a_{jj} = a_{jj} + \frac{a_{ij}^2}{a_{ii}} \tag{8}$$

where i = variable entered in the ith step

$j = v_1, v_2, \ldots, v_{i-1}$ are the variables entered in the regression before the ith step, and

$$g_{ik} = \frac{a_{ik}}{a_{ii}} \tag{9}$$

where $k = 1,2,\ldots,m$ are variables including y ($k \neq$ variables deleted and the variable entered in the ith step).

Regression coefficients are computed by:

$$\begin{aligned} b_i &= g_{iy} \\ b_{i-1} &= g_{(i-1)y} - b_i g_{(i-1)i} \\ b_{i-2} &= g_{(i-2)y} - b_i g_{(i-2)i} - b_{i-1} g_{(i-2)(i-1)} \\ &\text{etc.,} \end{aligned} \tag{10}$$

and the value of the intercept as

$$b_0 = \bar{y} - \sum_{j=1}^{k} b_j \bar{x}_j \tag{11}$$

where k = number of independent variables in the regression.

Standard errors of regression coefficients are given by

$$s_{b_j} = \sqrt{a_{jj}}\, s_{y.12\ldots i} \qquad (12)$$

where j = $v_1, v_2, \ldots, v_i$ are variables in the regression, and t-values as

$$t_j = \frac{b_j}{s_{b_j}} \qquad (13)$$

Perform the reduction to eliminate the variable entered in the ith step:

$$a_{jk} = a_{jk} - a_{ji} g_{ik} \qquad (14)$$

where i = variable entered in the ith step

j = 1,2,...,m (j ≠ variables deleted or variables in the regression)

k = 1,2,...,m (k ≠ variables deleted and the variable entered in the ith step)

$$a_{ji} = \frac{a_{ji}}{-a_{ii}} \qquad (15)$$

$$a_{ii} = \frac{1}{a_{ii}} \qquad (16)$$

Subroutine PROBT

This subroutine obtains maximum likelihood estimates of a and b for the probit equation $Y = a+bX$. An iterative scheme is used. The input to the subroutine consists of k different levels $X_1, X_2, \ldots, X_k$ of a stimulus applied to $N_1, N_2, \ldots, N_k$ objects with $R_1, R_2, \ldots, R_k$ responses respectively. The procedures described here assume that the distribution of critical values is normal. The computational steps are as follows:

1. Compute the proportions of objects responding to various levels of a stimulus:

$$p_i = \frac{R_i}{N_i} \tag{1}$$

where $i = 1, 2, \ldots, k$ are levels of a stimulus.

2. Compute the initial estimates of a and b for the probit equation, $Y = a+bX$, as follows:

$$b = \frac{\sum_{i=1}^{m} X_i Z_i - \frac{\left(\sum_{i=1}^{m} X_i\right)\left(\sum_{i=1}^{m} Z_i\right)}{m}}{\sum_{i=1}^{m} X^2_i - \frac{\left(\sum_{i=1}^{m} X_i\right)^2}{m}} \tag{2}$$

$$a = \bar{Z} - b\bar{X} \tag{3}$$

where X_i = ith level of a stimulus

Z_i = 5 plus the standard normal variable corresponding to p_i

m = number of p values which are not equal to 0.0 and 1.0

3. Compute values of expected probit using the initial estimates of a and b:

$$Y_i = a + bX_i \tag{4}$$

where $i = 1, 2, \ldots, k$

4. Corresponding to each value of Y, compute the following:

a. Weighting coefficient for probit analysis:

$$W_i = \frac{D^2_i}{P_i Q_i} \tag{5}$$

where D_i = density of the normal curve corresponding to the standard normal variable $Y_i - 5$

P_i = cumulative normal distribution value corresponding to $Y_i - 5$

$Q_i = 1 - P_i$

b. Working probit:

For $Y_i \leq 5.0$

$$y_i = Y_i - \frac{P_i}{D_i} + p_i \frac{1}{D_i} \tag{6}$$

For $Y_i > 5.0$

$$y_i = Y_i + \frac{Q_i}{D_i} - (1-p_i)\frac{1}{D_i} \tag{7}$$

5. Compute:

$$S_1 = \sum_{i=1}^{k} N_i W_i X^2_i - \frac{\left(\sum_{i=1}^{k} N_i W_i X_i\right)^2}{\sum_{i=1}^{k} N_i W_i} \tag{8}$$

$$S_2 = \sum_{i=1}^{k} N_i W_i X_i y_i - \frac{\left(\sum_{i=1}^{k} N_i W_i X_i\right)\left(\sum_{i=1}^{k} N_i W_i y_i\right)}{\sum_{i=1}^{k} N_i W_i} \tag{9}$$

$$S_3 = \sum_{i=1}^{k} N_i W_i y^2_i - \frac{\left(\sum_{i=1}^{k} N_i W_i y_i\right)^2}{\sum_{i=1}^{k} N_i W_i} \tag{10}$$

6. Compute new estimates of a and b for the probit equation:

$$b = \frac{S_2}{S_1} \tag{11}$$

$$a = \frac{\sum_{i=1}^{k} N_i W_i y_i}{\sum_{i=1}^{k} N_i W_i} - b \cdot \frac{\sum_{i=1}^{k} N_i W_i X_i}{\sum_{i=1}^{k} N_i W_i} \tag{12}$$

7. Compute new values of expected probit and compare them against the values computed in the previous iteration:

$$Y'_i = a + bX_i \tag{13}$$

$$DSQ = \sum_{i=1}^{k} (Y_i - Y')^2 \tag{14}$$

If the difference between two consecutive values of DSQ is less than or equal to 10^{-7}, go to step 8 and compute χ^2. Otherwise, set $Y_i = Y_i'$, where $i = 1, 2, \ldots, k$, and go back to step 4 for another iteration.

8. Compute χ^2 for the test of the final probit equation:

$$\chi^2 = \sum_{i=1}^{k} \frac{(R_i - N_i P_i)^2}{N_i P_i (1-P_i)} \tag{15}$$

where P_i = cumulative normal distribution value corresponding to z_i

$z_i = (a+bX_i) - 5$

a and b are computed for the final probit equation.

9. Degrees of freedom for χ^2:

$$d.f. = k - 2 \tag{16}$$

Canonical Correlation

In the Scientific Subroutine Package, canonical correlation analysis is normally performed by calling the following five subroutines:

1. CORRE - to compute means, standard deviations, and correlation matrix
2. MINV - to invert a part of the correlation matrix
3. EIGEN - to compute eigenvalues and eigenvectors
4. NROOT - to compute eigenvalues and eigenvectors of real nonsymmetric matrix of the form $B^{-1}A$
5. CANOR - to compute canonical correlations and coefficients

The subroutine CORRE works in either of two ways: (1) it expects all observations in core, or (2) it triggers a user-provided input subroutine, DATA, to read one observation at a time into a work area. In either case, the user must provide a subroutine named DATA (see "Subroutines Required" in the comment cards description of subroutine CORRE).

Subroutine CANOR

This subroutine performs a canonical correlation analysis between two sets of variables.

The matrix of intercorrelations, R, is partitioned into four submatrices:

$$R = \left[\begin{array}{c|c} R_{11} & R_{12} \\ \hline R_{21} & R_{22} \end{array}\right] \qquad (1)$$

R_{11} = intercorrelations among p variables in the first set (that is, left-hand variables)

R_{12} = intercorrelations between the variables in the first and second sets

R_{21} = the transpose of R_{12}

R_{22} = intercorrelations among q variables in the second set (that is, right-hand variables)

The equation:

$$\left| R_{22}^{-1} R_{21} R_{11}^{-1} R_{12} - \lambda I \right| = 0 \qquad (2)$$

is then solved for all values of λ, eigenvalues, in the following matrix operation:

$$T = R_{11}^{-1} R_{12} \qquad (3)$$

$$A = R_{21} T \qquad (4)$$

The subroutine NROOT calculates eigenvalues (λ_i), with associated eigenvectors, of $R_{22}^{-1} A$, where i = 1, 2, ..., q.

For each subscript i = 1, 2, . . ., q, the following statistics are calculated:

Canonical correlation:

$$CANR = \sqrt{\lambda_i} \qquad (5)$$

where λ_i = i^{th} eigenvalue

Chi-square:

$$\chi^2 = -\left[n - 0.5\,(p + q + 1)\right] \log_e \Lambda \qquad (6)$$

where n = number of observations

$$\Lambda = \prod_{j=i}^{q} (1 - \lambda_j);$$

Degrees of freedom for χ^2:

$$DF = \left[p - (i-1)\right]\left[q - (i-1)\right] \qquad (7)$$

i^{th} set of right-hand coefficients:

$$b_k = v_{ki} \qquad (8)$$

where v_{ki} = eigenvector associated with λ_i

k = 1, 2, . . ., q;

i^{th} set of left-hand coefficients:

$$a_j = \frac{\sum_{k=1}^{q} t_{jk}\, b_k}{CANR} \qquad (9)$$

where $\left\{ t_{jk} \right\} = T = R_{11}^{-1} R_{12}$

j = 1, 2, ..., p

Design Analysis (see Smoothing, Regression, Factorization)

In the Scientific Subroutine Package, analysis of variance is normally performed by calling the following three subroutines in sequence:

1. AVDAT - to place data in properly distributed positions of storage
2. AVCAL - to apply the operators sigma and delta in order to compute deviates for analysis of variance
3. MEANQ - to pool the deviates and compute sums of squares, degrees of freedom, and mean squares

Subroutine AVDAT

This subroutine places data for analysis of variance in properly distributed positions of storage.

The size of data array X required for an analysis-of-variance problem is calculated as follows:

$$n = \prod_{i=1}^{k} (L_i + 1) \qquad (1)$$

where L_i = number of levels of i^{th} factor

k = number of factors

The input data placed in the lower part of the array X are moved temporarily to the upper part of the array. From there, the data are redistributed according to the equation (4) below. Prior to that, multipliers, s_j, to be used in finding proper positions of storage, are calculated as follows:

$$s_1 = 1 \qquad (2)$$

$$s_j = \prod_{i=1}^{j-1} (L_i + 1) \qquad (3)$$

where $j = 2, 3, \ldots, k$

Then a position for each data point is calculated by the following equation:

$$S = KOUNT_1 + \sum_{j=2}^{k} s_j \cdot (KOUNT_j - 1) \qquad (4)$$

where $KOUNT_j$ = value of j^{th} subscript of the data to be stored.

The subroutine increments the value(s) of subscript(s) after each data point is stored.

Subroutine AVCAL

This subroutine performs the calculus for the general k-factor experiment: operator Σ and operator Δ. An example is presented in terms of k = 3 to illustrate these operators.

Let x_{abc} denote the experimental reading from the a^{th} level of factor A, the b^{th} level of factor B, and the c^{th} level of factor C. The symbols A, B, and C will also denote the number of levels for each factor so that a = 1, 2, ..., A; b = 1, 2, ..., B; and c = 1, 2, ..., C.

With regard to the first factor A:

operator $\sum_a \equiv$ sum over all levels a = 1, 2, ..., A, holding the other subscripts at constant levels, and

operator $\underset{a}{\triangle} \equiv$ multiply all items by A and subtract the result of $\sum_a$ from all items

In mathematical notation, these operators are defined as follows:

$$\sum_a x_{abc} \equiv X_{.bc} \equiv \sum_{a=1}^{A} x_{abc} \qquad (1)$$

$$\underset{a}{\triangle} x_{abc} \equiv A\, x_{abc} - X_{.bc} \qquad (2)$$

The operators Σ and Δ will be applied sequentially to all factors A, B, and C. Upon the completion of these operations, the storage array X contains deviates to be used for analysis-of-variance components in the subroutine MEANQ.

Subroutine MEANQ

This subroutine performs the mean square operation for the general k-factor experiment in the following two steps:

1. Square each value of deviates for analysis of variance stored in the array X (the result of the operators Σ and Δ applied in the subroutine AVCAL).

2. Add the squared value into summation storage. In a three-factor experiment, for example, the squared value is added into one of seven storages ($7 = 2^3 - 1$) as shown in the first column of Table 1. The symbols A, B, and C in the first column denote factor A, factor B, and factor C.

After the mean square operation is completed for all values in the storage array X, the subroutine forms sums of squares of analysis of variance by dividing the totals of squared values by proper divisors. These divisors for the three-factor experiment mentioned above are shown in the second column of Table 1. The symbols A, B, and C in the second column denote the number of levels for each factor.

The subroutine, then, forms mean squares by dividing sums of squares by degrees of freedom. The third column of the summary table shows the degrees of freedom. The symbols A, B, and C denote the number of levels for each factor.

Table 1. Table Showing Summation Storages, Divisors to Form Sum of Squares, and Degrees of Freedom (Subroutine MEANQ)

Designation of Store and of Quantity Contained in it	Divisor Required to Form Sum of Squares of Analysis of Variance	Degrees of Freedom Required to Form Mean Squares
$(A)^2$	ABC·A	(A-1)
$(B)^2$	ABC·B	(B-1)
$(AB)^2$	ABC·AB	(A-1) (B-1)
$(C)^2$	ABC·C	(C-1)
$(AC)^2$	ABC·AC	(A-1) (C-1)
$(BC)^2$	ABC·BC	(B-1) (C-1)
$(ABC)^2$	ABC·ABC	(A-1) (B-1) (C-1)

Discriminant Analysis

In the Scientific Subroutine Package, discriminant analysis is normally performed by calling the following three subroutines in sequence:

1. DMATX - to compute means of variables in each group and a pooled dispersion matrix
2. MINV - to invert the pooled dispersion matrix
3. DISCR - to compute coefficients of discriminant functions and evaluate the functions for each observation (individual)

Subroutine DMATX

This subroutine calculates means of variables in each group and a pooled dispersion matrix for the set of groups in a discriminant analysis.

For each group k = 1, 2, ..., g, the subroutine calculates means and sums of cross-products of deviations from means as shown below.

Means:

$$\bar{x}_{jk} = \frac{\sum_{i=1}^{n_k} x_{ijk}}{n_k} \qquad (1)$$

where n_k = sample size in the k^{th} group

$j = 1, 2, \ldots, m$ are variables

Sum of cross-products of deviations from means:

$$S_k = \left\{ s_{j\ell}^{k} \right\} = \sum (x_{ijk} - \bar{x}_{jk})\ (x_{i\ell k} - \bar{x}_{\ell k}) \qquad (2)$$

where $j = 1, 2, \ldots, m$

$\ell = 1, 2, \ldots, m$

The pooled dispersion matrix is calculated as follows:

$$D = \frac{\sum_{k=1}^{g} S_k}{\sum_{k=1}^{g} n_k - g} \qquad (3)$$

where g = number of groups

Subroutine DISCR

This subroutine performs a discriminant analysis by calculating a set of linear functions that serve as indices for classifying an individual into one of K groups.

For all groups combined, the following are obtained.

Common means:

$$\bar{X}_j = \frac{\sum_{k=1}^{g} n_k \bar{x}_{jk}}{\sum_{k=1}^{g} n_k} \qquad (1)$$

where g = number of groups

j = 1, 2, ..., m are variables

n_k = sample size in the k^{th} group

$\bar{x}_{jk}$ = mean of j^{th} variable in k^{th} group

Generalized Mahalanobis D^2 statistics, V:

$$V = \sum_{i=1}^{m} \sum_{j=1}^{m} d_{ij} \sum_{k=1}^{g} n_k (\bar{x}_{ik} - \bar{X}_i)(\bar{x}_{jk} - \bar{X}_j) \qquad (2)$$

where d_{ij} = the inverse element of the pooled dispersion matrix D

V can be used as chi-square (under assumption of normality) with m(g-1) degrees of freedom, to test the hypothesis that the mean values are the same in all the g groups for these m variables. For each discriminant function $k_* = 1, 2, \ldots, g$, the following statistics are calculated.

Coefficients:

$$C_{ik*} = \sum_{j=1}^{m} d_{ij} \bar{x}_{jk} \qquad (3)$$

where $i = 1, 2, \ldots, m$

$k = k*$

Constant:

$$C_{ok*} = -1/2 \sum_{j=1}^{m} \sum_{l=1}^{m} d_{jl} \bar{x}_{jk} \bar{x}_{lk} \qquad (4)$$

For each i^{th} case in each k^{th} group, the following calculations are performed.

Discriminant functions:

$$f_{k*} = \sum_{j=1}^{m} C_{jk} x_{ijk} + C_{ok*} \qquad (5)$$

where $k* = 1, 2, \ldots, g$

Probability associated with largest discriminant function:

$$P_L = \frac{1}{\sum_{k*=1}^{g} e^{(f_{k*} - f_L)}} \qquad (6)$$

where f_L = the value of the largest discriminant function

L = the subscript of the largest discriminant function

C                                                                       DISC 100
C       USAGE                                                           DISC 110
C          CALL DISCR (K,M,N,X,XBAR,D,CMEAN,V,C,P,LG)                   DISC 120
C                                                                       DISC 130
C       DESCRIPTION OF PARAMETERS                                       DISC 140
C          K     - NUMBER OF GROUPS. K MUST BE GREATER THAN ONE.        DISC 150
C          M     - NUMBER OF VARIABLES                                  DISC 160
C          N     - INPUT VECTOR OF LENGTH K CONTAINING SAMPLE SIZES OF  DISC 170
C                  GROUPS.                                              DISC 180
C          X     - INPUT VECTOR CONTAINING DATA IN THE MANNER EQUIVA-   DISC 190
C                  LENT TO A 3-DIMENSIONAL FORTRAN ARRAY, X(1,1,1),     DISC 200
C                  X(2,1,1), X(3,1,1), ETC.  THE FIRST SUBSCRIPT IS     DISC 210
C                  CASE NUMBER, THE SECOND SUBSCRIPT IS VARIABLE NUMBER DISC 220
C                  AND THE THIRD SUBSCRIPT IS GROUP NUMBER.  THE        DISC 230
C                  LENGTH OF VECTOR X IS EQUAL TO THE TOTAL NUMBER OF   DISC 240
C                  DATA POINTS, T*M, WHERE T = N(1)+N(2)+...+N(K).      DISC 250
C          XBAR  - INPUT MATRIX (M X K) CONTAINING MEANS OF M VARIABLES DISC 260
C                  IN K GROUPS                                          DISC 270
C          D     - INPUT MATRIX (M X M) CONTAINING THE INVERSE OF       DISC 280
C                  POOLED DISPERSION MATRIX.                            DISC 290
C          CMEAN - OUTPUT VECTOR OF LENGTH M CONTAINING COMMON MEANS.   DISC 300
C          V     - OUTPUT VARIABLE CONTAINING GENERALIZED MAHALANOBIS   DISC 310
C                  D-SQUARE.                                            DISC 320
C          C     - OUTPUT MATRIX (M+1 X K) CONTAINING THE COEFFICIENTS  DISC 330
C                  OF DISCRIMINANT FUNCTIONS.  THE FIRST POSITION OF    DISC 340
C                  EACH COLUMN (FUNCTION) CONTAINS THE VALUE OF THE     DISC 350
C                  CONSTANT FOR THAT FUNCTION.                          DISC 360
C          P     - OUTPUT VECTOR CONTAINING THE PROBABILITY ASSOCIATED  DISC 370
C                  WITH THE LARGEST DISCRIMINANT FUNCTIONS OF ALL CASES DISC 380
C                  IN ALL GROUPS.  CALCULATED RESULTS ARE STORED IN THE DISC 390
C                  MANNER EQUIVALENT TO A 2-DIMENSIONAL AREA (THE       DISC 400
C                  FIRST SUBSCRIPT IS CASE NUMBER, AND THE SECOND       DISC 410
C                  SUBSCRIPT IS GROUP NUMBER).  VECTOR P HAS LENGTH     DISC 420
C                  EQUAL TO THE TOTAL NUMBER OF CASES, T (T = N(1)+N(2) DISC 430
C                  +...+N(K)).                                          DISC 440
C          LG    - OUTPUT VECTOR CONTAINING THE SUBSCRIPTS OF THE       DISC 450
C                  LARGEST DISCRIMINANT FUNCTIONS STORED IN VECTOR P.    DISC 460
C                  THE LENGTH OF VECTOR LG IS THE SAME AS THE LENGTH    DISC 470
C                  OF VECTOR P.                                         DISC 480
C                                                                       DISC 490
C       REMARKS                                                         DISC 500
C          THE NUMBER OF VARIABLES MUST BE GREATER THAN OR EQUAL TO     DISC 510
C          THE NUMBER OF GROUPS.                                        DISC 520

Factor Analysis (see Eigenanalysis)

In the Scientific Subroutine Package, factor analysis is normally performed by calling the following five subroutines in sequence:

1. CORRE - to find means, standard deviations, and correlation matrix
2. EIGEN - to compute eigenvalues and associated eigenvectors of the correlation matrix
3. TRACE - to select the eigenvalues that are greater than or equal to the control value specified by the user
4. LOAD - to compute a factor matrix
5. VARMX - to perform varimax rotation of the factor matrix

The subroutine CORRE works in either of two ways: (1) it expects all observations in core, or (2) it triggers a user-provided input subroutine, DATA, to read one observation at a time into a work area. In either case, the user must provide a subroutine named DATA (see "Subroutines Required" in the comment cards designation of subroutine CORRE).

Subroutine TRACE

This subroutine finds k, the number of eigenvalues that are greater than or equal to the value of a specified constant. The given eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_m$ must be arranged in descending order.

Cumulative percentages for these k eigenvalues are:

$$d_j = \sum_{i=1}^{j} \frac{\lambda_i}{m} \qquad (1)$$

where $j = 1, 2, \ldots, k$

m = number of eigenvalues (or variables)

$k \leq m$

Subroutine LOAD

This subroutine calculates the coefficients of each factor by multiplying the elements of each normalized eigenvector by the square root of the corresponding eigenvalue.

$$a_{ij} = v_{ij} \cdot \sqrt{\lambda_j} \qquad (1)$$

where i = 1, 2, ..., m are variables

j = 1, 2, ..., k are eigenvalues retained (see the subroutine TRACE)

k ≤ m

Subroutine VARMX

This subroutine performs orthogonal rotations on an m by k factor matrix such that:

$$\sum_j \left\{ m \sum_i \left(a_{ij}^2 / h_i^2 \right)^2 - \left[\sum_i \left(a_{ij}^2 / h_i^2 \right) \right]^2 \right\} \qquad (1)$$

is a maximum, where i = 1, 2, ..., m are variables, j = 1, 2, ..., k are factors, a_{ij} is the loading for the i^{th} variable on the j^{th} factor, and h_i^2 is the communality of the i^{th} variable defined below.

Communalities:

$$h_i^2 = \sum_{j=1}^{k} a_{ij}^2 \qquad (2)$$

where i = 1, 2, ..., m

Normalized factor matrix:

$$b_{ij} = a_{ij} / \sqrt{h_i^2} \qquad (3)$$

where i = 1, 2, ..., m

j = 1, 2, ..., k

Variance for factor matrix:

$$V_c = \sum_j \left\{ \left[m \sum_i \left(b_{ij}^2 \right)^2 - \left(\sum_i b_{ij}^2 \right)^2 \right] / m^2 \right\} \qquad (4)$$

where c = 1, 2, ... (iteration cycle)

Convergence test:

$$\text{If } V_c - V_{c-1} \leq 10^{-7} \qquad (5)$$

four successive times, the program stops rotation and performs the equation (28). Otherwise, the program repeats rotation of factors until the convergence test is satisfied.

Rotation of two factors:

The subroutine rotates two normalized factors (b_{ij}) at a time. 1 with 2, 1 with 3, ..., 1 with k, 2 with 3, ..., 2 with k, ..., k - 1 with k. This constitutes one iteration cycle.

Assuming that x and y are factors to be rotated, where x is the lower-numbered or left-hand factor, the following notation for rotating these two factors is used:

$$\begin{bmatrix} x_1 & y_1 \\ x_2 & y_2 \\ . & . \\ . & . \\ . & . \\ x_m & y_m \end{bmatrix} \cdot \begin{bmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{bmatrix} = \begin{bmatrix} X_1 & Y_1 \\ X_2 & Y_2 \\ . & . \\ . & . \\ . & . \\ X_m & Y_m \end{bmatrix} \quad (6)$$

where x_i and y_i are presently available normalized loadings, and X_i and Y_i, the desired normalized loadings, are functions of ϕ, the angle of rotation. The computational steps are (a) through (e) below.

(a) Calculation of NUM and DEN:

$$A = \sum_i (x_i + y_i)\ (x_i - y_i)$$

$$B = 2 \sum_i x_i\, y_i$$

$$C = \sum_i \left[(x_i+y_i)\ (x_i-y_i) + 2x_i\, y_i \right] \left[(x_i + y_i)\ (x_i - y_i) - 2x_i\, y_i \right]$$

$$D = 4 \sum_i (x_i + y_i)\ (x_i - y_i)\ x_i\, y_i \quad (7)$$

$$NUM = D - 2AB/m$$

$$DEN = C - [\,(A + B)\ (A - B)\,]/m$$

(b) Comparison of NUM and DEN:

The following four cases may arise.

NUM < DEN, go to (b1) below

NUM > DEN, go to (b2) below

(NUM + DEN) $\geq \epsilon$*, go to (b3) below

(NUM + DEN) $< \epsilon$, skip to the next rotation

* ϵ is a small tolerance factor.

(b1) $$\tan 4\theta = |NUM|/|DEN| \quad (8)$$

If $\tan 4\theta < \epsilon$ and

(i) DEN is positive, skip to the next rotation.

(ii) DEN is negative, set $\cos\phi = \sin\phi = (\sqrt{2})/2$ and go to (e) below.

If $\tan 4\theta \geq \epsilon$, calculate:

$$\cos 4\theta = 1/\sqrt{1 + \tan^2 4\theta} \quad (9)$$

$$\sin 4\theta = \tan 4\theta \cdot \cos 4\theta \quad (10)$$

and go to (c) below.

(b2) $$\text{ctn}\,4\theta = |NUM|/|DEN| \quad (11)$$

If $\text{ctn}4\theta < \epsilon$, set $\cos 4\theta = 0$ and $\sin 4\theta = 1$. Go to (c) below.

If $\text{ctn}4\theta \geq \epsilon$, calculate:

$$\sin 4\theta = 1/\sqrt{1 + \text{ctn}^2 4\theta} \quad (12)$$

$$\cos 4\theta = \text{ctn}4\theta \cdot \sin 4\theta \quad (13)$$

and go to (c) below.

(b3) Set $\cos 4\theta = \sin 4\theta = (\sqrt{2})/2$ and go to (c) below.

(c) Determining $\cos\theta$ and $\sin\theta$:

$$\cos 2\theta = \sqrt{(1 + \cos 4\theta)/2} \quad (14)$$

$$\sin 2\theta = \sin 4\theta / 2\cos 2\theta \quad (15)$$

$$\cos\theta = \sqrt{(1 + \cos 2\theta)/2} \quad (16)$$

$$\sin\theta = \sin 2\theta / 2\cos\theta \quad (17)$$

(d) Determining $\cos\phi$ and $\sin\phi$:

(d1) If DEN is positive, set

$$\cos\phi = \cos\theta \quad (18)$$

$$\sin\phi = \sin\theta \quad (19)$$

and go to (d2) below.

If DEN is negative, calculate

$$\cos\phi = \frac{\sqrt{2}}{2}\cos\theta + \frac{\sqrt{2}}{2}\sin\theta \quad (20)$$

$$\sin\phi = \left| \frac{\sqrt{2}}{2} \cos\theta - \frac{\sqrt{2}}{2} \sin\theta \right| \quad (21)$$

and go to (d2) below.

(d2) If NUM is positive, set

$$\cos\phi = |\cos\phi| \quad (22)$$

$$\sin\phi = |\sin\phi| \quad (23)$$

and go to (e) below.

If NUM is negative, set

$$\cos\phi = |\cos\phi| \quad (24)$$

$$\sin\phi = -|\sin\phi| \quad (25)$$

(e) Rotation:

$$X_i = x_i \cos\phi + y_i \sin\phi \quad (26)$$

$$Y_i = x_i \sin\phi + y_i \cos\phi \quad (27)$$

where $i = 1, 2, \ldots, m$

After one cycle of $k(k-1)/2$ rotations is completed, the subroutine goes back to calculate the variance for the factor matrix by equation (4).

Denormalization:

$$a_{ij} = b_{ij} \cdot h_i \quad (28)$$

where $i = 1, 2, \ldots, m$

$j = 1, 2, \ldots, k$

Check on communalities:

Final communalities $$f_i^2 = \sum_{j=1}^{k} a_{ij}^2 \quad (29)$$

Difference $$d_i = h_i^2 - f_i^2 \quad (30)$$

where $i = 1, 2, \ldots, m$

Time Series (see Smoothing)

Subroutine AUTO

This subroutine calculates the autocovariances for lags 0, 1, 2, ..., (L-1), given a time series of observations A_1, A_2, ..., A_n and a number L.

$$R_j = \frac{1}{n-j+1} \sum_{i=1}^{n-j+1} (A_i - AVER)\,(A_{i+j-1} - AVER) \quad (1)$$

where $AVER = \frac{1}{n} \sum_{i=1}^{n} A_i$

n = number of observations in time series A

j = 1, 2, 3, ..., L represent time lags 0, 1, 2, ..., (L-1)

Subroutine CROSS

This subroutine calculates the cross covariances of series B lagging and leading A, given two time series $A_1, A_2, \ldots, A_n$ and $B_1, B_2, \ldots, B_n$ and given a number L.

(a) B lags A:

$$R_j = \frac{1}{n-j+1} \sum_{i=1}^{n-j+1} (A_i - \text{AVERA})\,(B_{i+j-1} - \text{AVERB}) \qquad (1)$$

(b) B leads A:

$$S_j = \frac{1}{n-j+1} \sum_{i=1}^{n-j+1} (A_{i+j-1} - \text{AVERA})\,(B_i - \text{AVERB}) \qquad (2)$$

where $$\text{AVERA} = \frac{1}{n} \sum_{i=1}^{n} A_i$$

$$\text{AVERB} = \frac{1}{n} \sum_{i=1}^{n} B_i$$

n = number of observations in each series

j = 1, 2, ..., L represent time lags (or leads) of 0, 1, 2, ..., (L-1)

Subroutine SMO

This subroutine calculates the smoothed or filtered series, given a time series A_1, A_2, ..., A_n, a selection integer L, and a weighting series W_1, W_2, ..., W_m.

$$R_i = \sum_{j=1}^{m} A_p \cdot W_j \qquad (1)$$

where $p = j \cdot L - L + k$

$k = i - IL + 1$

$i = IL$ to IH

$$IL = \frac{L(m-1)}{2} + 1 \qquad (2)$$

$$IH = n - \frac{L(m-1)}{2} \qquad (3)$$

L = a given selection integer. For example, L = 4 applies weights to every 4th item of the time series.

m = number of weights. Must be an odd integer. (If m is an even integer, any fraction resulting from the calculation of $\frac{L(m-1)}{2}$ in (2) and (3) above will be truncated.)

n = number of items in the time series

From IL to IH elements of the vector R are filled with the smoothed series, and other elements with zeros.

Subroutine EXSMO

This subroutine calculates a smoothed series S_1, S_2, ..., S_{NX}, given time series X_1, X_2, ..., X_{NX} and a smoothing constant α. Also, at the end of the computation, the coefficients A, B, and C are given for the expression $A + B(T) + C(T)^2/2$. This expression can be used to find estimates of the smoothed series for a given number of time periods, T, ahead.

The subroutine has the following two stages for i = 1, 2, ..., NX, starting with A, B, and C either given by the user or provided automatically by the subroutine (see below).

(a) Find S_i for one period ahead:

$$S_i = A + B + 0.5C \tag{1}$$

(b) Update coefficients A, B, and C:

$$A = X_i + (1 - \alpha)^3 (S_i - X_i) \tag{2}$$

$$B = B + C - 1.5 (\alpha^2) (2 - \alpha) (S_i - X_i) \tag{3}$$

$$C = C - (\alpha^3) (S_i - X_i) \tag{4}$$

where α = smoothing constant specified by the user

$(0.0 < \alpha < 1.0)$

If coefficients A, B, and C are not all zero (0.0), take given values as initial values. However, if A = B = C = 0.0, generate initial values of A, B, and C as follows:

$$C = X_1 - 2X_2 + X_3 \tag{5}$$

$$B = X_2 - X_1 - 1.5C \tag{6}$$

$$A = X_1 - B - 0.5C \tag{7}$$

Nonparametric Statistics

Subroutine KOLMO

Given a sample of n independent and identically distributed random variables $X_1, X_2, \ldots, X_n$ with continuous cumulative distribution function F(x), this subroutine tests the difference in absolute value between the empirical distribution $F_n(x)$ and theoretical distribution F(x), using Kolmogorov-Smirnov's limiting distribution.

For this purpose:

1. The order statistics $\{x_{(i)}\}$ are determined from the set $\{x_i\}$ by sorting $\{x_i\}$ into a nondecreasing sequence.
2. The empirical cumulative distribution function $F_n(x)$ is computed. This is the following step-function:

$$F_n(x) = \begin{cases} 0 & x < x_{(1)} \\ k/n & x_{(k)} \leq x < x_{(k+1)}; \; k=1,\ldots,n-1 \\ 1 & x_{(n)} \leq x \end{cases}$$

3. The maximum deviation D_n in absolute value between the empirical and theoretical distribution is computed:

$$D_n = \max_{-\infty<x<\infty} |F_n(x) - F(x)|$$

Since $F_n(x)$ and F(x) are nondecreasing functions, the result is:

$$D_n = \max_{1\leq k\leq n} \left| F_n\left[x_{(k)}\right] - F\left[x_{(k)}\right] \right|$$

D_n is a random variable, and L(z) is the limiting cumulative distribution function of $n^{1/2} D_n$:

$$\lim_{n\to\infty} \text{Prob}\{n^{1/2} D_n < z\} = L(z)$$

4. Finally,

$$z = n^{1/2} D_n$$

and the probability of being greater than or equal to the computed value of $n^{1/2} D_n$

$$P = 1 - L(z)$$

are computed.

Generally, theoretical distribution functions are to be included by the user, as specified in the program. However, four functions are evaluated in KOLMO, as follows:

$$\int_{-\infty}^{x} dF(t) = F(x) \qquad (1)$$

is evaluated at the points of the set $\{X_{(i)}\}$, where F(x) is one of the following:

- The normal pdf with mean u and variance s^2
- The exponential pdf with mean u and variance s^2
- The Cauchy pdf with median u, and first quartile s - u
- The uniform pdf with endpoints u and s

Any user-written pdf should evaluate (1) above, using the parameters u and s at his convenience. Instructions given in the program KOLMO should be followed.

Lilliefors (1967) notes that critical values determined by this test are not correct when one or more parameters are estimated from the sample. The user should refer to his article for notes on approximations which may be considered if such estimates are used.

Subroutine KOLM2

Given a sample of n i.i.d. (independent and identically distributed) random variables X, and a sample of m i.i.d. random variables Y, this subroutine tests the difference between the two empirical distribution functions $F_n(x)$ and $G_m(y)$ using Kolmogorov-Smirnov's limiting distribution. For this purpose:

1. The sets X and Y are sorted into the ordered sets $\{X_{(i)}\}$ and $\{Y_{(i)}\}$, which are nondecreasing sequences.

2. The empirical cumulative distribution functions $F_n(x)$ for the set X, and $G_m(y)$ for the set Y are computed. For example,

$$F_n(x) = \begin{cases} 0 & x < x_{(1)} \\ k/n & x_{(k)} \le x < x_{(k+1)} ; \; k=1,..,n-1 \\ 1 & x_{(n)} \le x \end{cases}$$

3. The maximum difference in absolute value between the two sample distribution functions is computed:

$$D_{m,n} = \max_{x,\,y} \left| F_n(x) - G_m(y) \right|$$

The statistic $\sqrt{\frac{mn}{m+n}}\, D_{m,n}$ is a random variable with limiting cumulative distribution function L(z), which is described under "Subroutine SMIRN" in this manual. That is,

$$\lim_{m,n \to \infty,\,\infty} \text{Prob}\left\{ \sqrt{\frac{mn}{m+n}}\, D_{m,n} < z \right\} = L(z)$$

4. Finally, the probability (asymptotic) of the statistic $\sqrt{\frac{mn}{m+n}}\, D_{m,n}$ being not less than its computed value, under the assumption of equality of the two theoretical distribution functions from which X and Y were taken, is computed:

$$P = 1 - L(z)$$

Subroutine SMIRN

This subroutine computes the values of Kolmogorov-Smirnov's limiting distribution for a given argument x.

$$L(x) = \begin{cases} 0 & x \le 0 \\ 1 - 2 \sum_{k=1}^{\infty} (-1)^{k-1} \exp(-2k^2x^2) & x > 0 \end{cases} \quad (1)$$

L(x) is the limit (Kolmogorov) of the cumulative distribution function of $\sqrt{n}\, D_n$, and of (Smirnov) $[mn/(m+n)]^{1/2} D_{m,n}$ where:

D_n is the maximum, over all x, of the difference $|F_n(x) - F(x)|$ between the sample distribution function $F_n(x)$ and the continuous theoretical distribution function F(x), and

$D_{m,n}$ is the maximum, over all x, of the difference between the two sample distribution functions $F_m(x)$ and $G_n(x)$, from two independent samples of sizes m and n.

When x is very small, the series (1) converges slowly, but, using Jacobi's Theta-functions $\theta_2(u,t)$ and $\theta_4(u,t)$:

$$\theta_2(u,t) = 2 \sum_{k=0}^{\infty} \exp[i\pi(k+1/2)^2 t] \cos[(2k+1)u]$$

$$\theta_4(u,t) = 1 - 2 \sum_{k=0}^{\infty} (-1)^{k-1} \exp(i\pi k^2 t) \cos(2ku)$$

and using the Jacobi imaginary transformation

$$\theta_4(0,t) = (-it)^{-1/2} \theta_2(0, -1/t)$$

it follows that:

$$L(x) = \theta_4(0, 2ix^2/\pi)$$

$$= (\sqrt{2\pi}/x) \sum_{k=1}^{\infty} \exp[-(2k-1)^2 \pi^2/8x^2]$$

which converges quickly when x is small. The computation here uses, with errors $E_i(x)$, i = 1, 2:

$$L(x) = \begin{cases} 0 & x \le 0.27 \\ (\sqrt{2\pi}/x) \sum_{k=1}^{3} \exp\left[-(2k-1)^2 \pi^2 / 8x^2\right] + E_1(x); & 0.27 < x < 1.0 \\ 1 - 2 \sum_{k=1}^{4} (-1)^{k-1} \exp(-2k^2 x^2) + E_2(x) & 1.0 \le x < 3.1 \\ 1 & 3.1 \le x < \infty \end{cases}$$

where:

$$E_1(x) \le 6\,(10^{-15}) \quad \text{when } x < 1$$

$$E_2(x) < 10^{-20} \quad \text{when } x \ge 1$$

Subroutine CHISQ

This subroutine calculates degrees of freedom and chi-square for a given contingency table A of observed frequencies with n rows (conditions) and m columns (groups). The degrees of freedom are:

$$d.f. = (n - 1)(m - 1) \quad (1)$$

If one or more cells contain an expected value less than 1.0, chi-square will be computed, but the error code will be set to one.

The following totals are computed:

$$T_i = \sum_{j=1}^{m} A_{ij}; \quad i = 1, 2, \ldots, n \text{ (row totals)} \quad (2)$$

$$T_j = \sum_{i=1}^{n} A_{ij}; \quad j = 1, 2, \ldots, m \text{ (column totals)} \quad (3)$$

$$GT = \sum_{i=1}^{n} T_i \quad \text{(grand total)} \quad (4)$$

Chi-square is obtained for two cases.

(a) For 2 x 2 table:

$$\chi^2 = \frac{GT\left(\left|A_{11}A_{22} - A_{12}A_{21}\right| - \frac{GT}{2}\right)^2}{(A_{11}+A_{12})(A_{21}+A_{22})(A_{11}+A_{21})(A_{12}+A_{22})} \quad (5)$$

(b) For other contingency tables:

$$\chi^2 = \sum_{i=1}^{n}\sum_{j=1}^{m} \frac{\left(A_{ij} - E_{ij}\right)^2}{E_{ij}} \quad (6)$$

where $E_{ij} = \frac{T_i T_j}{GT}$

$i = 1, 2, \ldots, n$

$j = 1, 2, \ldots, m$

Subroutine KRANK

The subroutine computes the Kendall rank correlation coefficient, given two vectors of n observations for two variables, A and B. The observations on each variable are ranked from 1 to n. Tied observations are assigned the average of the tied ranks. Ranks are sorted in sequence of variable A.

A correction factor for ties is obtained:

$$T_a = \sum \frac{t(t-1)}{2} \quad \text{for variable A}$$

$$T_b = \sum \frac{t(t-1)}{2} \quad \text{for variable B} \qquad (1)$$

where t = number of observations tied for a given rank

The Kendall rank correlation coefficient is then computed for the following two cases:

(a) if T_a and T_b are zero,

$$\tau = \frac{S}{\frac{1}{2} n (n-1)} \qquad (2)$$

where n = number of ranks

S = total score calculated for ranks in variable B by selecting each rank in turn, adding 1 for each larger rank to its right, subtracting 1 for each smaller rank to its right

(b) if T_a and/or T_b are not zero,

$$\tau = \frac{S}{\sqrt{\frac{1}{2} n (n-1) - T_a}\ \sqrt{\frac{1}{2} n (n-1) - T_b}} \qquad (3)$$

The standard deviation is calculated:

$$s = \sqrt{\frac{2(2n+5)}{9n(n-1)}} \qquad (4)$$

The significance of τ can be measured by

$$z = \frac{\tau}{s} \qquad (5)$$

Subroutine MPAIR

This subroutine performs the Wilcoxon matched-pairs signed-ranks test, given two vectors of n observations of matched samples. The computational steps are as follows:

1. For each matched pair, determine the signed difference (d_j) between the two scores.

2. Rank these d's without respect to sign. In doing so, (a) disregard those d's equal to zero (0), and (b) with tied d's, assign the average of the tied ranks.

3. Affix to each rank the sign (+ or -) of the d in step 1 above.

4. Compute T = the sum of positive ranks or the sum of negative ranks, whichever is smaller.

5. Compute mean:

$$\mu = \frac{K(K+1)}{4} \qquad (1)$$

where K = the total number of d's which are not zero (0).

6. Compute standard deviation:

$$\sigma = \sqrt{\frac{K(K+1)\ (2K+1)}{24}} \qquad (2)$$

7. Compute Z:

$$Z = \frac{T - \mu}{\sigma} \qquad (3)$$

Z is approximately normally distributed with zero mean and unit variance.

8. Compute the probability, p, associated with the value as extreme as Z by the subroutine NDTR.

Note: p is the probability for a one-tailed test; thus for a two-tailed test, the user should double the value of p.

Subroutine QTEST

This subroutine determines the Cochran Q-test statistic, given a matrix A of dichotomous data with n rows (sets) and m columns (groups).

Row and column totals are calculated:

$$L_i = \sum_{j=1}^{m} A_{ij} \quad \text{(row totals)} \tag{1}$$

where $i = 1, 2, \ldots, n$

$$G_j = \sum_{i=1}^{n} A_{ij} \quad \text{(column totals)} \tag{2}$$

where $j = 1, 2, \ldots, m$

The Cochran Q statistic is computed:

$$Q = \frac{(m-1)\left[m\sum_{j=1}^{m} G_j^2 - \left(\sum_{j=1}^{m} G_j\right)^2\right]}{m\sum_{i=1}^{n} L_i - \sum_{i=1}^{n} L_i^2} \tag{3}$$

The degrees of freedom are:

$$\text{d.f.} = m - 1 \tag{4}$$

Subroutine SIGNT

This subroutine performs a sign test, given two vectors of n observations of two matched samples. The computational steps are as follows:

1. Find the sign of the difference between the two numbers of each pair.

2. Find K = the number of pairs whose differences are not zero (0). Disregard those pairs whose differences are zero (0).

3. Find M = the number of (+) differences or the number of (-) differences, whichever is fewer.

4. If K is less than or equal to 25, the probability associated with a value as small as the observed value of M is given by the binomial distribution as:

$$p = \sum_{i=0}^{M} \binom{K}{i} P^i Q^{K-i} \qquad (1)$$

where $P = Q = 0.5$

$$\binom{K}{i} = \frac{K!}{i!\ (K-i)!}$$

The equation (1) is rewritten to simplify the calculation as follows:

$$p = \frac{\sum_{i=0}^{M} \binom{K}{i}}{2^K} \qquad (2)$$

If K is greater than 25, the probability is calculated by the normal approximation to the binomial distribution as follows:

Mean: $$\mu = KP = \frac{1}{2} K \qquad (3)$$

Standard deviation: $$\sigma = \sqrt{KPQ} = \frac{1}{2}\sqrt{K} \qquad (4)$$

Value of Z: $$Z = \frac{(M+0.5) - \mu}{\sigma} \qquad (5)$$

Then the probability, p, associated with the value as extreme as Z is obtained by the subroutine NDTR.

Note: p computed by this subroutine is the probability for a one-tailed test; thus for a two-tailed test, the user should double the value of p.

For reference see S. Siegel, Nonparametric Statistics for the Behavioral Sciences, McGraw-Hill, New York, 1956, chapter 5.

Subroutine SRANK

This subroutine measures the correlation between two variables by means of the Spearman rank correlation coefficient, given two vectors of n observations for the variables.

The observations on each variable are ranked from 1 to n. Tied observations are assigned the average of the tied ranks.

The sum of squares of rank differences is calculated:

$$D = \sum_{i=1}^{n} (A_i - B_i)^2 \qquad (1)$$

where A_i = first ranked vector

B_i = second ranked vector

n = number of ranks

A correction factor for ties is obtained:

$$T_a = \sum \frac{t^3 - t}{12} \quad \text{over variable A} \qquad (2)$$

$$T_b = \sum \frac{t^3 - t}{12} \quad \text{over variable B}$$

where t = number of observations tied for a given rank

The Spearman rank correlation coefficient is then computed for the following two cases:

(a) if T_a and T_b are zero,

$$r_s = 1 - \frac{6D}{n^3 - n} \qquad (3)$$

(b) if T_a and/or T_b are not zero,

$$r_s = \frac{X + Y - D}{2\sqrt{XY}} \qquad (4)$$

where $X = \frac{n^3 - n}{12} - T_a$ (5)

$$Y = \frac{n^3 - n}{12} - T_b \qquad (6)$$

The statistic used to measure the significance of r_s is:

$$t = r_s \sqrt{\frac{n - 2}{1 - r_s^2}} \qquad (7)$$

The degrees of freedom are:

d.f. = n - 2 (8)

Subroutine TWOAV

This subroutine determines the Friedman two-way analysis of variance statistic, given a matrix A with n rows (groups) and m columns (cases). Data in each group is ranked from 1 to m. Tied observations are assigned the average of the tied ranks.

The sum of ranks is calculated:

$$R_j = \sum_{i=1}^{n} A_{ij} \qquad (1)$$

Friedman's statistic is then computed:

$$\chi_r^2 = \frac{12}{nm(m+1)} \sum_{j=1}^{m} (R_j)^2 - 3n(m+1) \qquad (2)$$

The degrees of freedom are:

$$d.f. = m - 1 \qquad (3)$$

Subroutine UTEST

This subroutine tests whether two independent groups are from the same population by means of the Mann-Whitney U-test, given an input vector A with the smaller group preceding the larger group. The scores for both groups are ranked together in ascending order. Tied observations are assigned the average of the tied ranks.

The sum of ranks in the larger group, R2, is calculated. The U statistic is then computed as follows:

$$U' = n_1 n_2 + \frac{n_2 (n_2 + 1)}{2} - R_2 \qquad (1)$$

where n_1 = number of cases in smaller group

n_2 = number of cases in larger group

$U = n_1 n_2 - U'$

if $U' < U$, set $U = U'$ (2)

A correction factor for ties is obtained:

$$T = \sum \frac{t^3 - t}{12} \qquad (3)$$

where t = number of observations tied for a given rank

The standard deviation is computed for two cases:

(a) if $T = 0$

$$s = \sqrt{\frac{n_1 n_2 (n_1 + n_2 + 1)}{12}} \qquad (4)$$

(b) if $T > 0$

$$s = \sqrt{\left(\frac{n_1 n_2}{N(N-1)}\right)\left(\frac{N^3 - N}{12} - T\right)} \qquad (5)$$

where N = total number of cases $(n_1 + n_2)$

The significance of U can be measured by

$$Z = \frac{U - \overline{X}}{s} \qquad (6)$$

where $\overline{X}$ = mean $= \frac{n_1 n_2}{2}$

Z is set to zero if n_2 is less than 20.

Subroutine WTEST

This subroutine computes the Kendall coefficient of concordance, given a matrix A of n rows (variables) and m columns (cases). The observations on all variables are ranked from 1 to m. Tied observations are assigned the average of the tied ranks.

A correction factor for ties is obtained:

$$T = \sum_{i=1}^{n} \frac{t^3 - t}{12} \qquad (1)$$

where t = number of observations tied for a given rank

Sums of ranks are calculated:

$$Y_j = \sum_{i=1}^{n} R_{ij} \qquad (2)$$

where j = 1, 2, . . . , m

From these, the mean of sums of ranks is found:

$$\bar{R} = \frac{\sum_{j=1}^{m} Y_j}{m} \qquad (3)$$

The sum of squares of deviations is derived:

$$s = \sum_{j=1}^{m} (Y_j - \bar{R})^2 \qquad (4)$$

The Kendall coefficient of concordance is then computed:

$$W = \frac{s}{\frac{1}{12} n^2 (m^3 - m) - n T} \qquad (5)$$

For m larger than 7, chi-square is:

$$\chi^2 = n (m - 1) W \qquad (6)$$

The degrees of freedom are:

$$\text{d.f.} = n - 1 \qquad (7)$$

Subroutine GAUSS

This subroutine computes a normally distributed random number with a given mean and standard deviation.

An approximation to normally distributed random numbers Y can be found from a sequence of uniform random numbers† using the formula:

$$Y = \frac{\sum_{i=1}^{K} X_i - \frac{K}{2}}{\sqrt{K/12}} \qquad (1)$$

where X_i is a uniformly distributed random number, $0 < X_i < 1$

K is the number of values X_i to be used

Y approaches a true normal distribution asymptotically as K approaches infinity. For this subroutine, K was chosen as 12 to reduce execution time. Equation (1) thus becomes:

$$Y = \sum_{i=1}^{12} X_i - 6.0$$

The adjustment for the required mean and standard deviation is then:

$$Y' = Y * S + AM \qquad (2)$$

where Y' is the required normally distributed random number

S is the required standard deviation

AM is the required mean

```

Distribution Functions

Subroutine NDTR

This subroutine computes y = P(x) = Prob ($X \le x$), where X is a random variable distributed normally with mean zero and variance one.

$$P(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} \exp(-u^2/2)du$$

The following approximation† is used:

$$P(x) = 1 - f(x) \sum_{i=1}^{5} a_i w^i ; \quad x \ge 0$$

where:

$$w = 1/(1 + px)$$

$$f(x) = \exp(-x^2/2) / \sqrt{2\pi}$$

$$P = 0.2316419$$

$$a_1 = 0.3193815$$

$$a_2 = -0.3565638$$

$$a_3 = 1.781478$$

$$a_4 = -1.821256$$

$$a_5 = 1.330274$$

The maximum error is $7(10^{-7})$; f(x) is also presented in output.

Subroutine BDTR

This subroutine computes $P=I_x(m,n)=\text{Prob}(X \le x)$ where X is a random variable following the beta distribution with degrees of freedom (continuous parameters) m and n. For computation to take place, $0 \le x \le 1$, $0.5 \le m \le 10^{+5}$, and $0.5 \le n \le 10^{+5}$. D, the ordinate of the beta density at x, is also presented in the output.

For $0 \le x \le 1$, $I_x(m,n)$ may be written as:

$$I_x(m,n) = \int_0^x f(m,n,y)\,dy$$

where:

$$f(m,n,y) = \frac{1}{B(m,n)} y^{m-1}(1-y)^{n-1} \qquad (1)$$

$$B(m,n) = \frac{\Gamma(m)\,\Gamma(n)}{\Gamma(m+n)}; \quad D = f(m,n,x)$$

$I_x(m,n)$ can be reduced to a binomial partial sum which can be evaluated by means of a continued fraction expansion.

Let $N = m+n-1$ and $r = m-1$. Then:

$$I_x(m,n) = I_x(r+1,\ N-r)$$

$$I_x(r+1,\ N-r) = \sum_{s=r+1}^{N} \binom{N}{s} x^s (1-x)^{N-s} \qquad (2)$$

$$= \binom{N}{r+1} x^{r+1} (1-x)^{N-r-1} S$$

where $0 \le s \le N$

S is a continued fraction, with 80 terms being sufficient for the desired accuracy.

$$S = \frac{1}{1-}\frac{c_1}{1+}\frac{d_1}{1-}\frac{c_2}{1+}\frac{d_2}{1-}\ \cdots\ \frac{c_{80}}{1+}\frac{d_{80}}{1} \qquad (3)$$

$$c_i = \frac{(N-i-r)(r+i)}{(r+2i-1)(r+2i)} \frac{x}{1-x} \qquad (4)$$

$$d_i = \frac{i(N+i)}{(r+2i+1)(r+2i)} \frac{x}{1-x} \qquad (5)$$

The above continued fraction expansion of $I_x(m,n)$ holds for positive m and n (integers or nonintegers), $N \geq 0$ $(m+n \geq 1)$, and $r \geq 0$ $(m \geq 1)$. In order to fulfill these last two conditions, if $m < 1$, the following transformation must be made before computation of $I_x(m,n)$ can take place:

$$I_x(m,n) = \frac{\Gamma(m+n)}{\Gamma(m+1)\Gamma(n)} x^m (1-x)^n + I_x(m+1,n) \quad (6)$$

The quantities on the right-hand side of equation (6) are those which are computed.

It is known that $I_x(m,n) = I_{1-x}(n,m)$. Thus, either of the two parameter sets indicated by this equation may be used in computing the beta integral. The parameter set selection is made by applying the following empirically derived rule:

> Let p and q be the degrees of freedom corresponding to z, where $z = x$ if $x \leq .5$ or $(1-x)$ otherwise. If the quantity $[(p-1) - (p+q-1) z^{6/5} + 2]$ is positive, use the parameter set corresponding to z. Otherwise, use the parameter set corresponding to (1-z).

If $0 \leq x \leq 10^{-8}$ or $0 \leq 1-x \leq 10^{-8}$, the approximation is made that x = 0 or 1 respectively. P and D are then set according to the following table:

$0 \leq x \leq 10^{-8}$		$0 \leq 1-x \leq 10^{-8}$	
P = 0		P = 1	
If:	then:	If:	then:
A < 1	$D = 10^{75}$	B < 1	$D = 10^{75}$
A = 1	D = 1/B(m,n)	B = 1	D = 1/B(m,n)
A > 1	D = 0	B > 1	D = 0

If either or both m and n are within 10^{-8} of 1, the beta integral is solved explicitly for m = 1, n = 1, or m = n = 1:

If:	then:
A = 1, B = 1	P = x
A = 1, B ≠ 1	$P = 1 - (1-x)^n$
A ≠ 1, B = 1	$P = x^m$

If m or n is greater than 1000, the chi-square approximation is used:

$z_1 = 2m(1-x)/x$ is distributed as χ^2 with 2n degrees of freedom and $P = 1 - P_{\chi 2}(z_1)$ for m > 1000.

$z_2 = 2nx/(1-x)$ is distributed as χ^2 with 2 m degrees of freedom and $P = P_{\chi 2}(z_2)$ for n > 1000.

If both m and n are greater than 1000, the approximation corresponding to z_1 is used.

The values of P very near zero or one may be somewhat imprecise. To eliminate possible misinterpretation of results, if $0 \leq P \leq 10^{-8}$ or $0 \leq 1-P \leq 10^{-8}$, P is set to 0 or 1 respectively.

Subroutine CDTR

This subroutine computes P = P (x) = Prob. $(X \leq x)$, where X is a random variable following the χ^2 distribution with continuous parameter m. The value of x must be greater than or equal to zero and $0.5 \leq m \leq 2\ (10^5)$ for computation to take place. D, the ordinate of the χ^2 density at x, is also presented in the output.

For $x \geq 0$, P(x) may be written as:

$$P(x) = \int_0^x f(m,y)\, dy \qquad (1)$$

where $f(m,y) = y^{(m-2)/2}\ e^{-y/2} / (2^{m/2}\, \Gamma(\frac{m}{2}))$

and D = f(m,x)

To evaluate the integral, $\theta = \frac{m}{2} - [\frac{m}{2}]$ is first defined where $[\frac{m}{2}]$ denotes the largest integer less than or equal to $\frac{m}{2}$. θ is thus the fractional part of $\frac{m}{2}$.

Substituting this expression into the integral and performing the proper reductions, the following results are obtained.

If:	then:
$0 < m < 2$	P (x) = T1 + T2
$2 \leq m < 4$	P (x) = T1
$m \geq 4$	P (x) = T1 - 2T3

where:

$$T1 = \int_0^x \frac{y^{\theta}\ e^{-y/2}\, dy}{2^{1+\theta}\, \Gamma(1+\theta)}$$

$$T2 = f(2+2\theta, x)$$

$$T3 = \sum_{i=2}^{[\frac{m}{2}]} f(2i+2\theta, x)$$

T2 and T3 may be evaluated directly using logs and antilogs.

If $\theta = 0$ ($\frac{m}{2}$ is an integer), T1 is easily evaluated as:

$$T1 = 1 - e^{-x/2}$$

If $\theta > 0$, T1 can be expanded in the following infinite series:

$$T1 = \frac{z^{\theta}}{\Gamma(1+\theta)}\left(\frac{z}{1+\theta} - \frac{z^2}{2+\theta} + \frac{z^3}{2!\,(3+\theta)} - \frac{z^4}{3!\,(4+\theta)} \cdots\right) \qquad (2)$$

where $Z = \frac{x}{2}$

This series is used in the range $10^{-8} < x \leq 10$, and not more than 30 terms are necessary to ensure convergence within error bounds of 10^{-9}.

For $x > 10$, 1-T1 is evaluated by the Euler-McLaurin formula up to third-derivative terms (see reference (2), equation 23.1.30). One finds:

$$1 - T1 = \int_0^N h(u)\, du \qquad (3)$$

where $h(u) = \frac{1}{\Gamma(1+\theta)} (\frac{2u}{Nx})^{-(1+\theta)} u^{-1}\ e^{-Nx/2u}$

and $\int_0^N h(u)du = \sum_{u=o}^{N-1} h(u) + \frac{1}{2} h(N) - \frac{1}{12} h'(N)$

$$+ \frac{1}{720} h'''(N)$$ (Note: $h' = h'''$ = 0 at 0)

In order to achieve accuracy consistent with that obtained by the method of equation (2), N = 26 is used in equation (3).

If $0 \leq x \leq 10^{-8}$, the approximation x = 0 is made. P is set to 0; and D is set to 10^{75}, 0.5, or 0, corresponding to m less than 2, equal to 2, or greater than 2 respectively.

If m > 1000, Wilson and Hilferty's approximation is used. $(\chi^2/m)^{1/3}$ is approximately normally distributed with mean 1 - 2/9m and variance 2/9m (see reference (2), equation 26.4.14). If $m \leq 1000$ and $x > 2000$, or $m > 1000$ and $x > 10^6$, P is set to 1.

Since T1 may have an error of about 10^{-9}, values of P(x) very near zero or one may be somewhat imprecise. To eliminate possible misinterpretation of results, if $0 \leq P(x) \leq 10^{-8}$ or $0 \leq 1-P(x) \leq 10^{-8}$, P(x) is set to 0 or 1 respectively.

The χ^2 distribution is a member of the gamma family of probability distributions. The general form for distributions of this class is:

$$P_G(x) = \int_0^x G(n, A, \psi; u)\, du$$

where $G(n, a, \psi; u) = (u-a)^{n-1}\, e^{-(u-a)/\psi} / (\psi^n \Gamma(n))$

This subroutine may, therefore, also be used to compute the probability integral from zero to x and the corresponding ordinate at x for any member of this gamma family by setting:

$x = 2(u-a) / \psi$ and $m = 2n$

Then P(x) will be the desired probability and $2f(m,x)/\psi$ will be the desired ordinate.

Subroutine NDTRI

This subroutine computes $x = p^{-1}(y)$ such that $y = P(x) = \text{Prob}\ (X \leq x)$ where X is a random variable distributed normally with mean zero and variance one.
That is, given P(x), the following is solved for x:

$$P(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} \exp(-u^2/2)du$$

The following approximation† is used:

$$x = w - \sum_{i=0}^{2} a_i w^i \Big/ \sum_{i=0}^{3} b_i w^i \qquad (1)$$

where:

$$w = \sqrt{\ln(1/p^2)} \quad (0 < p \leq .5) \qquad (2)$$

$$a_0 = 2.515517$$

$$a_1 = 0.802853$$

$$a_2 = 0.010328$$

$$b_1 = 1.432788$$

$$b_2 = 0.189269$$

$$b_3 = 0.001308$$

If P(x) is greater than 0.5, 1 - P(x) is used as p in (2) above, and the result of (1), x, is negated.
The maximum error is 0.00045; f(x) is also calculated.

Subroutine MOMEN

This subroutine computes four moments for grouped data $F_1, F_2, \ldots, F_n$ on equal class intervals. The number of class intervals is computed as follows:

$$n = (UBO_3 - UBO_1)/UBO_2 \qquad (1)$$

where UBO_1 = given lower bound

UBO_2 = given class interval

UBO_3 = given upper bound

and the total frequency as follows:

$$T = \sum_{i=1}^{n} F_i \qquad (2)$$

where F_i = frequency count in i^{th} interval.

Then, the following are computed.

First moment (mean):

$$ANS_1 = \frac{\sum_{i=1}^{n} F_i \left[UBO_1 + (i-0.5)\ UBO_2\right]}{T} \qquad (3)$$

j^{th} moment:

$$ANS_j = \frac{\sum_{i=1}^{n} F_i \left[UBO_1 + (i-0.5)\ UBO_2 - ANS_1\right]^j}{T} \qquad (4)$$

$$j = 2,\ 3,\ 4$$

These moments are biased and not corrected for grouping.

Subroutine TTEST

This subroutine computes certain t-statistics on the means of populations under various hypotheses.

The sample means of $A_1, A_2, \ldots, A_{NA}$, and $B_1, B_2, \ldots, B_{NB}$ are normally found by the following formulas:

$$\bar{A} = \frac{\sum_{i=1}^{NA} A_i}{NA}; \qquad \bar{B} = \frac{\sum_{i=1}^{NB} B_i}{NB} \tag{1}$$

and the corresponding sample variances by:

$$SA^2 = \frac{\sum_{i=1}^{NA} (A_i - \bar{A})^2}{NA - 1}; \qquad SB^2 = \frac{\sum_{i=1}^{NB} (B_i - \bar{B})^2}{NB - 1} \tag{2}$$

The quantities μ and σ^2 stand respectively for population mean and variance in the following hypotheses.

Hypothesis: $\mu_B = A$; A = a given value (Option 1)

Let $\bar{B}$ = estimate of μ_B and set NA = 1. (A is stored in location A_1).

The subroutine computes:

$$ANS = \frac{\bar{B} - A}{SB} \cdot \sqrt{NB} \quad \text{(t-statistics)} \tag{3}$$

$$NDF = NB - 1 \quad \text{(degrees of freedom)} \tag{4}$$

Hypothesis: $\mu_A = \mu_B \left(\sigma_A^2 = \sigma_B^2\right)$ (Option 2)

The subroutine computes:

$$ANS = \frac{\bar{B} - \bar{A}}{S} \cdot \frac{1}{\sqrt{\frac{1}{NA} + \frac{1}{NB}}} \quad \text{(t-statistics)} \tag{5}$$

$$NDF = NA + NB - 2 \quad \text{(degrees of freedom)} \tag{6}$$

where $S = \sqrt{\frac{(NA-1)\,SA^2 + (NB-1)\,SB^2}{NA + NB - 2}}$ (7)

Hypothesis: $\mu_A = \mu_B \left(\sigma_A^2 \neq \sigma_B^2\right)$ (Option 3)

The subroutine computes:

$$ANS = \frac{\bar{B} - \bar{A}}{\sqrt{\frac{SA^2}{NA} + \frac{SB^2}{NB}}} \quad \text{(t-statistics)} \tag{8}$$

$$NDF = \frac{\left(\frac{SA^2}{NA} + \frac{SB^2}{NB}\right)^2}{\left(\frac{SA^2}{NA}\right)^2 \Big/ (NA+1) + \left(\frac{SB^2}{NB}\right)^2 \Big/ (NB+1)} - 2 \tag{9}$$

(degrees of freedom)

Note: The program returns a rounded NDF, not a truncated NDF.

Hypothesis: $\mu_A = \mu_B \left(\text{no assumption on } \sigma^2\right)$ (Option 4)

The subroutine computes:

$$ANS = \frac{\bar{D}}{SD} \cdot \sqrt{NB} \quad \text{(t-statistics)} \tag{10}$$

$$NDF = NB - 1 \quad \text{(degrees of freedom)} \tag{11}$$

where $\bar{D} = \bar{B} - \bar{A}$ (12)

$$SD = \sqrt{\frac{\sum_{i=1}^{NB} (B_i - A_i - \bar{D})^2}{NB - 1}} \tag{13}$$

NA = NB

Subroutine BISER

This subroutine computes a biserial coefficient of correlation between two continuous variables when one has been artificially dichotomized. The computational steps are as follows:

1. Compute the mean of the continuously measured variable, A:

$$\bar{A} = \frac{\sum_{i=1}^{N} A_i}{N} \qquad (1)$$

where N = number of observations in the sample.

2. Compute the standard deviation of the continuously measured variable, A:

$$s = \sqrt{\frac{\sum_{i=1}^{N} A^2_i - \frac{\left(\sum_{i=1}^{N} A_i\right)^2}{N}}{N-1}} \qquad (2)$$

3. Obtain the following information for the dichotomous variable, B:

p = proportion of the cases in the higher group

q = proportion of the cases in the lower group

y = ordinate of the normal distribution curve at the point of division between p and q proportions

4. Obtain $\bar{A}_p$ = mean of A values whose corresponding B values are in the higher group.

5. Then, compute the biserial coefficient of correlation, r_b, by the use of the following formula:

$$r_b = \frac{\bar{A}_p - \bar{A}}{s} \cdot \frac{p}{y} \qquad (3)$$

6. The standard error of r_b is estimated by the formula:

$$s_{r_b} = \frac{\sqrt{\frac{pq}{y} - r_b^2}}{\sqrt{N}} \qquad (4)$$

Subroutine PHI

This subroutine computes a phi coefficient between two variables which are dichotomous. The computational steps are as follows:

1. Two dichotomous variables are summarized in a 2 x 2 table as shown below:

		Variable 1: High	Variable 1: Low
Variable 2	High	A	B
	Low	C	D

A, B, C, and D stand for frequencies.

2. Compute the phi coefficient by the formula:

$$\phi = \frac{AD - BC}{\sqrt{(A+B)\,(C+D)\,(A+C)\,(B+D)}} \qquad (1)$$

3. Compute χ^2 as a function of phi coefficient as follows:

$$\chi^2 = N\,\phi^2 \qquad (2)$$

where N = number of observations.

χ^2, with one degree of freedom, may be tested at a required level of significance. If it is significant, the obtained phi coefficient is also significant.

4. Compute the maximal phi coefficient that can be attainable in a given problem by the formula:

$$\phi_{max} = \sqrt{\left(\frac{p_j}{q_j}\right)\left(\frac{q_i}{p_i}\right)} \qquad (3)$$

where p_i is the largest marginal proportion in a 2 x 2 contingency table, and p_j is the corresponding marginal proportion in the other variable.

Subroutine POINT

This subroutine computes a point-biserial correlation coefficient between two variables, one binary (dichotomized) and one continuous. The computational steps are as follows:

1. Compute the mean of the continuously measured variable, A:

$$\bar{A} = \frac{\sum_{i=1}^{N} A_i}{N} \tag{1}$$

where N = number of observations in the sample.

2. Compute the standard deviation of the continuously measured variable, A:

$$s = \sqrt{\frac{\sum_{i=1}^{N} A^2_i - \frac{\left(\sum_{i=1}^{N} A_i\right)^2}{N}}{N-1}} \tag{2}$$

3. Obtain the following information for the dichotomous variable, B:

N_p = number of cases in the higher group

N_q = number of cases in the lower group

4. Obtain $\bar{A}_p$ = mean of A values whose corresponding B values are in the higher group.

5. Then, compute the point-biserial correlation, r_{pb}:

$$r_{pb} = \frac{\bar{A}_p - \bar{A}}{s} \sqrt{\frac{N_p}{N_q}} \tag{3}$$

6. Compute the t ratio used to test the hypothesis of zero correlation:

$$t = r_{pb} \sqrt{\frac{N-2}{1-r^2_{pb}}} \tag{4}$$

7. The degrees of freedom for the t ratio are obtained by:

$$\text{d.f.} = N-2 \tag{5}$$

Subroutine TETRA

This subroutine computes a tetrachoric correlation coefficient between two variables where both of the variables have been reduced artifically to two categories. The computational steps are as follows:

1. Two dichotomous variables are summarized in a 2 x 2 table such as the one shown below.

		Variable 1: High	Variable 1: Low
Variable 2	High	A	B
	Low	C	D

A, B, C, and D stand for frequencies. If any frequency is zero (0), the tetrachoric correlation will not be computed.

2. Obtain the proportions of marginal totals:

$$p_1 = (A+C)/N \quad (1)$$

$$q_1 = (B+D)/N \quad (2)$$

$$p_2 = (A+B)/N \quad (3)$$

$$q_2 = (C+D)/N \quad (4)$$

where N = number of observations.

3. Obtain:

y_1 = ordinate of the normal distribution curve at the point of division between p_1 and q_1 proportions

y_2 = same as y_1 using p_2 and q_2 proportions

z_1 = standard normal variable corresponding to y_1

z_2 = standard normal variable corresponding to y_2

4. Then, compute the tetrachoric correlation coefficient by the use of the following formula:

$$\frac{AD - BC}{y_1 y_2 N^2} = r_t + \frac{1}{2} z_1 z_2 r_t^2 + \frac{1}{6}\left(z_1^2 - 1\right)\left(z_2^2 - 1\right) r_t^3 + \frac{1}{24} z_1 \left(z_1^2 - 3\right) z_2 \left(z_2^2 - 3\right) r_t^4 + \frac{1}{120}\left(z_1^4 - 6z_1^2 + 3\right)\left(z_2^4 - 6z_2^2 + 3\right) r_t^5 + \frac{1}{720} z_1 \left(z_1^4 - 10z_1^2 + 15\right) z_2 \left(z_2^4 - 10z_2^2 + 15\right) r_t^6 + \frac{1}{5040}\left(z_1^6 - 15z_1^4 + 45z_1^2 - 15\right)\left(z_2^6 - 15z_2^4 + 45z_2^2 - 15\right) r_t^7 \quad (5)$$

Note: r_t is found by the subroutine POLRT -- Newton-Raphson method of approximation to the root of the above equation.

5. For the purpose of testing $r_t = 0.0$, the standard error is estimated by the formula:

$$s_{r_t} = \frac{\sqrt{p_1 p_2 q_1 q_2}}{y_1 y_2 \sqrt{N}} \qquad (6)$$

6. In selecting the real root in $[-1, 1]$, if $r_t = a + bi$, and

$$|b| \leq .5(10^{-6})\,|a|$$

r_t is considered to be a real root.

```

Subroutine SRATE

This subroutine computes the survival rates of subjects alive n periods after diagnosis or treatment. The survival rate for each period is computed successively for each of K periods where K is specified and $K \leq n$. An example of the input to this subroutine is presented in Table 2.

Table 2. Example of Input to Subroutine SRATE

Periods after diagnosis	Alive at beginning of period	Died during period	Lost during period	Withdrawn alive during period
(i)	(L_i)	(D_i)	(U_i)	(W_i)
1	130	40	4	10
2	76	6	2	8
3	60	2	1	5
4	52	1	0	4
5	47	0	0	47

The input information includes:

- Periods after diagnosis. This column shows the time period elapsed from the date of diagnosis or treatment. A period may be any time interval.
- Alive at beginning of period. The first entry in this column indicates the initial number of subjects; in Table 2, $L_1 = 130$. Each entry thereafter is obtained by subtracting from the preceding number of subjects the total of those who are no longer in the program; in Table 2, $L_2 = L_1 - (D_1 + U_1 + W_1) = 130 - (40 + 4 + 10) = 76$.
- Died during period. This column indicates the number of subjects that died during the period.
- Lost during period. This column indicates the number of subjects whose survival status became unknown during the period.
- Withdrawn alive during period. This column indicates the number of living subjects withdrawn from the study during the period.

For the value of $i = 1, 2, \ldots, K$, the subroutine computes the following information:

1. Effective number exposed to risk of dying during period:

$$E_i = L_i - (U_i + W_i)/2 \qquad (1)$$

2. Proportion dying during period:

$$Q_i = \frac{D_i}{E_i} \qquad (2)$$

3. Proportion surviving during period:

$$P_i = 1 - Q_i \qquad (3)$$

4. i^{th} period survival rate:

$$R_i = \prod_{j=1}^{i} P_i \qquad (4)$$

5. Standard error of survival rate:

$$s_i = R_i \sqrt{\sum_{j=1}^{i} \frac{Q_j}{E_j - D_j}} \qquad (5)$$

Subroutines MPRC and DMPRC

These subroutines permute the rows or columns of a given m by n matrix A according to a transposition vector ITRA = $(t_1, \ldots, t_s)$ or its inverse. (See the general discussion under "Permutations" for definitions and notation.)

1. Mathematical background

Permuting the rows or columns of A according to the transposition vector ITRA means applying the permutation $(1, t_1), \ldots, (s, t_s)$ to the rows or columns of A, while permuting according to $ITRA^{-1}$ means applying the permutation $(s, t_s), \ldots, (1, t_1)$.

2. Programming considerations

If the columns of A are to be permuted, the input parameter IROCO must be nonzero, and s = n; if the rows are to be permuted, IROCO must be zero, and s = m. Similarly, if the input parameter INV is nonzero, the rows or columns of A are permuted according to ITRA; while if INV is zero, the rows or columns of A are permuted according to $ITRA^{-1}$.

If m and n are not both positive, or if ITRA is not a transposition vector on $S = \{1, \ldots, s\}$, the subroutines are prematurely terminated and the error parameter IER is set to -1 or 1, respectively. If there is no error, IER is set to zero.

The matrix A is assumed to be stored columnwise, and the permutation of the rows or columns of A is performed in s steps. At the i^{th} step, if the permutation is according to $ITRA^{-1}$, rows or columns i and s_i are interchanged; if the permutation is according to ITRA, rows or columns $s - i + 1$ and t_{s-i+1} are interchanged.

Subroutines SINV and DSINV

These subroutines invert a given symmetric positive definite matrix, using factorization by subroutines MFSD and DMFSD.

1. Mathematical background

Given an n by n symmetric positive definite matrix A, an upper triangular matrix $R=(r_{ij})$ exists such that

$$A = R^T R$$

Then $A^{-1} = R^{-1}(R^{-1})^T$. The elements $\bar{r}_{ik}$ of R^{-1} are computed using the following recursive formulas:

$$\bar{r}_{ik} = -(1/r_{ii}) \left(\sum_{m=i+1}^{k} r_{im} \bar{r}_{mk} \right) \qquad i < k$$

$$\bar{r}_{ik} = 1/r_{ii} \qquad i = k$$

$$\bar{r}_{ik} = 0 \qquad i > k$$

2. Programming considerations

The given symmetric positive definite matrix A is stored columnwise in compressed form, that is, only the upper triangular part in $\frac{n(n+1)}{2}$ successive storage locations.

Subroutine MFSD (DMFSD), which is called internally, returns the elements r_{ik} ($i \leq k$) of the upper triangular matrix R in the storage locations of A. The inverse (upper) triangular matrix R^{-1} and at last the resultant upper triangular part of the inverse matrix A^{-1} are calculated and stored columnwise in the same storage locations.

If any calculated radicand r_{kk}^2 ($k = 1, 2, 3, \ldots, N$) is not positive, further calculation is bypassed, and the error parameter IER is set to -1. This means that matrix A is not positive definite, possibly due to roundoff errors. IER is also set to -1 if the input parameter N is less than one.

Let all radicands be positive, and let r_{kk}^2 be the first radicand which is no longer greater than the internal tolerance $TOL = |EPS \cdot a_{kk}|$. The subroutine gives the warning IER = k-1; however, calculation is continued. The warning indicates that there may be loss of significance at factorization step k due to loss of significant digits in the calculation of r_{kk}^2.

Subroutines GELG and DGELG

These subroutines solve a system of general simultaneous linear equations by Gauss elimination. Consider the system of general simultaneous linear equations:

$$A * X = R \tag{1}$$

with an m by m coefficient matrix A and an m by n right-hand side matrix R both stored columnwise. Solution is done by means of Gauss elimination with complete pivoting. If matrix R is the identity matrix, solution X is the inverse of matrix A. The solution X is generated in matrix R. Thus, the computation of the solution requires no additional storage requirements.

Explicitly, the given system (1) is of the form:

$$\begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1m} \\ a_{21} & a_{22} & \cdots & a_{2m} \\ \cdots & \cdots & \cdots & \cdots \\ a_{m1} & a_{m2} & \cdots & a_{mm} \end{pmatrix} * \begin{pmatrix} x_{11} & x_{12} & \cdots & x_{1n} \\ x_{21} & x_{22} & \cdots & x_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ x_{m1} & x_{m2} & \cdots & x_{mn} \end{pmatrix}$$

$$= \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1n} \\ r_{21} & r_{22} & \cdots & r_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ r_{m1} & r_{m2} & \cdots & r_{mn} \end{pmatrix} \tag{2}$$

The first step is to search the whole matrix A for the element of greatest absolute value, say a_{ij}, and to select it as first pivot ($p = a_{ij}$). With a_{ij}, generate the internal absolute tolerance for testing loss of significance in the following way:

$$tol = |a_{ij}| \cdot \varepsilon$$

with a given relative tolerance ε.

Suppose that pivot a_{ij} is equal to a_{11}. If it is not, interchange the first rows of matrices A and R with the i^{th}, and the first column of matrix A with the j^{th}, and save column interchange information by storing the difference (j-1) of pivot column index j and step counter k = 1 [interchanging column 1 with column j means interchanging of variables x_{11} with x_{1j} (l = 1, 2, ..., n)].

Now transform the elements of pivot rows in matrices A and R by multiplying with 1/p, and the other elements by adding $-a_{\nu 1}$ times the new first rows of these two matrices to the other ν rows, thus getting:

$$a_{11}^{(1)} = + \frac{a_{11}}{p} \quad (l = 2, 3, \ldots, m) \tag{4}$$

$$r_{11}^{(1)} = + \frac{r_{11}}{p} \quad (l = 1, 2, \ldots, n) \tag{5}$$

$$a_{\nu l}^{(1)} = a_{\nu l} - a_{\nu 1} \cdot a_{11}^{(1)} \quad \begin{matrix} (l = 2, 3, \ldots, m; \\ \nu = 2, 3, \ldots, m) \end{matrix} \tag{6}$$

$$r_{\nu l}^{(1)} = r_{\nu l} - a_{\nu 1} \cdot r_{11}^{(1)} \quad \begin{matrix} (l = 1, 2, \ldots, n; \\ \nu = 2, 3, \ldots, m) \end{matrix} \tag{7}$$

If column interchange information is saved in the first position of the main diagonal, the result of the first step is the two matrices:

$$A^{(1)} = \begin{pmatrix} (j-1) & a_{12}^{(1)} & a_{13}^{(1)} & \cdots & a_{1m}^{(1)} \\ 0 & a_{22}^{(1)} & a_{23}^{(1)} & \cdots & a_{2m}^{(1)} \\ 0 & a_{32}^{(1)} & a_{33}^{(1)} & \cdots & a_{3m}^{(1)} \\ & \cdots & \cdots & \cdots & \\ 0 & a_{m2}^{(1)} & a_{m3}^{(1)} & \cdots & a_{mm}^{(1)} \end{pmatrix} \text{ and}$$

$$R^{(1)} = \begin{pmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \cdots & r_{1n}^{(1)} \\ r_{21}^{(1)} & r_{22}^{(1)} & \cdots & r_{2n}^{(1)} \\ \cdots & \cdots & \cdots & \cdots \\ r_{m1}^{(1)} & r_{m2}^{(1)} & \cdots & r_{mn}^{(1)} \end{pmatrix}$$

Now repeat this procedure m-2 times, starting at each step with the matrix $A^{(k)}$ of the step before

without first k rows and first k columns, and the matrix $R^{(k)}$ without first k rows. The total result after m-1 steps is the matrices:

$$A^{(m-1)} = \begin{pmatrix} (j_1\text{-}1) & a_{12}^{(1)} & a_{13}^{(1)} & \dots & a_{1m}^{(1)} \\ 0 & (j_2\text{-}2) & a_{23}^{(2)} & \dots & a_{2m}^{(2)} \\ 0 & 0 & (j_3\text{-}3) & \dots & a_{3m}^{(3)} \\ \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & & (j_m\text{-}m) \end{pmatrix} \quad \text{and}$$

$$R^{(m-1)} = \begin{pmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \dots & r_{1n}^{(1)} \\ r_{21}^{(2)} & r_{22}^{(2)} & \dots & r_{2n}^{(2)} \\ r_{31}^{(3)} & r_{32}^{(3)} & \dots & r_{3n}^{(3)} \\ \dots & \dots & \dots & \dots \\ r_{m1}^{(m)} & r_{m2}^{(m)} & \dots & r_{mn}^{(m)} \end{pmatrix}$$

Now work backward and set:

$$\left.\begin{aligned} r_{m-1,l}^{(m)} &= r_{m-1,l}^{(m-1)} - a_{m-1,m}^{(m-1)} \cdot r_{m,l}^{(m)} \quad (l = 1,2,\dots,n) \\ r_{m-2,l}^{(m)} &= r_{m-2,l}^{(m-2)} - a_{m-2,m-1}^{(m-2)} \cdot r_{m-1,l}^{(m)} \\ &\quad - a_{m-2,m}^{(m-2)} \cdot r_{m,l}^{(m)} \quad (l = 1,2,\dots,n) \\ &\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots \\ r_{1,l}^{(m)} &= r_{1l}^{(1)} - a_{12}^{(1)} \cdot r_{2l}^{(m)} - a_{13}^{(1)} \cdot r_{3l}^{(m)} \\ &\quad - \dots - a_{1m}^{(1)} \cdot r_{ml}^{(m)} \quad (l = 1,2,\dots,n) \end{aligned}\right\} \quad (8)$$

After each step of back substitution, rows of solution matrix $X = R^{(m)}$ have to be back-interchanged according to interchange information in the corresponding main diagonal element of matrix $A^{(m-1)}$, in order to get the correct sequence of right-hand side column elements $r_{\nu l}^{(m)}$ corresponding to the sequence of left-hand side column elements $a_{j_\nu}^{(j)}$.

The only case in which the above procedure can fail to give a solution occurs when at any step all elements of the rest-matrix of $A^{(k)}$ become zero, and no pivot element can be found. In this case the procedure is bypassed, and the error message ier = -1 is given. Actually, because of rounding errors, a further check of the absolute values of pivot elements is performed by the procedure. If at elimination step k this absolute value becomes less than tol (see equation 3), it is likely that matrix A is singular too. But as this is not necessarily the case, and as this test depends highly on the choice of the relative tolerance ε+ , the procedure gives only the warning ier = k-1, indicating that there is a possible loss of significance in the results computed by the algorithm++. In case of a well scaled matrix A and an appropriate choice of the relative tolerance, warning ier = k-1 may be interpreted to mean that matrix A has the rank k-1. If there is only one equation to solve (m=1), the test on loss of significance is suppressed.

+For subroutine GELG, a relative tolerance ϵ between 10^{-6} and 10^{-7} is suggested; and for subroutine DGELG, between 10^{-14} and 10^{-16}.

++For example, $\epsilon = 10^{-5}$ and warning ier = 3 mean that there is a possible loss of about five or more significant digits in the initial values of elimination step 4, and that matrix A seems to have the rank 3.

Subroutine RSLMC

This subroutine computes an approximate solution to a system of linear equations when the coefficient matrix has been factored into a product of two triangular matrices.

1. Mathematical background

Consider a system of linear equations

$$Ax = b \tag{1}$$

having a nonsingular coefficient matrix A. There exists a permutation P such that PA = LU, where L is lower triangular with unit diagonal, and U is upper triangular. Putting c = Pb we see that (1) is equivalent to the system

$$\begin{aligned} Ux &= y \\ Ly &= c \end{aligned} \tag{2}$$

Let $x^{(p)}$ be a trial solution of the given system. It can be improved by means of the iterative process

$$\begin{aligned} r^{(p)} &= b - Ax^{(p)} \\ Ad^{(p)} &= r^{(p)} \\ x^{(p+1)} &= x^{(p)} + d^{(p)} \end{aligned} \tag{3}$$

where the correction vector $d^{(p)}$ is computed using L and U as in (2).

If A is not too ill-conditioned, this process will give a satisfactory solution, provided that $r^{(p)}$, the residual vector, is computed with sufficient accuracy.

2. Programming considerations

This routine may be used to solve a nonsingular system of linear equations whose coefficient matrix has been factored by means of subroutine FACTR.

Let $\epsilon > 0$ be a relative precision parameter (input to RSLMC). In the following discussion we use the notation $\|x\| = \Sigma |x_i|$. The process (3) is applied to the system (1) starting with $x^{(0)} = 0$, and is stopped when one of the following situations occurs:

a. *IER = 0. The components of the correction* vector $d^{(p)}$ satisfy the inequalities

$$\left| d_i^{(p)} \right| \leq \epsilon \left| x_i^{(p)} \right| \qquad i = 1, 2, \ldots, n. \tag{4}$$

Then $x = x^{(p)}$ is returned as the solution.

b. Assume that $p > 1$, for some i the inequality (4) fails and

$$\left\| d^{(k)} \right\| \leq \frac{1}{2} \left\| d^{(k-1)} \right\| \qquad k = 1, 2, \ldots, p-1$$

$$\left\| d^{(p)} \right\| > \frac{1}{2} \left\| d^{(p-1)} \right\|$$

Then:

IER = 1 if $\left\| d^{(p)} \right\| \leq \epsilon \left\| x^{(p)} \right\|$,

IER = 2 if $\left\| d^{(p)} \right\| > \epsilon \left\| x^{(p)} \right\|$.

c. IER = 3. $\left\| d^{(1)} \right\| > \frac{1}{2} \left\| d^{(0)} \right\|$. In this case the trial solution is too far from the exact solution and the process cannot converge. In general this happens when A is badly ill-conditioned.

IER = 4. U is singular.

In all cases $x = x^{(p)}$ is returned.

Note: To obtain accuracy in the computation of the residual vector, each component is computed in double-precision arithmetic.

Subroutine FACTR

This subroutine determines a decomposition of a real nonsingular matrix as a product of a lower triangular matrix with unit diagonal and an upper triangular matrix.

1. Mathematical background

Let A be a real nonsingular matrix of order n. In general, A can be factored into a product of the form A = L U, where L is lower triangular with unit diagonal and U is upper triangular.

The elements of L and U may be computed recursively as follows:

$$\bar{a}_{ip} = a_{ip} - \sum_{k=1}^{p-1} l_{ik} u_{kp} \qquad i=p, p+1, \ldots, n$$

$$l_{ip} = \bar{a}_{ip} / \bar{a}_{pp} \qquad i=p, p+1, \ldots, n$$

$$u_{pp} = \bar{a}_{pp}$$

$$u_{pj} = a_{pj} - \sum_{k=1}^{p-1} l_{pk} u_{kj} \qquad j=p+1, p+2, \ldots, n$$

Using these formulas for $p = 1, 2, \ldots, n$, the decomposition can be carried out in n stages.

2. Programming considerations

Even if A is nonsingular and well-conditioned, the above process can fail when a leading principal submatrix of A is singular; furthermore, the process is numerically unstable whenever a leading principal submatrix is ill-conditioned.

In order to avoid these inconveniences, a technique of partial pivoting combined with an equilibration of the matrix has been built into the algorithm.

Initially, the maximum norm of each row vector is computed:

$$N_p = \max_j \left| a_{pj} \right| \qquad p=1, 2, \ldots, n$$

If any $N_p = 0$, the error parameter IER is set to 3 and further calculations are bypassed. Otherwise the reciprocals $1/N_p$ are computed and stored in the vector PER.

Then, assuming that the first p-1 columns of L and p-1 rows of U have been computed, the p^{th} stage of the factorization process is:

a. Computation of the $\bar{a}_{ip}$.

$$\bar{a}_{ip} = a_{ip} - \sum_{k=1}^{p-1} l_{ik} u_{kp} \qquad i=p, p+1, \ldots, n$$

Each term $\bar{a}_{ip}$ replaces the corresponding term of A in storage.

b. Equilibrated partial pivoting.

Let m be the smallest row subscript such that

$$(1/N_p) \left| \bar{a}_{mp} \right| = \max_{i \geq p} \left\{ (1/N_i) \left| \bar{a}_{ip} \right| \right\}$$

If $\bar{a}_{mp} = 0$, the error message IER = 3 is given and further calculations are bypassed. If $\bar{a}_{mp} \neq 0$, the m^{th} and p^{th} rows of A are interchanged, PER(p) is moved to PER(m), and the number m is stored in PER(p). Thus the first p positions of PER contain the information on the permutations needed so far in the form of a transposition vector.

c. Computation of the p^{th} column of L.

$$l_{ip} = \bar{a}_{ip} / \bar{a}_{pp} \qquad i=p+1, p+2, \ldots, n$$

These terms of L replace the corresponding terms of A in storage. The diagonal terms of L, which are all equal to 1, are not stored.

d. Computation of the p^{th} row of U

$$u_{pp} = \bar{a}_{pp}$$

$$u_{pj} = a_{pj} - \sum_{k=1}^{p-1} l_{pk} u_{kj} \qquad j=p+1, \ldots, n$$

These terms replace the corresponding terms of A.

Note: Double-precision arithmetic is used to compute the inner products needed in steps (1) and (4).

Subroutines MFGR and DMFGR

The following calculations are performed for a general rectangular matrix:

1. Determine rank and linearly independent rows and columns of a given matrix.
2. Express a submatrix of maximal rank as product of triangular factors.
3. Express nonbasic rows in terms of basic ones.
4. Express basic variables in terms of free ones.

1. Theoretical background

Calculation (1) is most critical. It is not claimed that MFGR will give the correct rank in all cases, due to the intrinsic difficulty caused by performing calculations with a finite number of digits.

The rank is determined using the standard Gaussian elimination technique with complete pivoting. This implies that the rows and columns of the given m by n matrix A are interchanged at each elimination step if necessary. The interchange information is recorded in two integer permutation vectors IROW and ICOL:

The i^{th} $\left\{\begin{matrix}\text{row}\\\text{column}\end{matrix}\right\}$ of the interchanged matrix corresponds

to the $\left\{\begin{matrix}\text{IROW(I)}^{th}\ \text{row}\\\text{ICOL(I)}^{th}\ \text{column}\end{matrix}\right\}$ in the original matrix A.

Initially IROW(J) = J and ICOL(J) = J.

The notation A^i is used for the interchanged matrix implied at the i^{th} elimination step.†

a. First elimination step

Let a_{jk} be the absolutely greatest element of matrix A, which is found first in a columnwise scan. The internal tolerance TOL is set equal to $|EPS \cdot a_{jk}|$.

If $|a_{jk}| \leq TOL$, further calculation is bypassed. Otherwise rows 1 and j and columns 1 and k of matrix A are interchanged, giving A^1 . The same interchanges must be applied to IROW, interpreted as column vector, and to ICOL, interpreted as row vector.

A^1 is uniquely expressed as product $L^1 \cdot D^1 \cdot U^1$ by imposing the following conditions:

(I) U^1 is the n by n identity matrix except for the first row.

† Superscripts do not mean powers. They merely indicate the number of the elimination step at which the result is obtained.

(II) L^1 is the m by m identity matrix except for the first column. The first diagonal element has a value of one.

(III) D^1 is an m by n matrix with first diagonal element equal to one, while all remaining elements of the first row and column are equal to zero.

Partitioning of matrices A^1, L^1, D^1, U^1 leads to:

$$\begin{pmatrix} a_{11}^1 & A_{12}^1 \\ A_{21}^1 & A_{22}^1 \end{pmatrix} = \begin{pmatrix} 1 & \emptyset \\ L_{21}^1 & I \end{pmatrix} \begin{pmatrix} 1 & \emptyset \\ \emptyset & D_{22}^1 \end{pmatrix} \begin{pmatrix} u_{11}^1 & U_{12}^1 \\ \emptyset & I \end{pmatrix}^{\dagger}$$

or explicitly:

$$a_{11}^1 = u_{11}^1$$

$$A_{12}^1 = U_{12}^1$$

$$A_{21}^1 = L_{21}^1 \cdot u_{11}^1$$

$$A_{22}^1 = L_{21}^1 U_{12}^1 + D_{22}^1$$

This means:

(I) The elements of the first row of U^1 are

$$u_{11}^1 = a_{11}^1,\ u_{12}^1 = a_{12}^1, \ldots,\ u_{1n}^1 = a_{1n}^1$$

(II) The elements of the first column of L^1 are

$$l_{11}^1 = 1,\ l_{21}^1 = a_{21}^1/a_{11}, \ldots,\ l_{m1}^1 = a_{m1}^1/a_{11}^1$$

(III) The elements of submatrix D_{22}^1 of D^1 are

$$d_{ik}^1 = a_{ik}^1 - l_{i1}^1 \cdot u_{1k}^1 = a_{ik}^1 - \frac{a_{i1}^1 \quad a_{1k}^1}{a_{11}^1};$$

$i = 2, \ldots, m$
$k = 2, \ldots, n$

---

† Capital letters are used as notation for matrices or vectors throughout. $\emptyset$ means zero matrix, I means identity matrix; dimensions are implied by compatibility.

Note that it is possible to record all nontrivial entries of L^1, D^1, U^1 in the storage locations occupied by the original A, storing only:

$$\begin{pmatrix} u_{11}^1 & U_{12}^1 \\ L_{21}^1 & D_{22}^1 \end{pmatrix}$$

b. Second elimination step

Let d_{jk}^1, $j \geqq 2$, $k \geqq 2$ be the absolutely largest element of D_{22}^1. If $|d_{jk}^1| \leqq TOL$, D_{22}^1 is interpreted as being the zero matrix.

If D_{22}^1 is not zero in the above sense, it may be decomposed analogously. In the compact scheme,

$$\begin{pmatrix} u_{11}^1 & U_{12}^1 \\ L_{21}^1 & D_{22}^1 \end{pmatrix}$$

rows 2 and j and columns 2 and k are interchanged, obtaining:

$$\begin{pmatrix} u_{11}^1 & U_{12}^2 \\ L_{21}^2 & D_{22}^2 \end{pmatrix}$$

The same interchanges must be performed with IROW (interpreted as column vector), with ICOL (interpreted as row vector), and with A^1 giving result A^2:

$$A^2 = \begin{pmatrix} 1 & \emptyset \\ L_{21}^2 & I \end{pmatrix} \begin{pmatrix} 1 & \emptyset \\ \emptyset & D_{22}^2 \end{pmatrix} \begin{pmatrix} u_{11}^1 & U_{12}^2 \\ \emptyset & I \end{pmatrix}$$

Now D_{22}^2 may be expressed uniquely as the product of the form LDU, imposing conditions I, II, III. The result is:

$$D_{22}^2 = \begin{pmatrix} 1 & \emptyset \\ L_{32}^2 & I \end{pmatrix} \begin{pmatrix} 1 & \emptyset \\ \emptyset & D_{33}^2 \end{pmatrix} \begin{pmatrix} u_{22}^2 & U_{23}^2 \\ \emptyset & I \end{pmatrix}$$

It is easily seen that $A^2 = L^2 D^2 U^2$,

with:
$$L^2 = \begin{pmatrix} 1 & \emptyset & \emptyset \\ l_{21}^2 & 1 & \emptyset \\ L_{31}^2 & L_{32}^2 & I \end{pmatrix}$$

$$D^2 = \begin{pmatrix} 1 & 0 & \emptyset \\ 0 & 1 & \emptyset \\ \emptyset & \emptyset & D^2_{33} \end{pmatrix}$$

$$U^2 = \begin{pmatrix} u^1_{11} & u^2_{12} & U^2_{13} \\ 0 & u^2_{22} & U^2_{23} \\ \emptyset & \emptyset & I \end{pmatrix}$$

where $L^2_{21} = \begin{pmatrix} l^2_{21} \\ L^2_{31} \end{pmatrix}$, $U^2_{12} = (u^2_{12}, U^2_{13})$

c. Final result of elimination process

At the next elimination step D^2_{33} is factorized, and so on. Now assume that finally $D^r_{r+1,\ r+1}$ equals zero in the sense that all its elements are absolutely less than TOL. This means that A has the rank r, and the end result is the factorization $A^r = L^r D^r U^r$:

$$A^r = \begin{pmatrix} 1 & 0 & \cdots & 0 & \emptyset \\ l^2_{21} & 1 & & 0 & \emptyset \\ \vdots & \vdots & & \vdots & \vdots \\ l^r_{r1} & l^r_{r2} & \cdots & 1 & \emptyset \\ L^r_{r+1,\ 1} & L_{r+1,\ 2} & \cdots & L^r_{r+1,\ r} & I \end{pmatrix} \cdot$$

$$\begin{pmatrix} 1 & 0 \cdots 0 & \emptyset \\ 0 & 1 \cdots 0 & \emptyset \\ \vdots & \vdots & \vdots \\ 0 & 0 \cdots 1 & \emptyset \\ \emptyset & \emptyset \cdots \emptyset & D^r_{r+1,\ r+1} \end{pmatrix} \cdot$$

$$\begin{pmatrix} u^1_{11} & u^2_{12} & \cdots & u^r_{1r} & U^r_{1,\ r+1} \\ 0 & u^2_{22} & \cdots & u^r_{2r} & U^r_{2,\ r+1} \\ \vdots & & & \vdots & \vdots \\ 0 & 0 & \cdots & u^r_{rr} & U^r_{r,\ r+1} \\ \emptyset & \emptyset & \cdots & \emptyset & I \end{pmatrix}$$

Neglecting the small elements in $D^r_{r+1,\ r+1}$ this may be written more compactly as:

$$A^r = \begin{pmatrix} L \\ LR \end{pmatrix} \begin{pmatrix} U, UR \end{pmatrix}$$

with: $$L = \begin{pmatrix} 1 & 0 \cdots 0 \\ l^2_{21} & 1 \quad 0 \\ \vdots & \vdots \\ l^r_{r1} & l^r_{r2} \cdots 1 \end{pmatrix}$$

$$LR = (L^r_{r+1,\ 1},\ L^r_{r+1,\ 2}, \ldots,\ L^r_{r+1,\ r})$$

$$U = \begin{pmatrix} u^1_{11} & u^2_{12} \cdots u^r_{1r} \\ 0 & u^2_{22} \quad \vdots \\ \vdots & \quad\ddots\ \vdots \\ 0 & 0 \quad \cdots u^r_{rr} \end{pmatrix}$$

$$UR = \begin{pmatrix} U^r_{1,\ r+1} \\ U^r_{2,\ r+1} \\ \vdots \\ U^r_{r,\ r+1} \end{pmatrix}$$

L is of dimension r by r and unit lower triangular.
U is of dimension r by r and upper triangular.
LR is of dimension m - r by r; if the given matrix A is row regular (that is, m = r), LR is absent in the final factorization.
UR is of dimension r by n-r; if the given matrix A is column regular (that is, n = r), UR is absent in the final factorization.

d. Further calculations performed

The problem of matrix factorization arises in connection with the solution of systems of equations AX=R. Three different cases must be distinguished:

(1) $r = m = n$
A is nonsingular, and AX=R has a uniquely determined solution.

(2) $r < m$
A is not row regular; solutions of AX = R exist only if the linear combinations among the rows of A are also valid among the rows of R.

(3) $r < n$

A is not column regular; $AX = \emptyset$ has nontrivial solutions.

The cases (2) and (3) may occur combined.

The solution, if it exists, is uniquely determined if r = n; otherwise it contains n - r free parameters. It is quite natural to ask for the linear combinations among the rows of given matrix A and for the linear forms expressing basic variables in terms of free ones. Therefore, instead of LR and UR, matrices C and H are returned, containing linear combinations and homogeneous solutions respectively.

Observe carefully that the calculated factorization belongs to the interchanged matrix A^r. Therefore $A^r X^r = R^r$ is dealt with instead of AX = R, where $\begin{Bmatrix} X^r \\ R^r \end{Bmatrix}$ is obtained from $\begin{Bmatrix} X \\ R \end{Bmatrix}$ using the $\begin{Bmatrix} \text{ICOL(I)}^{th} \\ \text{IROW(J)}^{th} \end{Bmatrix}$ element of $\begin{Bmatrix} X \\ R \end{Bmatrix}$ as $\begin{Bmatrix} I^{th} \\ J^{th} \end{Bmatrix}$ element of $\left\{ \begin{matrix} X^r \\ R^r \end{matrix} \quad ; \quad \begin{matrix} I = 1,\ldots, n \\ J = 1,\ldots, m \end{matrix} \right\}$.

Let X^r, R^r be partitioned into $\begin{pmatrix} X_1 \\ X_2 \end{pmatrix}$ and $\begin{pmatrix} R_1 \\ R_2 \end{pmatrix}$.

Then:

$$\begin{pmatrix} L \\ LR \end{pmatrix} (U,\ UR) \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} = \begin{pmatrix} R_1 \\ R_2 \end{pmatrix}$$

or explicitly:

$$L \cdot U \cdot X_1 + L \cdot UR \cdot X_2 = R_1$$
$$LR \cdot U \cdot X_1 + LR \cdot UR \cdot X_2 = R_2$$

Since L and U are nonsingular, this implies:

$$X_1 = U^{-1} \cdot L^{-1} \cdot R_1 - U^{-1} \cdot UR \cdot X_2$$
$$LR \cdot L^{-1} R_1 = R_2$$

For the convenience of the user, LR is replaced by $LR \cdot L^{-1} = C$; UR is replaced by $-U^{-1}\ UR = H$, while L and U remain untouched. Consistency requires that $R_2 = CR_1$, and homogeneous solutions are given by $X_1 = HX_2$. In case of a consistent system of equations $A^r X^r = R^r$, the general solution is $X^r = \begin{pmatrix} X_1 \\ X_2 \end{pmatrix}$ with $X_1 = U^{-1} L^{-1} R_1 + HX_2$, while the values of the free variables contained in X_2 may be chosen arbitrarily.

2. Format of Results

Subroutine MFGR returns matrices L, U, C, H, D in the storage area originally occupied by the input matrix A in the compact scheme shown in Figure 9.

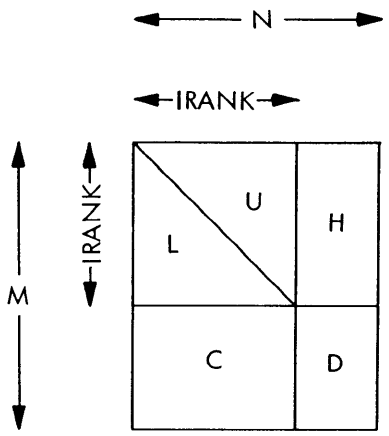

Figure 9. Format scheme (MFGR)

3. Numerical examples

a. Let $A = \begin{pmatrix} 5 & 5 \\ 1 & 1 \end{pmatrix}$, EPS = 1.0E-7

Subroutine MFGR returns as results:

L = (1), U = (5), C = (0.2), H = (-1.0)

combined in the compact scheme:

$$\begin{pmatrix} 5.0 & -1.0 \\ 0.2 & 0.6E\text{-}7 \end{pmatrix} = \left(\begin{array}{c|c} U & H \\ \hline C & D \end{array}\right)$$

IRANK = 1
ICOL = (1, 2)
IROW = (1, 2)

The value 0.6E-7 is obtained instead of the correct value 0, due to roundoff errors.

This example shows that a proper choice of EPS is somewhat greater than 10^{-d}, if d is the number of significant digits in the representation of floating point numbers.

With EPS = 0, MFGR would give the incorrect value of 2 for the rank. The choice EPS = 0 may well result in an incorrect value less than the correct rank, as shown by the following.

If the element a_{22} is slightly decreased, resulting in a matrix A of correct rank equal to 2, then subroutine MFGR gives an incorrect value of 1 for the rank with any choice of the relative tolerance EPS, even with EPS = 0.

b. Let $A = \begin{pmatrix} 1 & 3 & 5 \\ 1 & 3 & 5 \\ 1 & 3 & 1 \\ 1 & 1 & 3 \\ 1 & 3 & 5 \end{pmatrix}$, EPS = 1.0E-7

Subroutine MFGR returns as results:

$$L = \begin{pmatrix} 1 & 0 & 0 \\ 0.2 & 1 & 0 \\ 0.6 & -0.3333330 & 1 \end{pmatrix}$$

$$U = \begin{pmatrix} 5 & 3 & 1 \\ 0 & 2.4 & 0.8 \\ 0 & 0 & 0.6666664 \end{pmatrix}$$

$$C = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}$$

combined in the compact scheme:

$$\begin{pmatrix} 5 & 3 & 1 \\ 0.2 & 2.4 & 0.8 \\ 0.6 & -0.3333330 & 0.6666664 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} = \begin{pmatrix} U \\ L \\ C \end{pmatrix}$$

IRANK = 3
ICOL = (3, 2, 1)
IROW = (1, 3, 4, 2, 5)

Linear dependencies among rows:

row (2) = 1 · row (1) + 0 · row (3) + 0 · row (4)
row (5) = 1 · row (1) + 0 · row (3) + 0 · row (4)

$$L \cdot U = \begin{pmatrix} a_{13} & a_{12} & a_{11} \\ a_{33} & a_{32} & a_{31} \\ a_{43} & a_{42} & a_{41} \end{pmatrix} = \begin{pmatrix} 5 & 3 & 1 \\ 1 & 3 & 1 \\ 3 & 1 & 1 \end{pmatrix}$$

c. Let $A = \begin{pmatrix} 1 & 1 & 3 & 3 & 1 \\ 1 & 1 & 3 & 5 & 3 \\ 1 & 3 & 1 & 5 & 5 \end{pmatrix}$, EPS = 1.0E-7

Subroutine MFGR returns as results:

$$L = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0.6 & 0.2 & 1 \end{pmatrix}, \quad U = \begin{pmatrix} 5 & 1 & 3 \\ 0 & 2 & -2 \\ 0 & 0 & 1.6 \end{pmatrix}$$

$$H = \begin{pmatrix} -0.48E-7 & -0.9999992 \\ -0.2499999 & -0.2500009 \\ -0.2499999 & 0.7499991 \end{pmatrix}$$

combined in the compact scheme:

$$\begin{pmatrix} 5 & 1 & 3 & -0.48E-7 & -0.9999992 \\ 1 & 2 & -2 & -0.2499999 & -0.2500009 \\ 0.6 & 0.2 & 1.6 & -0.2499999 & 0.7499991 \end{pmatrix} = \begin{pmatrix} U & H \\ L & \end{pmatrix}$$

IRANK = 3
ICOL = (4, 2, 3, 1, 5)
IROW = (2, 3, 1)

Homogeneous solution of A · X = 0

$$x_4 = -0.48E-7 \cdot x_1 - 0.9999992 \cdot x_5$$
$$x_2 = -0.2499999 \cdot x_1 - 0.2500009 \cdot x_5$$
$$x_3 = -0.2499999 \cdot x_1 + 0.7499991 \cdot x_5$$

x_1 and x_5 may be chosen arbitrarily.

$$L \cdot U = \begin{pmatrix} a_{24} & a_{22} & a_{23} \\ a_{34} & a_{32} & a_{33} \\ a_{14} & a_{12} & a_{13} \end{pmatrix} = \begin{pmatrix} 5 & 1 & 3 \\ 5 & 3 & 1 \\ 3 & 1 & 3 \end{pmatrix}$$

Subroutines GELS and DGELS

These subroutines solve a system of simultaneous linear equations with symmetric coefficient matrix by Gauss elimination. Consider the system of simultaneous linear equations

$$A * X = R \qquad (1)$$

with symmetric m by m coefficient matrix, the upper triangular part of which is stored by column in m * (m+1)/2 successive storage locations, and an m by n right-hand side matrix R stored by column in m * n successive storage locations. Solution is done by Gauss elimination with pivoting in the main diagonal of matrix A. If matrix R is the identity matrix, solution X is the inverse of matrix A. Solution matrix X is placed in positions of the right-hand side matrix R and is stored by column also. Thus, the computation of the solution requires no extra m by n array of storage. Only an auxiliary storage array named AUX with (m-1) storage locations is necessary.

Explicitly, the given system (1) is of the form:+

$$\begin{pmatrix} \underline{a_{11}} & \underline{a_{12}} & \underline{a_{13}} & \cdots & \underline{a_{1m}} \\ a_{21} & \underline{a_{22}} & \underline{a_{23}} & \cdots & \underline{a_{2m}} \\ a_{31} & a_{32} & \underline{a_{33}} & \cdots & \underline{a_{3m}} \\ a_{m1} & a_{m2} & a_{m3} & \cdots & \underline{a_{mm}} \end{pmatrix} * \begin{pmatrix} x_{11} & x_{12} & \cdots & x_{1n} \\ x_{21} & x_{22} & \cdots & x_{2n} \\ x_{31} & x_{32} & \cdots & x_{3n} \\ x_{m1} & x_{m2} & \cdots & x_{mn} \end{pmatrix}$$

$$= \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1n} \\ r_{21} & r_{22} & \cdots & r_{2n} \\ r_{31} & r_{32} & \cdots & r_{3n} \\ r_{m1} & r_{m2} & \cdots & r_{mn} \end{pmatrix} \qquad (2)$$

The first step is to search the main diagonal of matrix A for the element of greatest absolute value, say a_{jj}, and to select it as first pivot ($p = a_{jj}$). The reason for pivoting only in the main diagonal of A is that rest-matrices of $A^{(k)}$

+Note that subroutines GELS and DGELS require only the upper triangular part of matrix A; that is, the elements a_{11}; a_{12}, a_{22}; a_{13}, a_{23}, a_{33};...; a_{1m}, a_{2m},..., a_{mm}. These elements are underlined in formula (2).

$(k = 1,2,\ldots,m-1)$ must remain symmetrical during the whole algorithm. With a_{jj}, generate the internal absolute tolerance for testing usefulness of the symmetric algorithm in the following way:

$$\text{tol} = |a_{jj}| \cdot \varepsilon \qquad (3)$$

with a given relative tolerance ε .

Suppose that pivot element a_{jj} is equal to a_{11}. If it is not, interchange the first rows of matrices A and R with the j^{th} and the first column of matrix A with the j^{th}, and save column interchange information by storing the difference (j-1) of pivot column index j and step counter k = 1 [interchanging column 1 with column j means interchanging variables x_{11} with x_{1j} $(1 = 1,2,\ldots,n)$].

Now transform the elements of pivot rows in matrices A and R by division with p, and the other elements by adding $-a_{\nu 1}$ times the new first rows of these two matrices to the other ν rows, thus getting:++

$$a_{11}^{(1)} = \frac{a_{11}}{p} \quad (1 = 1,2,\ldots,m) \qquad (4)$$

$$r_{11}^{(1)} = \frac{r_{11}}{p} \quad (1 = 1,2,\ldots,n) \qquad (5)$$

$$a_{\nu 1}^{(1)} = a_{\nu 1} - a_{\nu 1} \cdot a_{11}^{(1)} \quad \begin{matrix}(1 = 2,3,\ldots,m,\\ \nu = 2,3,\ldots,m)\end{matrix} \qquad (6)$$

$$r_{\nu 1}^{(1)} = r_{\nu 1} - a_{\nu 1} \cdot r_{11}^{(1)} \quad \begin{matrix}(1 = 1,2,\ldots,n;\\ \nu = 2,3,\ldots,m)\end{matrix} \qquad (7)$$

As column interchange information is saved in the first position of the main diagonal, the result of the first step is the two matrices:

$$A^{(1)} = \begin{pmatrix} \underline{(j-1)} & a_{\underline{12}}^{(1)} & a_{\underline{13}}^{(1)} & \cdots & a_{\underline{1m}}^{(1)} \\ 0 & a_{\underline{22}}^{(1)} & a_{\underline{23}}^{(1)} & \cdots & a_{\underline{2m}}^{(1)} \\ 0 & a_{32}^{(1)} & a_{\underline{33}}^{(1)} & \cdots & a_{\underline{3m}}^{(1)} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & a_{m2}^{(1)} & a_{m3}^{(1)} & \cdots & a_{\underline{mm}}^{(1)} \end{pmatrix} \quad \text{and}$$

$$R^{(1)} = \begin{pmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \cdots & r_{1n}^{(1)} \\ r_{21}^{(1)} & r_{22}^{(1)} & \cdots & r_{2n}^{(1)} \\ r_{31}^{(1)} & r_{32}^{(1)} & \cdots & r_{3n}^{(1)} \\ \cdots & \cdots & \cdots & \cdots \\ r_{m1}^{(1)} & r_{m2}^{(1)} & \cdots & r_{mn}^{(1)} \end{pmatrix}$$

It is easily seen from equations (4) - (7) that the rest of matrix $A^{(1)}$ -- that is, matrix $A^{(1)}$ without the first row and first column -- is symmetrical and that actually only the underlined elements must be calculated and stored. Therefore, the range of index 1 in formula (6) reduces to $1 = \nu, \nu+1,\ldots,m$.

Now repeat this procedure m-2 times, starting at each step with the matrix $A^{(k)}$ of the step before without the first k rows and first k columns, and the matrix $R^{(k)}$ without the first k rows. The total result after m-1 steps is the matrices:

$$A^{(m-1)} = \begin{pmatrix} (j_1-1) & a_{12}^{(1)} & a_{13}^{(1)} & \cdots & a_{1m}^{(1)} \\ 0 & (j_2-2) & a_{23}^{(2)} & \cdots & a_{2m}^{(2)} \\ 0 & 0 & (j_3-3) & \cdots & a_{3m}^{(3)} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & (j_m-m) \end{pmatrix} \quad \text{and}$$

$$R^{(m-1)} = \begin{pmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \cdots & r_{1n}^{(1)} \\ r_{21}^{(2)} & r_{22}^{(2)} & \cdots & r_{2n}^{(2)} \\ r_{31}^{(3)} & r_{32}^{(3)} & \cdots & r_{3n}^{(3)} \\ \cdots & \cdots & \cdots & \cdots \\ r_{m1}^{(m)} & r_{m2}^{(m)} & \cdots & r_{mn}^{(m)} \end{pmatrix}$$

++Note that transformation of pivot row in matrix A destroys pivot column, which is, due to symmetry, stored in the same locations. As pivot column is used unchanged for transformation of rest of A and R, it has to be saved in auxiliary array AUX before transforming pivot row.

Now work backward and set:

$$
\left.
\begin{aligned}
r^{(m)}_{m-1,l} &= r^{(m-1)}_{m-1,l} - a^{(m-1)}_{m-1,m} \cdot r^{(m)}_{ml} \quad (l = 1,2,\ldots,n) \\
r^{(m)}_{m-2,l} &= r^{(m-2)}_{m-2,l} - a^{(m-2)}_{m-2,m-1} \cdot r^{(m)}_{m-1,l} \\
&\cdots\cdots\cdots \\
r^{(m)}_{1l} &= r^{(1)}_{1l} - a^{(1)}_{12} \cdot r^{(m)}_{2l} - a^{(1)}_{13} \cdot r^{(m)}_{3l} \\
&\quad - a^{(m-2)}_{m-2,m} \cdot r^{(m)}_{ml} \quad (l = 1,2,\ldots,n) \\
&\quad - \ldots - a^{(1)}_{1m} \cdot r^{(m)}_{ml} \quad (l = 1,2,\ldots,n)
\end{aligned}
\right\} \quad (8)
$$

After each step of back substitution, rows of solution matrix $X = R^{(m)}$ have to be back-interchanged according to interchange information in the corresponding main diagonal element of matrix $A^{(m-1)}$, in order to get the correct sequence of right-hand side column elements corresponding to the sequence of left-hand side row elements.

The only case in which the procedure described above can fail to give a solution occurs when at any step all elements in the main diagonal of the rest-matrix of $A^{(k)}$ become zero, and no pivot element can be found. In this case, the procedure is bypassed and the error message ier = -1 is given. This may -- but does not necessarily -- mean, that matrix A is singular. Possibly subroutines GELG or DGELG (which are working with complete pivoting) will be able to find a solution in cases where subroutines GELS or DGELS fail. Actually, because of rounding errors, a further check of the absolute values of pivot elements is performed by the procedure. If at elimination step k this absolute value becomes less than tol (see equation 3), it is likely that there was loss of significance in the computation of the diagonal elements. But as this may not necessarily be the case, and as this test depends highly on the choice of the relative tolerance ε [+], the procedure gives only the warning ier = k-1, which indicates that there is a possible loss of significance in the results computed by the algorithm.[++] But here it is also possible that subroutines GELG or DGELG will give better results. If there is only one equation to solve (m = 1), the test on loss of significance is suppressed.

[+] For subroutine GELS, a relative tolerance between 10^{-6} and 10^{-7} is suggested; and for subroutine DGELS, between 10^{-14} and 10^{-16}.

[++] For example, $\varepsilon = 10^{-5}$ and warning ier = 3 mean that there is a possible loss of about five or more significant digits in the initial values of elimination step 4.

Subroutines GELB and DGELB

These subroutines solve a system of simultaneous linear equations with a coefficient matrix of band structure by Gauss elimination. Consider the system of simultaneous linear equations

$$A * X = R \qquad (1)$$

with an m by m coefficient matrix A of band structure and an m by n right-hand side matrix R. Solution is done by means of Gauss elimination with column pivoting in matrix A. If R is the identity matrix, solution X is the inverse of matrix A. Solution matrix X is placed in positions of right-hand side matrix R and is stored in the same way -- that is, columnwise in m*n successive storage locations. Thus, the computation of the solution requires no extra m by n array of storage.

As storing matrix A by row results in a much more effective inner loop than storing by column, the procedure assumes that band matrix A is stored by row in successive storage locations, the number of which is equal to the number of elements appearing in the main diagonal and upper and lower codiagonals. The elements to be handed to the procedure by the user are underlined in the following explicit writing of formula (1) in the special case of a 7 by 7 matrix A with three upper and two lower codiagonals:

$$\begin{bmatrix} \underline{a_{11}} & \underline{a_{12}} & \underline{a_{13}} & \underline{a_{14}} & 0 & 0 & 0 \\ \underline{a_{21}} & \underline{a_{22}} & \underline{a_{23}} & \underline{a_{24}} & \underline{a_{25}} & 0 & 0 \\ \underline{a_{31}} & \underline{a_{32}} & \underline{a_{33}} & \underline{a_{34}} & \underline{a_{35}} & \underline{a_{36}} & 0 \\ 0 & \underline{a_{42}} & \underline{a_{43}} & \underline{a_{44}} & \underline{a_{45}} & \underline{a_{46}} & \underline{a_{47}} \\ 0 & 0 & \underline{a_{53}} & \underline{a_{54}} & \underline{a_{55}} & \underline{a_{56}} & \underline{a_{57}} \\ 0 & 0 & 0 & \underline{a_{64}} & \underline{a_{65}} & \underline{a_{66}} & \underline{a_{67}} \\ 0 & 0 & 0 & 0 & \underline{a_{75}} & \underline{a_{76}} & \underline{a_{77}} \end{bmatrix} *$$

$$\begin{pmatrix} x_{11} & x_{12} \cdots x_{1n} \\ x_{21} & x_{22} \cdots x_{2n} \\ x_{31} & x_{32} \cdots x_{3n} \\ \cdots\cdots\cdots\cdots \\ x_{71} & x_{72} \cdots x_{7n} \end{pmatrix} = \begin{pmatrix} r_{11} & r_{12} \cdots r_{1n} \\ r_{21} & r_{22} \cdots r_{2n} \\ r_{31} & r_{32} \cdots r_{3n} \\ \cdots\cdots\cdots\cdots \\ r_{71} & r_{72} \cdots r_{7n} \end{pmatrix} \qquad (2)$$

Immediately following the matrix elements there must be some auxiliary storage locations used by the procedure, such that in the general case of an m by m matrix A with "mud" upper and "mld" lower codiagonals the total number of storage locations of array A is:+

$$ma = m \cdot mc - \frac{(mc-mld-1)(mc-mld)}{2} \qquad (3)$$

with $mc = \min(m, 1 + mud + mld)$. (4)

That means, in the special case of formula (2), that the 33 underlined elements of matrix A must be stored by row in the first 33 successive locations of array A, which consists of 36 storage locations.

In the first part of the procedure, matrix A is searched for its absolutely greatest element, say a_{ij}, and the absolute tolerance for testing loss of significance

$$tol = \varepsilon \cdot |a_{ij}| \qquad (5)$$

is generated with a given relative tolerance ε++. Close together with this search, the elements of matrix A are moved backward, and a triangular area of zeros is inserted in the last positions of the first (mc-mud-1) rows, according to storage requirements of the Gauss algorithm for band matrices. After these manipulations, the special matrix A of formula (2) will occupy the 36 positions of array A by row as shown in Figure 10 (the underlined elements are the main diagonal elements of matrix A).

In order to make the description of the band-algorithm easier, the elements of array A are renamed according to their arrangement in Figure 10,

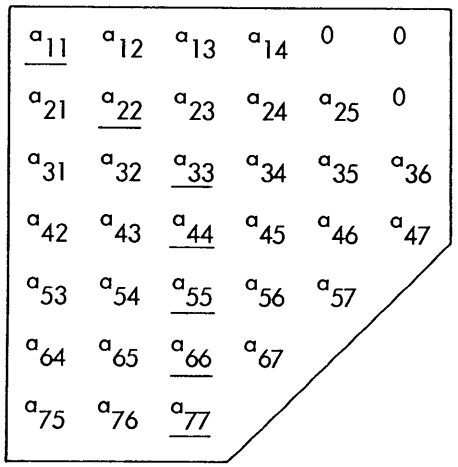

Figure 10. Array A

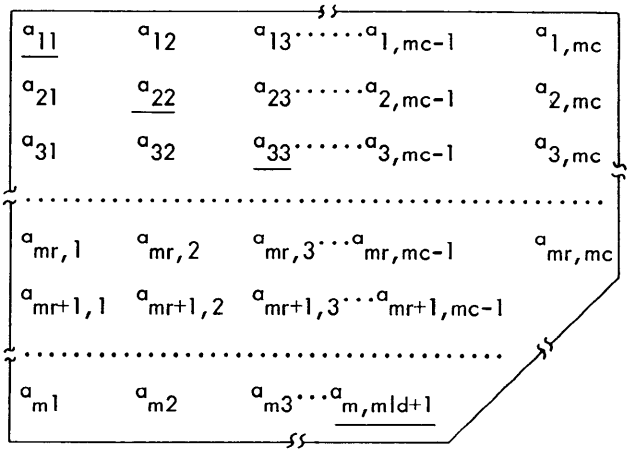

Figure 11. Array A renamed

thus generally giving the array shown in Figure 11 (main diagonal elements are underlined).

Each of the first mr = m-(mc - mld - 1) rows in this array contains mc elements; in the following rows the number of elements decreases steadily by 1 until the last row, which contains mld + 1 elements.

Now Gauss elimination can start. In the first step, search the first column of matrix A (that is, the elements of the first column of array A with row indexes from 1 up to 1 + mld) for the absolutely greatest element, say a_{j1} ($1 \le j \le 1 + mld$), and select it as pivot element ($p = a_{j1}$). Assume that j = 1. If it is not, interchange the first rows in array A and matrix R with the j^{th} rows. Now, transform the elements of the pivot rows (that is, the first rows) of array A and matrix R by division with p, and the elements of the following mld rows by adding $-a_{\nu 1}$ times the first rows to the ν^{th} rows ($\nu = 2,3,\ldots, 1 + mld$). At the same time, shift back the elements of the ν^{th} rows in array A by one position and insert a zero in the last position of each transformed row. This transformation is described by the following set of formulas:

$$a_{11}^{(1)} = \frac{a_{11}}{p} \quad (l = 1,2,\ldots, mc) \tag{6}$$

$$r_{11}^{(1)} = \frac{r_{11}}{p} \quad (l = 1,2,\ldots, n) \tag{7}$$

$$\left.\begin{aligned} a_{\nu,l-1}^{(1)} &= a_{\nu 1} - a_{\nu 1} \cdot a_{11}^{(1)} \\ &\quad (l = 2,3,\ldots, mc) \\ a_{\nu,mc}^{(1)} &= 0 \end{aligned}\right\} \quad (\nu = 2,3,\ldots, 1+mld) \tag{8}$$

$$r_{\nu 1}^{(1)} = r_{\nu 1} - a_{\nu 1} \cdot r_{11}^{(1)} \quad \begin{matrix}(l = 1,2,\ldots,n; \\ \nu = 2,3,\ldots, \\ 1+mld)\end{matrix} \tag{9}$$

Rows with row indexes greater than 1 + mld remain unchanged; nevertheless, they are marked with the superscript 1. The result of the first step is shown in Figure 12 (main diagonal elements are underlined).

$$R^{(1)} = \begin{pmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \cdots & r_{1n}^{(1)} \\ r_{21}^{(1)} & r_{22}^{(1)} & \cdots & r_{2n}^{(1)} \\ r_{31}^{(1)} & r_{32}^{(1)} & \cdots & r_{3n}^{(1)} \\ \vdots & & & \\ r_{m1}^{(1)} & r_{m2}^{(1)} & \cdots & r_{mn}^{(1)} \end{pmatrix}$$

This procedure is now repeated (m-1) times, starting at the k^{th} step with array $A^{(k-1)}$ and matrix $R^{(k-1)}$.

+Note that the user must provide this number of storage locations of array A by the dimension statement in his main program.

++In case of a matrix A without lower codiagonals, tol is set equal to zero, whether ε is zero or not.

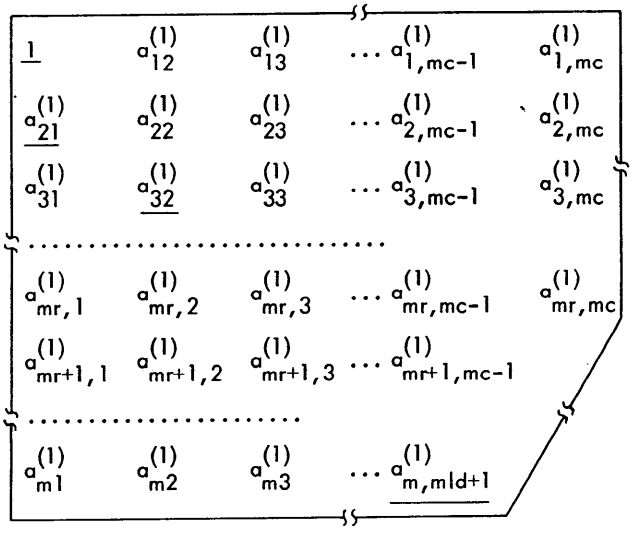

Figure 12. Array $A^{(1)}$

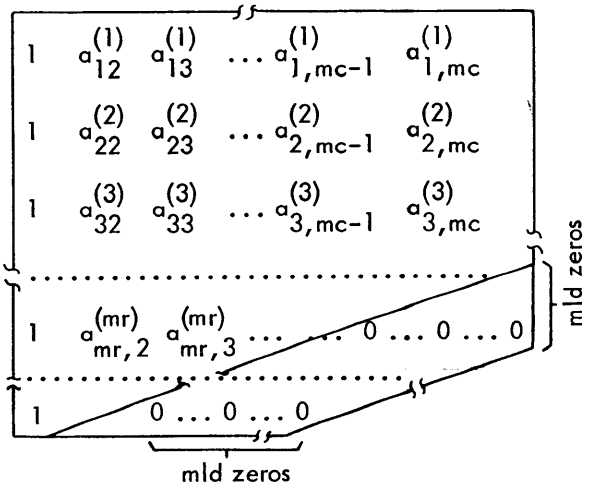

Figure 13. Array $A^{(m)}$

The rows which must be worked through at the k^{th} step are the rows with indexes i = k, k + 1,..., ilr = min (m, k + mld). As soon as ilr becomes greater than mr, the number of elements in any row of array A which have to be transformed decreases by one in each step k. The total results after m steps are shown in Figure 13.

$$R^{(m)} = \begin{bmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \cdots & r_{1n}^{(1)} \\ r_{21}^{(2)} & r_{22}^{(2)} & \cdots & r_{2n}^{(2)} \\ r_{31}^{(3)} & r_{32}^{(3)} & \cdots & r_{3n}^{(3)} \\ \vdots & & & \\ r_{mr,1}^{(mr)} & r_{mr,2}^{(mr)} & \cdots & r_{mr,n}^{(mr)} \\ \vdots & & & \\ r_{m1}^{(m)} & r_{m2}^{(m)} & \cdots & r_{mn}^{(m)} \end{bmatrix}$$

Now, working backward, generate solution matrix X in the locations of right-hand side matrix R by means of the following equations:

$$\begin{aligned}
r_{m-1,l}^{(m)} &= r_{m-1,l}^{(m-1)} - a_{m-1,2}^{(m-1)} \cdot r_{m,l}^{(m)} \\
&\qquad (l = 1, 2, \ldots, n) \\
r_{m-2,l}^{(m)} &= r_{m-2,l}^{(m-2)} - a_{m-2,2}^{(m-2)} \cdot r_{m-1,l}^{(m)} \\
&\quad - a_{m-2,3}^{(m-2)} \cdot r_{m,l}^{(m)} \quad (l = 1, 2, \ldots, n) \\
&\cdots\cdots\cdots\cdots \\
r_{m-mc+1,l}^{(m)} &= r_{m-mc+1,l}^{(m-mc+1)} - a_{m-mc+1,2}^{(m-mc+1)} \\
&\quad \cdot r_{m-mc+2,l}^{(m)} - \cdots - a_{m-mc-1,mc}^{(m-mc+1)} \\
&\quad \cdot r_{m,l}^{(m)} \quad (l = 1, 2, \ldots, n) \\
r_{11}^{(m)} &= r_{11}^{(1)} - a_{12}^{(1)} \cdot r_{21}^{(m)} - a_{13}^{(1)} \cdot r_{31}^{(m)} \\
&\quad - \cdots - a_{1,mc}^{(1)} \cdot r_{mc,1}^{(m)} \quad (l = 1, 2, \ldots, n)
\end{aligned} \tag{10}$$

Note that in the first mc-1 equations of formula (10) the number of terms to be subtracted increases steadily by 1 until this number has reached mc-1. From the (mc-1)st equation up to the last equation the number of terms to be subtracted remains constant.

The only case in which the procedure described above can fail to give a solution occurs when at any step (say the k^{th} step) all elements in the k^{th} column of the transformed matrix A [that is, the elements in the first column of array A with row indexes k up to ilr = min (m, k + mld)] become zero, and no pivot element can be found. In this case, the procedure is bypassed and the error message ier = -1 is given. Actually, because of rounding errors, a further check of the absolute values of pivot elements is performed by the procedure. If at elimination step k this absolute value becomes less than tol (see equation 5 and second footnote), it is likely that matrix A is singular, too. But, as this may not necessarily be the case and as this test depends highly on the choice of the relative tolerance ϵ [+], the procedure gives only the warning ier = k-1, which indicates that there is a possible loss of significance in the results computed by the algorithm. [++] In case of a well scaled matrix A and an appropriate choice of the relative tolerance, warning ier = k-1 may be interpreted as meaning that the rank of A is less than m but not less than k - 1. If there are no lower codiagonals (mld = 0), the test on loss of significance is suppressed.

+For subroutine GELB, a relative tolerance between 10^{-6} and 10^{-7} is suggested; and for subroutine DGELB, between 10^{-14} and 10^{-16}.

++For example, $\epsilon = 10^{-5}$ and warning ier = 3 mean that there is a possible loss of about 5 or more significant digits in the initial values of elimination step 4, and that matrix A seems to have a rank less than m but not less than 3.

Subroutines MTDS and DMTDS

Given a general matrix A and a nonsingular upper triangular matrix T, these subroutines will perform one of the following six operations, depending on the value of an input parameter IOP:

IOP = 1: A is replaced by $T^{-1}A$.
IOP = -1: A is replaced by AT^{-1}.
IOP = 2: A is replaced by $(T^{-1})\,{}^{T}A$.
IOP = -2: A is replaced by $A(T^{-1})^{T}$.
IOP = 3: A is replaced by $(T^{T}T)^{-1}A$.
IOP = -3: A is replaced by $A(T^{T}T)^{-1}$.

1. Mathematical background

a. Calculation of $X = T^{-1}A$ is done using backward substitution to obtain X from $TX = A$.

b. Calculation of $Y = (T^{-1})\,{}^{T}A$ is done using forward substitution to obtain Y from $T^{T}Y = A$.

c. Calculation of $Z = (T^{T}T)^{-1}A$ is done by first solving $T^{T}Y = A$ and then solving $TZ = Y$.

The remaining three operations are reducible to the above three.

2. Applications

Subroutines MTDS and DMTDS may be used to compute the solution of a system of equations $BX = A$ with symmetric positive definite coefficient matrix B. The first step towards the solution is the triangular factorization of B by means of subroutine MFSD or DMFSD. The second step, which may be repeated for different sets of right-hand sides A, is the calculation of $(T^{T}T)^{-1}A$ by means of MTDS or DMTDS with IOP = 3. Another useful application is the computation of the product $A^{T}B^{-1}A$ with symmetric positive definite B and arbitrary A in only three steps and without additional storage requirements:

a. Replace B by T where $B = T^{T}T$.
b. Replace A by $C = (T^{T})^{-1}A$.
c. Replace B by $C^{T}C$.

Subroutines MLSS and DMLSS

These subroutines will compute the least-squares solution of minimal length of a system of linear equations

$$AX = R \tag{1}$$

with symmetric positive semidefinite coefficient matrix A. That is, they will determine that vector X of smallest Euclidean length $\|X\|$ for which $\|AX - R\|$ = minimum.

The matrix A is not used directly as input. Instead, MLSS expects the matrices U, T, and T_u and the permutation P that would be obtained if subroutine MFSS were used with A as input matrix (for details see MFSS under "Final result of elimination").

The given vector R is replaced by the solution vector X.

1. Mathematical background

Instead of (1), solve the system of equations:

$$(PAP^T)PX = PR \tag{2}$$

Any solution PX of (2) determines the solution P^{-1} (PX) of (1); therefore it suffices to consider (2).

Using the decomposition:

$$PAP^T = \begin{bmatrix} I & O \\ U^T & I \end{bmatrix} \begin{bmatrix} A_S & O \\ O & O \end{bmatrix} \begin{bmatrix} I & U \\ O & I \end{bmatrix} \tag{3}$$

where $A_S = (T)^T T$ (see MFSS), it is easy to see that (2) is equivalent to the system:

$$A_S(X_1 + UX_2) = R_1 \tag{4}$$

$$OX_2 = R_2 - U^T R_1$$

where $PX = \begin{bmatrix} X_1 \\ X_2 \end{bmatrix}$ and $PR = \begin{bmatrix} R_1 \\ R_2 \end{bmatrix}$. If rank(A) = n, formula (3) reduces to $PAP^T = A_S$, and (4) is

$$A_S X = R \tag{4'}$$

In solving (2), or equivalently (4), three cases must be distinguished:

a. Rank(A) = n. Then the unique solution PX is given by $PX = A_S^{-1} R$, which is computed easily using the triangular decomposition $A_S = (T)^T T$.

b. Rank(A) = r < n and $R_2 = U^T R_1$ (a compatible system). Then the solution of minimal length is:

$$X_1 = (I + UU^T)^{-1} T^{-1(T^{-1})} T R_1$$

$$X_2 = U^T X_1$$

Using the identity $(I + UU^T)^{-1} = I - U(I + U^T U)^{-1} U^T$ and the triangular factorization of $(I + U^T U) = T_u^T T_u$, X_1 may be computed by the following sequence of operations:

$$X_1 = T^{-1}(T^T)^{-1} R_1$$

$$X_2 = T_u^{-1}(T_u^{-1})^T U^T X_1$$

$$X_1 = X_1 - UX_2$$

c. Rank(A) = r< n and $R_2 \neq U^T R_1$ (an incompatible system). Then the least-squares solution of minimal length is:

$$X_1 = (I + UU^T)^{-1} T^{-1} (T^T)^{-1} (I + UU^T)^{-1} (R_1 + UR_2)$$

$$X_2 = U^T X_1$$

X_1 may be computed using the following sequence of operations:

$$X_1 = R_1 + UR_2$$

$$X_2 = -T_u^{-1}(T_u^{-1})^T U^T X_1$$

$$X_1 = T^{-1}(T^T)^{-1}(X_1 + UX_2)$$

$$X_2 = -T_u^{-1}(T_u^{-1})^T U^T X_1$$

$$X_1 = X_1 + UX_2$$

2. Programming considerations

Cases a, b and c above are easily combined into one sequence of operations:

(1) X = PR (interchange given right-hand side)
(2) $X_1 = X_1 + U X_2$
(3) $X_2 = -U^T X_1$
(4) $X_2 = (T_u)^{-1} ((T_u)^T)^{-1} X_2$
(5) $X_1 = X_1 + U X_2$
(6) $X_1 = T^{-1}(T^T)^{-1} X_1$
(7) $X_2 = -U^T X_1$
(8) $X_2 = (T_u)^{-1} ((T_u)^T)^{-1} X_2$
(9) $X_1 = X_1 + U X_2$
(10) $X_2 = (U^T) X_1$
(11) $X = P^{-1} X$ (reinterchange calculated solution)

In case a, the only steps performed are (1), (6), (11).
In case b, only steps (1) and (6) up to (11) are performed.
In case c, all steps are performed.

Subroutines MCHB and DMCHB

These subroutines will compute a triangular factorization

$$A = (T_u)^T T_u \tag{1}$$

of an m by m symmetric positive definite band matrix A. They may also be used to replace a given m by n matrix R by $A^{-1}R$, $T_u^{-1}R$, or $(T_u^{-1})^T R$, depending on the value of an input parameter IOP, as shown in Table 3.

1. Mathematical background

The upper triangular matrix T_u is computed using the following recursive formulas:

$$t_{kj} = (1/t_{kk})\left(a_{kj} - \sum_{i=1}^{k-1} t_{ik}t_{ij}\right) \quad \begin{matrix} k = 1, \ldots, m \\ j = k, k+1, \ldots, m \end{matrix} \tag{2}$$

(Any symbol $\sum_{i=j}^{k} x_i$ is to be interpreted as zero if $j > k$.)

In the special case $j = k$, equation (2) may be written:

$$t_{kk} = \sqrt{a_{kk} - \sum_{i=1}^{k-1} t_{ik}^2}, \quad k = 1, 2, \ldots, m \tag{3}$$

When A is a symmetric band matrix with mud upper codiagonals, all elements a_{kj} are equal to zero if $j > k + mud$. From formulas (2) and (3) it is easy to see that the same is true for t_{kj}:

$$t_{kj} = 0 \text{ if } j > k + mud \tag{4}$$

Therefore formulas (2) and (3) reduce to:

$$t_{kj} = (1/t_{kk})\left(a_{kj} - \sum_{i=i_o}^{k-1} t_{ik}t_{ij}\right) \quad \begin{matrix} k = 1, 2, \ldots, m \\ j = k+1, \ldots, \min(m, k+mud) \end{matrix} \tag{5}$$

$$i_o = \max(1, j-mud)$$

$$t_{kk} = \sqrt{a_{kk} - \sum_{i=i_o}^{k-1} t_{ik}^2} \quad k = 1, 2, \ldots, m \tag{6}$$

$$i_o = \max(1, k-mud)$$

Computing $(T_u^{-1})^T$ is equivalent to solving for Y in the system of equations:

$$T_u^T Y = R \tag{7}$$

The solution of (7) is computed using the following recursive scheme:

$$y_{kj} = (1/t_{kk})\left(r_{kj} - \sum_{i=i_o}^{k-1} t_{ik}y_{ij}\right) \quad \begin{matrix} k = 1, 2, \ldots, m \\ j = 1, 2, \ldots, n \end{matrix} \tag{8}$$

$$i_o = \max(1, k-mud)$$

After each y_{kj} is computed, it may be stored in the location of r_{kj}.

Analogously, computing $T_u^{-1} R$ is the same as solving for X in the system of equations:

$$T_u X = R \tag{9}$$

The solution of (9) is given using a similar recursive scheme:

$$x_{kj} = (1/t_{kk})\left(r_{kj} - \sum_{i=k+1}^{i_o} t_{ki}x_{ij}\right) \quad \begin{matrix} k = m, m-1, \ldots, 1 \\ j = 1, 2, \ldots, n \end{matrix} \tag{10}$$

$$i_o = \min(m, k+mud)$$

$A^{-1}R$ is computed by first computing $S = (T_u^T)^{-1}R$ in the locations of R, and then computing $T_u^{-1}S$, again in the locations of R. If $R = I$, this process replaces R with the inverse A^{-1} of A. Note that in general A^{-1} is no longer a band matrix.

2. Programming considerations

The input matrix A is assumed to be stored in compressed form, that is, main diagonal and mud upper codiagonals rowwise in successive storage locations. Therefore, the total storage requirement for matrix A is $m + mud\,(2m-mud-1)/2$ storage locations. The general m by n matrix R is assumed to be stored columnwise in nm successive storage locations.

The operations performed by the subroutines depend on the actual value of the decision parameter IOP.

Table 3 shows input and output depending on the value of IOP.

Table 3. Dependence of Input and Output on IOP

	IOP	0	1	-1	2	-2	3	-3
INPUT	A in compressed form	A	A	T_u	A	T_u	A	T_u
	R column-wise	irrelevant	R	R	R	R	R	R
OUTPUT	A in compressed form	T_u	T_u	T_u	T_u	T_u	T_u	T_u
	R column-wise	unchanged	$A^{-1}R$	$A^{-1}R$	$T_u^{-1}R$	$T_u^{-1}R$	$(T_u^{-1})^T R$	$(T_u^{-1})^T R$

If IOP is not equal to one of the values listed in Table 3, no action except error message IER = -1 takes place. In this case A and R remain unchanged. The same is true if mud (the number of upper codiagonals of A) is negative or if m (the number of rows of A) is less than 1+mud.

There is one way in which the factorization described above may fail to give a solution, which is easily seen from equation (6). If at any step the radicand of equation (6) is not positive, the procedure is bypassed, and the error message IER = -1 is given. The interpretation may be that matrix A is not positive-definite; however, failure is also possible due to roundoff errors.

Backsubstitutions may fail too, as is easily seen from equations (8) and (10). If any main diagonal element of T_u is equal to zero (this is only possible if T_u is given by input), the procedure is bypassed, and the error message IER = -1 is given.

A further test on possible loss of significance in the factorization part is performed by the subroutines. If at the kth factorization step the radicand of equation (6) is not greater than $|\ EPS.a_{kk}\ |$, with the relative tolerance EPS given by input, the subroutines give the message IER = k-1.

For subroutine MCHB a relative tolerance between 10^{-6} and 10^{-7} is suggested, and for subroutine DMCHB, between 10^{-14} and 10^{-16}. The message IER = k-1, in case EPS = 10^{-D}, means that there are about D or more significant digits lost in the computation of the radicand in formula (6) at the kth factorization step. The interpretation may be that there is loss of significance in the factorized matrix from the kth row on, while the results of rows 1 up to k-1 may be better. Loss of significance in the lower part of the factorized matrix may affect the results of matrix divisions.

Subroutine MFSS and DMFSS

Given a symmetric positive semidefinite matrix A, MFSS will:

(1) Determine the rank and linearly independent rows (and columns)

(2) Compute a triangular factorization of a symmetric submatrix of maximal rank

(3) Express nonbasic rows (and columns) in terms of basic ones and express nonbasic variables in terms of free ones.

1. Mathematical background

The rank is determined using the method of Cholesky (square root method) with pivoting along the main diagonal. Pivoting on diagonal elements means that the same permutation is applied to the rows and columns of A, thereby preserving symmetry. The interchange information is recorded in the auxiliary vector TRAC. The notation A^m is used for the interchanged matrix determined during the mth step. The given matrix A is assumed to be stored column-wise in compressed form, that is, upper triangular part only.

$$A = \begin{bmatrix} a_{11} & a_{12} \cdots & a_{1n} \\ & a_{22} \cdots & a_{2n} \\ & & a_{nn} \end{bmatrix}$$

To allow for easy pivoting, the diagonal terms of A are moved into vector TRAC.

The following two facts will be used repeatedly:

(I) If $S=(s_{ik})$ is symmetric with $s_{11} > 0$, then S admits the unique decomposition:

$$S = \begin{bmatrix} t & 0 \\ V^T & I \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & D \end{bmatrix} \begin{bmatrix} t & V \\ 0 & I \end{bmatrix} = \tag{1}$$

$$\begin{bmatrix} s_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}$$

where $t = \sqrt{s_{11}}$, $V = (1/t)S_{12}$ and $D = S_{22} - V^TV$.

(II) If S is symmetric positive semidefinite:

$$s_{jj} \geq 0 \text{ for all } j \text{ and } |s_{ik}| \leq \max_j(s_{jj}) \text{ for all } i,k \tag{2}$$

a. First step

Let $a_{jj} = \max_i(a_{ii})$. If $a_{jj} = 0$, formula (2) implies $A = 0$, and further calculations are bypassed. Assuming $a_{jj} > 0$, rows 1 and $k_1 = j$ and columns 1 and k_1 of A are interchanged, obtaining A^1. TRAC(k_1) is replaced by TRAC(1), and k_1 is stored in TRAC(1). Decomposition of A^1 gives:

$$A^1 = \begin{bmatrix} A^1_{11} & A^1_{12} \\ A^1_{21} & A^1_{22} \end{bmatrix} = \begin{bmatrix} t^1_{11} & 0 \\ (V^1)^T & I \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & D^1 \end{bmatrix} \begin{bmatrix} t^1_{11} & V^1 \\ 0 & I \end{bmatrix}$$

where $t^1_{11} = \sqrt{a^1_{11}}$, $V^1 = (1/t^1_{11})A^1_{12}$ and $D^1 = A^1_{22} - (V^1)^TV^1$. D^1 is not calculated explicitly, only its diagonal terms are computed and stored in locations TRAC(2) through TRAC(n).

The first row of A^1 is replaced by t^1_{11}, V^1. The compressed storage scheme now looks like this:

$$\begin{matrix} t^1_{11} & V^1 \\ & A^1_{22} \end{matrix}$$

b. General step

Suppose that after m steps ($1 \leq m < n$) we have determined a transposition vector ($k_1, k_2, \ldots, k_m$), an m by m nonsingular upper triangular matrix:

$$T^m = \begin{bmatrix} t^1_{11} & t^2_{12} \cdots & t^m_{1m} \\ & t^2_{22} \cdots & t^m_{2m} \\ & & t^m_{mm} \end{bmatrix}$$

an m by (n-m) matrix:

$$V^m = \begin{bmatrix} V^m_1 \\ V^m_2 \\ \cdot \\ \cdot \\ \cdot \\ V^m_m \end{bmatrix}$$

and an (n-m) by (n-m) matrix D^m such that:

$$A^m = \begin{bmatrix} A^m_{11} & A^m_{12} \\ A^m_{21} & A^m_{22} \end{bmatrix} = \begin{bmatrix} (T^m)^T & 0 \\ (V^m)^T & I \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ 0 & D^m \end{bmatrix} \cdot \begin{bmatrix} T^m & V^m \\ 0 & I \end{bmatrix} \quad (3)$$

where $A^m = P^m A (P^m)^T$, and P^m is the permutation matrix associated with the transposition vector $(k_1,\ldots,k_m)$. Again, D^m is not known explicitly, but is computable from:

$$D^m = A^m_{22} - (V^m)^T V^m \quad (4)$$

T^m, V^m and A^m_{22} are assumed to be stored in the following way:

T^m V^m

A^m_{22}

If $A^m_{22} = 0$, it follows from (4) and the fact that D^m is positive semidefinite that $D^m = 0$. Then (3) is the desired factorization, and the process terminates. If $A^m_{22} \neq 0$, there is at least one positive diagonal term a^m_{kk}, and we may compute:

$$t = d^m_{jj}/a^m_{jj} = \max_k \left\{ d^m_{kk}/a^m_{kk} \;\middle|\; a^m_{kk} > 0 \right\}$$

From (4) and (2), $\max_{i,k} \left| d^m_{ik} \right| \leq t \max_{i,k} \left| a^m_{ik} \right|$.

If $t \leq \epsilon$, the norm of D^m is small compared to the norm of A^m_{22}, and we interpret this as $D^m = 0$. Assuming $t > \epsilon$, rows m+1 and $k_{m+1} = m+j$ and columns m+1 and k_{m+1} are interchanged in the compressed storage areas, obtaining

T^m V'^m

A'^m_{22}

TRAC(k_{m+1}) is replaced by TRAC(m+1), and k_{m+1} is stored in TRAC(m+1). As a result of these interchanges:

$$QA^mQ = \begin{bmatrix} (T^m)^T & 0 \\ (V'^m)^T & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & D'^m \end{bmatrix} \begin{bmatrix} T^m & V'^m \\ 0 & I \end{bmatrix} \quad (5)$$

where $D'^m = A'^m_{22} - (V'^m)^T V'^m$, and Q is the permutation matrix associated with the transposition $(m+1, k_{m+1})$. Now decompose D'^m:

$$D'^m = \begin{bmatrix} t^{m+1}_{m+1,m+1} & 0 \\ (V^{m+1}_{m+1})^T & I \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & D^{m+1} \end{bmatrix} \begin{bmatrix} t^{m+1}_{m+1,m+1} & V^{m+1}_{m+1} \\ 0 & I \end{bmatrix}$$

and store $t^{m+1}_{m+1,m+1}$, V^{m+1}_{m+1} in the first row of A'^m_{22}. Let A^{m+1}_{22} denote the remaining rows and columns of A'^m_{22}, and rename the elements of V'^m as follows:

$$V'^m = \begin{bmatrix} t^{m+1}_{1,m+1} & V^{m+1}_1 \\ t^{m+1}_{m,m+1} & V^{m+1}_m \end{bmatrix}$$

The storage area now looks like this:

T^m $t^{m+1}_{1,m+1}$ V^{m+1}_1

$t^{m+1}_{m+1,m+1}$ V^{m+1}_{m+1}

A^{m+1}_{22}

Let T^{m+1} be the enlarged triangular t-array indicated above, (that is, add the column of t's to T^m), and let V^{m+1} be the V-array. An easy calculation shows that we are back in the situation (3), (4) with m replaced by m+1. This completes step m+1.

c. Final result of elimination

The above process is continued until for some m=r, say, $D^r = 0$ (in the sense mentioned above) or until m=n whichever comes first. In the case r < n, the result is the factorization:

$$A^r = P^r A (P^r)^T = \begin{bmatrix} (T^r)^T & 0 \\ (V^r)^T & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} T^r & V^r \\ 0 & I \end{bmatrix}$$

where P^r is the permutation matrix associated with the permutation:

$$P^r = (r,k_r)(r-1,k_{r-1})..(1,k_1)$$

T^r is nonsingular, and we may compute $U^r = (T^r)^{-1}V^r$ in the same storage locations occupied by V^r. An easy calculation shows:

$$A^r = \begin{bmatrix} I & 0 \\ (U^r)^T & I \end{bmatrix} \begin{bmatrix} A_s & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} I & U^r \\ 0 & I \end{bmatrix}$$

where $A_s = (T^r)^T T^r$. We also compute $I + (U^r)^T U^r$ and store it in the last n-r rows and columns of A, producing the storage scheme:

$$\begin{matrix} T^r & U^r \\ I + (U^r)^T U^r \end{matrix}$$

We now operate on $I + (U^r)^T U^r$ in the same way that we operated on A. Whenever it is necessary to interchange two columns of this matrix, we also interchange the same columns of U^r in the storage area. Interchange information is recorded in TRAC (r+1) up to TRAC(n). The foregoing proof establishes a permutation matrix Q and an (n-r) by (n-r) nonsingular upper triangular T_u such that:

$$(T_u)^T T_u = Q(I + (U^r)^T U^r)Q^T = I + (U^r Q^T)^T (U^r Q^T)$$

Let $T = T^r$, $U = U^r Q^T$ and $P^{n-r} = \begin{bmatrix} I & 0 \\ 0 & Q \end{bmatrix}$. An easy calculation then gives the final results:

$$A^n = PAP^T = \begin{bmatrix} I & 0 \\ U^T & I \end{bmatrix} \begin{bmatrix} A_s & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} I & U \\ 0 & I \end{bmatrix} \quad (6)$$

$$(T_u)^T T_u = I + U^T U \quad (7)$$

where $P = P^{n-r}P^r$. The final storage scheme is

$$\begin{matrix} T & U \\ & T_u \end{matrix}$$

TRAC contains the permutation P^T in the form of a transposition vector $(k_1, k_2, \ldots, k_n)$.

d. Dependencies among rows and columns

The basic rows of A^n are $A_b = A_s [I, U]$. The nonbasic rows are then $U^T A_b$. Of course basic columns are $(A_b)^T$, and nonbasic columns are $(A_b)^T U$.

e. Systems of equations

Subroutines MFSS and DMFSS may be used to solve systems of equations

$$AX = R$$

with positive semidefinite coefficient matrix A. Using the permutation P, this system is transformed into the system

$$A^n X^n = R^n \quad (8)$$

where $X^n = PX$ and $R^n = PR$. If A has rank r=n, equation (8) is

$$A_s X^n = R^n$$

which is easily solved since $A_s^{-1} = T^{-1}(T^{-1})^T$.

Assuming $r < n$, the vectors X^n, R^n are partitioned as follows:

$$X^n = \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} \text{ and } R^n = \begin{bmatrix} R_1 \\ R_2 \end{bmatrix},$$

where X_1 consists of the first r elements of X^n, etc. Using the decomposition (6), it is easy to see that (8) is equivalent to:

$$\begin{aligned} A_s(X_1 + UX_2) &= R_1 \\ 0X_2 &= -U^T R_1 + R_2 \end{aligned} \quad (9)$$

(By equivalent systems we mean they have the same solutions.)
If $R_2 = U^T R_1$ (a compatible system), equation (9) has the n-r parameter family of solutions:

$$\begin{aligned} X_1 &= A_s^{-1} R_1 - UX_2 \\ X_2 &= \text{arbitrary} \end{aligned} \quad (10)$$

If $R_2 \neq U^T R_1$ (an incompatible system), it is natural to ask for a least-squares solution of (8), that is a vector X^n such that $\|A^n X^n - R^n\|^2 = \text{minimum}$. This problem leads to the system of equations:

$$(A^n)^2 X^n = A^n R^n \tag{11}$$

Given the factorization (6) of A^n, it is easy to show that $B^n = (A^n)^2$ admits the factorization:

$$B^n = \begin{bmatrix} I & 0 \\ U^T & I \end{bmatrix} \begin{bmatrix} B_s & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} I & U \\ 0 & I \end{bmatrix}$$

where $B_s = A_s(I+UU^T)A_s$. Using this fact, (11) is equivalent to:

$$\begin{aligned} B_s(X_1 + UX_2) &= A_s(R_1 + UR_2) \\ 0 \cdot X_2 &= 0 \cdot R_2 \end{aligned} \tag{12}$$

which is clearly a compatible system. Therefore (12) has the solutions:

$$\begin{aligned} X_1 &= B_s^{-1}A_s(R_1 + UR_2) - UX_2 \\ X_2 &= \text{arbitrary} \end{aligned} \tag{13}$$

Now the identity $(I + UU^T)^{-1} = I - U(I + U^TU)^{-1}U^T$ shows that it suffices to know $(I + U^TU)^{-1}$ in order to compute B_s^{-1}. But by (7):

$$(I + U^TU)^{-1} = T_u^{-1}(T_u^{-1})^T$$

and T_u^{-1} is easy to compute, since T_u is upper triangular.

f. Solutions of minimal length

The solutions (10) or (13) contain n-r free parameters X_2, and it is possible to choose them so that X^n has minimal Euclidean length, that is so that $\|X^n\| = \min$. Some easy calculations show that in the compatible case (10), X^n is given by:

$$X_1 = (I + UU^T)^{-1}A_s^{-1}R_1$$

$$X_2 = U^TX_1$$

and in the incompatible case (13), X^n is:

$$X_1 = (I + UU^T)^{-1}A_s^{-1}(I + UU^T)^{-1}(R_1+UR_2)$$

$$X_2 = U^TX_1$$

g. Accuracy

Determining the rank of a matrix on a computer is a difficult matter, and it is not claimed that MFSS will compute the correct rank in all cases. This is an intrinsic difficulty due to the fact that we work with finite arithmetic.

h. Error returns

Normally IRANK contains the computed rank r. A nonpositive value returned in IRANK means:

IRANK = 0 A has no positive diagonal element, or $|\epsilon| \geq 1$.

IRANK = -1 A nonpositive dimension of A was specified.

IRANK = -2 $I + U^TU$ is ill-conditioned and/or the relative tolerance ϵ was specified incorrectly.

Subroutines MFSD and DMFSD

These subroutines will compute a triangular factorization of a symmetric positive definite matrix using the square root method of Cholesky.

1. Mathematical background

Given an n by n symmetric positive definite matrix A, we compute an upper triangular matrix R such that

$$A = R^T R$$

The elements r_{ik} of R are computed using the following recursive formulas:

$$r_{1k} = a_{1k}/r_{11} \qquad k=1,\ 2,\ 3,\ \ldots\ ,\ n$$

$$r_{jk} = (1/r_{jj})\left(a_{jk} - \sum_{i=1}^{j-1} r_{ij}r_{ik}\right) \qquad j=2,\ 3,\ \ldots\ ,\ n$$

$$k=j,\ j+1,\ \ldots\ ,\ n$$

Note: The determinant of A is $\det(A) = \left(\prod_{i=1}^{n} r_{ii}\right)^2$.

2. Programming considerations

The given matrix A is assumed stored columnwise in compressed form, that is upper triangular part only. MFSD stores the solution R in the same locations as A.

If any calculated radicand r_{kk}^2 $(k=1,\ 2,\ \ldots,n)$ is not positive, further calculation is bypassed, and the error parameter IER is set to -1. This means that A is not positive definite, possibly due to roundoff errors. IER is also set to -1 if the input parameter n is less than 1.

Let all radicands be positive and let r_{kk}^2 be the first radicand which is no longer greater than the internal tolerance TOL = $|\text{EPS } a_{kk}|$. The subroutine then gives the warning IER = k-1; however, calculation is continued. The warning indicates that there may be loss of significance at factorization step k due to loss of significant digits in the calculation of r_{kk}^2.

Subroutines LLSQ and DLLSQ

These subroutines obtain the solution of linear least-squares problems. Consider a real m by n matrix A of rank n ($m \geq n$) with elements a_{ik} ($i = 1,2,\ldots,m$; $k = 1,2,\ldots,n$) and l right-hand side column vectors B_j ($j = 1,2,\ldots,l$) of dimension m, written as an m by l right-hand side matrix B with elements b_{ik} ($i = 1,2,\ldots,m$; $k = 1,2,\ldots,l$). The problem is to determine l column vectors X_j ($j = 1,2,\ldots,l$) of dimension n -- written as an n by l matrix X with elements x_{ik} ($i = 1,2,\ldots,n$; $k = 1,2,\ldots,l$)-- such that:

$$\| B_j - A * X_j \| = \min_j \quad (j = 1,2,\ldots,l) \qquad (1)$$

where $\| R \|$ indicates the Euclidean norm of any column vector R with elements r_i ($i = 1,2,\ldots,m$); that is:

$$\| R \| = \sqrt{\sum_{i=1}^{m} r_i^2} \qquad (2)$$

In the special case m = n, solution of the linear least-squares problem means solution of the system of simultaneous linear equations:

$$A * X = B \qquad (3)$$

Solution of the given problem is based on the well known principle that transformation of any column vector R by an orthogonal matrix Q does not change its norm $\|R\|$; that is:

$$\| Q * R \| = \| R \| \qquad (4)$$

Writing the given problem in the following form:

$$\begin{pmatrix} b_{11} & b_{12} & \cdots & b_{1l} \\ b_{21} & b_{22} & \cdots & b_{2l} \\ b_{31} & b_{32} & \cdots & b_{3l} \\ \vdots & \vdots & & \vdots \\ b_{m1} & b_{m2} & \cdots & b_{ml} \end{pmatrix} - \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ a_{31} & a_{32} & \cdots & a_{3n} \\ \vdots & \vdots & & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{pmatrix} \cdot$$

$$\begin{pmatrix} x_{11} & x_{12} & \cdots & x_{1l} \\ x_{21} & x_{22} & \cdots & x_{2l} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \cdots & x_{nl} \end{pmatrix} = \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1l} \\ r_{21} & r_{22} & \cdots & r_{2l} \\ r_{31} & r_{32} & \cdots & r_{3l} \\ \vdots & \vdots & & \vdots \\ r_{m1} & r_{m2} & \cdots & r_{ml} \end{pmatrix} \qquad (5)$$

the orthogonal transformation matrix Q is determined so that matrix A is transformed to upper triangular form; that is, all elements a_{ik} with $i > k$ are transformed to zero. An effective way to realize this decomposition is via Householder transformations. The algorithm is a recursive n-step procedure defined by the following recursion formulas:

$$A^{(1)} = A \qquad (6)$$

$$A^{(k+1)} = P^{(k)} * A^{(k)} \quad (k = 1,2,\ldots,n) \qquad (7)$$

In order to get an upper triangular matrix $A^{(n+1)}$, every matrix $P^{(k)}$ ($k = 1,2,\ldots,n$) should be defined so that it is symmetric and orthogonal, and so that it transforms all elements of the k^{th} column of $A^{(k)}$ below the main diagonal to zero. All these restrictions to $P^{(k)}$ are satisfied, setting:

$$p^{(k)} = I - \beta_k * U^{(k)} * U^{(k)^T} \qquad (8)$$

with

$$\beta_k = \frac{1}{\sigma_k \, (\sigma_k + a_{kk}^{(k)})} \qquad (9)$$

and

$$\sigma_k = \pm \sqrt{\sum_{i=k}^{m} (a_{ik}^{(k)})^2} \quad \text{with} \begin{cases} + \text{ for } a_{kk}^{(k)} \geq 0 \\ - \text{ for } a_{kk}^{(k)} < 0 \end{cases} \qquad (10)$$

where I is the identity matrix.

$U^{(k)T}$ denotes the transpose of column vector $U^{(k)}$, the m components of which are defined as follows:

$$u_i^{(k)} = 0 \quad \text{for } i < k \tag{11}$$

$$u_k^{(k)} = \sigma_k + a_{kk}^{(k)} \tag{12}$$

$$u_i^{(k)} = a_{ik}^{(k)} \quad \text{for } i > k \tag{13}$$

Neither matrices $P^{(k)}$ $(k = 1,2,\ldots,n)$ nor matrix $Q = P^{(n)} * P^{(n-1)} * \ldots * P^{(1)}$ are computed explicitly, since from (7) and (8):

$$A^{(k+1)} = A^{(k)} - U^{(k)} * Y^{(k)T} \tag{14}$$

with

$$Y^{(k)T} = \beta_k * U^{(k)T} * A^{(k)} \tag{15}$$

Writing the components of row vector $Y^{(k)T}$ explicitly:

$$y_j^{(k)} = 0 \quad \text{for } j < k \tag{16}$$

$$y_k^{(k)} = 1 \tag{17}$$

$$y_j^{(k)} = \beta_k \sum_{i=k}^{m} u_i^{(k)} \cdot a_{ij}^{(k)} \quad \text{for } j > k \tag{18}$$

Using (14), (16), (17), and (18), the explicit transformation formulas for matrix $A^{(k)}$ appear as follows:

$$a_{kk}^{(k+1)} = -\sigma_k \tag{19}$$

$$a_{ik}^{(k+1)} = 0 \qquad (i = k+1, k+2, \ldots, m) \tag{20}$$

$$a_{ij}^{(k+1)} = a_{ij}^{(k)} - u_i^{(k)} \cdot y_j^{(k)}$$

$(j = k+1, k+2, \ldots, n$ and for fixed j, $i = k, k+1, \ldots, m)$ (21)

All other elements of matrix $A^{(k)}$ do not change. Naturally, the same transformation is performed on matrix B.

Using (6) and (7):

$$B^{(1)} = B \tag{22}$$

$$B^{(k+1)} = P^{(k)} * B^{(k)} \qquad (k = 1,2,\ldots,n) \tag{23}$$

Using (8) and (23):

$$B^{(k+1)} = B^{(k)} - U^{(k)} * Z^{(k)T} \tag{24}$$

with

$$Z^{(k)T} = \beta_k * U^{(k)T} * B^{(k)} \tag{25}$$

or explicitly:

$$b_{ij}^{(k+1)} = b_{ij}^{(k)} - u_i^{(k)} \cdot z_j^{(k)} \qquad \begin{matrix}(j = 1,2,\ldots,l;\\ i = 1,2,\ldots,m)\end{matrix} \tag{26}$$

with

$$z_j^{(k)} = \beta_k \sum_{i=k}^{m} u_i^{(k)} \cdot b_{ij}^{(k)} \qquad (j = 1,2,\ldots,l) \tag{27}$$

In order to keep roundoff errors as small as possible, column interchange is performed in such a way that, at the k^{th} stage, the column of $A^{(k)}$ is chosen to be reduced next, which will maximize $\left|a_{kk}^{(k+1)}\right|$. Using (19) and (10), the index of this column is determined by giving the maximum overall j of:

$$s_j^{(k)} = \sum_{i=k}^{m} (a_{ij}^{(k)})^2 \qquad (j = k, k+1, \ldots, n) \tag{28}$$

After $A^{(k+1)}$ has been computed, it is possible to compute $s_j^{(k+1)}$ as follows:

$$s_j^{(k+1)} = s_j^{(k)} - (a_{kj}^{(k+1)})^2 \qquad (j = k+1, k+2, \ldots, n) \tag{29}$$

since the orthogonal transformations leave the column lengths invariant.

After having computed matrices $A^{(n+1)}$ (upper triangular matrix) and $B^{(n+1)}$, the computation of the n by l solution matrix X is performed by back substitution according to the following formulas:

$$x_{ni} = \frac{1}{a_{nn}^{(n+1)}} \cdot b_{ni}^{(n+1)} \qquad (i = 1, 2, \ldots, l) \tag{30}$$

$$x_{ki} = \frac{1}{a_{kk}^{(n+1)}} \left(b_{ki}^{(n+1)} - a_{k,k+1}^{(n+1)} \cdot x_{k+1,i} \right.$$

$$- a_{k,k+2}^{(n+1)} \cdot x_{k+2,i} - \ldots - a_{k,n-1}^{(n+1)} \cdot x_{n-1,i}$$

$$\left. - a_{kn}^{(n+1)} \cdot x_{ni} \right)$$

$$(k = n-j+1;\ j = 2, 3, \ldots, n \text{ and}$$
$$i = 1, 2, \ldots, l \text{ for fixed } j) \tag{31}$$

After any row of matrix X has been computed, back interchange of rows is performed according to column interchanges in matrices $A^{(k)}$ in order to get the correct sequence of components in the solution vectors X_j.

Finally, the vector of linear least squares with components

$$lsq_j = \sum_{i=n+1}^{m} (b_{ij}^{(n+1)})^2 \qquad (j = 1, 2, \ldots, l) \tag{32}$$

is computed, which gives the squares of the minimized Euclidean norms $\|B_j - A * X_j\|$ for all right-hand side column vectors B_j $(j = 1, 2, \ldots, l)$.

The only case in which the whole procedure can fail occurs when, at any stage k, no column with nonzero parameter σ_k can be found; that is, no nonzero main diagonal element can be generated. In this case, the rank of matrix A is less than n. With respect to roundoff errors, the test is made in the following way.

At first, all elements $s_j^{(1)}$ are computed according to (28) and the maximum overall j (that is, σ_1^2) is determined. With the relative tolerance ε given by input, the following absolute tolerance is generated:

$$tol = \sigma_1 \cdot \varepsilon \tag{33}$$

If at any stage k $(= 1, 2, \ldots, n+1)$ the square root of the maximum overall $j = k+1, \ldots, n$ of $s_j^{(k+1)}$, say piv, is not greater than tol, the rank of matrix A is declared to be $k < n$, and the procedure returns an error message to the calling program, thus indicating that no solution could be found. In this case, the last n - k elements of vector IPIV denote the useless columns of matrix A; the remaining useful columns form a base of matrix A.

Matrices: Eigenanalysis and Related Topics

Subroutine EIGEN

This subroutine computes the eigenvalues and eigenvectors of a real symmetric matrix.

Given a symmetric matrix A of order N, eigenvalues are to be developed in the diagonal elements of the matrix. A matrix of eigenvectors R is also to be generated.

An identity matrix is used as a first approximation of R.

The initial off-diagonal norm is computed:

$$\nu_I = \left\{ \sum_{i<k} 2A_{ik}^2 \right\}^{1/2} \qquad (1)$$

ν_I = initial norm

A = input matrix (symmetric)

This norm is divided by N at each stage to produce the threshold.

The final norm is computed:

$$\nu_F = \frac{\nu_I \times 10^{-6}}{N} \qquad (2)$$

This final norm is set sufficiently small that the requirement that any off-diagonal element A_{lm} shall be smaller than ν_F in absolute magnitude defines the convergence of the process.

An indicator is initialized. This indicator is later used to determine whether any off-diagonal elements have been found that are greater than the present threshold.

Each off-diagonal element is selected in turn and a transformation is performed to annihilate the off-diagonal (pivotal) element, as shown by the following equations:

$$\lambda = -A_{lm} \qquad (3)$$

$$\mu = 1/2\,(A_{11} - A_{mm}) \qquad (4)$$

$$\omega = \text{sign}\,(\mu)\,\frac{\lambda}{\sqrt{\lambda^2 + \mu^2}} \qquad (5)$$

$$\sin\theta = \frac{\omega}{\sqrt{2\,(1+\sqrt{1-\omega^2})}} \qquad (6)$$

$$\cos\theta = \sqrt{1-\sin^2\theta} \qquad (7)$$

$$B = A_{il} \cos\theta - A_{im} \sin\theta \quad (8)$$

$$A_{im} = A_{il} \sin\theta + A_{im} \cos\theta \quad (9)$$

$$A_{il} = B \quad (10)$$

$$B = R_{il} \cos\theta - R_{im} \sin\theta \quad (11)$$

$$R_{im} = R_{il} \sin\theta + R_{im} \cos\theta \quad (12)$$

$$R_{il} = B \quad (13)$$

$$A_{ll} = A_{11}\cos^2\theta + A_{mm} \sin^2\theta - 2A_{lm} \sin\theta \cos\theta \quad (14)$$

$$A_{mm} = A_{ll} \sin^2\theta + A_{mm} \cos^2\theta + 2A_{lm} \sin\theta \cos\theta \quad (15)$$

$$A_{lm} = (A_{ll} - A_{mm}) \sin\theta \cos\theta + A_{lm} (\cos^2\theta - \sin^2\theta) \quad (16)$$

The above calculations are repeated until all of the pivotal elements are less than the threshold.

Subroutine NROOT

This subroutine calculates the eigenvalues, λ_i, and the matrix of eigenvectors, V, of a real square non-symmetric matrix of the special form $B^{-1}A$, where both B and A are real symmetric matrices and B is positive-definite. This subroutine is normally called by the subroutine CANOR in performing a canonical correlation analysis. The computational steps are as follows.

A symmetric matrix (storage mode 1) is formed by using the upper triangle elements of the square matrix B. Then the eigenvalues, h_i, and the matrix of eigenvectors, H, of the symmetric matrix are calculated by the subroutine EIGEN.

The reciprocal of square root of each eigenvalue is formed as follows:

$$\mu_i = \frac{1}{\sqrt{h_i}} \qquad (1)$$

where i = 1, 2, ..., m

m = order of matrix B

The matrix $B^{-1/2}$ is formed by multiplying the j^{th} column vector of H by μ_j, where j = 1, 2, ..., m.

The symmetric matrix $S = (B^{-1/2})' AB^{-1/2}$ is formed in the following two matrix multiplications:

$$Q = (B^{-1/2})' A \qquad (2)$$

$$S = QB^{-1/2} \qquad (3)$$

and eigenvalues, λ_i, and the matrix of eigenvectors, M, of S are calculated by the subroutine EIGEN.

The matrix $W = B^{-1/2}M$ is formed, and the vectors in W are normalized to form the matrix of eigenvectors, V, by the following equation:

$$V_{ij} = \frac{W_{ij}}{\sqrt{SUMV_j}} \qquad (4)$$

where i = 1, 2, ..., m

j = 1, 2, ..., m

$$SUMV_j = \sum_{i=1}^{m} W_{ij}^2 \qquad (5)$$

Subroutine ATEIG

This subroutine computes the eigenvalues of a real upper almost-triangular matrix (Hessenberg form -- see subroutine HSBG) using the double QR iteration of J. G. F. Francis.

1. Mathematical background

a. Definition of the QR iteration

Let A be a real or complex nonsingular matrix of order n. Then a decomposition of A exists of the form

$$A = Q\,R$$

where Q is unitary and R is upper triangular. If the diagonal elements of R are real and positive, Q is unique. Consider now the sequence of matrices $A^{(p)}$ defined recursively by

$$A^{(o)} = A,\ A^{(p)} = Q^{(p)}\,R^{(p)},\ A^{(p+1)} = R^{(p)}\,Q^{(p)}\ p \geq 0.$$

Note that $A^{(p+1)} = Q^{(p)*}\,A^{(p)}\,Q^{(p)}$ for $p \geq 0$; hence it follows that $A^{(p)}$ is similar to A for all p.

Furthermore, if A satisfies certain conditions, it can be proved that $A^{(p)}$ tends to an upper triangular matrix as $p \to \infty$; thus the eigenvalues of A are the diagonal elements of this limit matrix.

b. Convergence

If the moduli of the eigenvalues are distinct, the elements $a^{(p)}_{ij}$ below the main diagonal of $A^{(p)}$ tend to zero, as $d^{o}|\lambda_i|^p/|\lambda_j|^p$, the eigenvalues being subscripted so that $|\lambda_i| > |\lambda_{i+1}|$.

Thus, in general, the eigenvalues appear on the main diagonal, starting from the last position, in increasing order of moduli.

So, when the smallest eigenvalue λ_n has been found, we can reduce the order of the matrix by neglecting the last row and column and find λ_{n-1} by the same process, without any special deflation.

Note that the speed of convergence is considerably improved when the origin of the eigenvalues is shifted close to λ_n.

Such a shift, say $s^{(p)}$, can be introduced before an iteration and the opposite one afterwards. Then the iteration can be written as:

$$A^{(p)} - s^{(p)}\,I = Q^{(p)}\,R^{(p)}$$

$$A^{(p+1)} = R^{(p)}\,Q^{(p)} + s^{(p)}\,I$$

In general, $A^{(p)}_{n,n}$, for p large enough, can provide an efficient value for $s^{(p)}$.

c. Use of the Hessenberg form

The Hessenberg form is preserved under the QR iteration. Thus, a reduction of the initial matrix to the Hessenberg form can give a significant saving of computation in each iteration for the QR decomposition, the lower part of the matrix consisting only of the codiagonal terms.

Before each iteration, the codiagonal terms will be inspected. If some of these are zero, the matrix will be split according to this occurrence, and the iteration will be applied to the lower main submatrix only.

d. The double QR iteration

Let A be a diagonalizable real upper Hessenberg matrix. Such a matrix must be expected to have complex conjugate pairs of eigenvalues. If these pairs are the only eigenvalues of equal modulus, it can be shown that they will appear as the latent roots of main submatrices of order 2. In this case, if a shift is close to one of these roots, it will be complex, and we will have to deal with complex matrices, although the initial one is real. The use of the double QR iteration avoids this inconvenience.

Taking $s^{(p+1)} = \bar{s}^{(p)}$, consider the transformation giving $A^{(p+2)}$ from $A^{(p)}$:

$$A^{(p+2)} = Q^{(p+1)*}\,Q^{(p)*}\,A^{(p)}\,Q^{(p)}\,Q^{(p+1)}$$

It can be proved that the product $Q^{(p)}Q^{(p+1)}$ derives from the QR decomposition of the matrix $M = (A^{(p)} - s^{(p)}\,I)\,(A^{(p)} - s^{(p+1)}I)$, which is real.

In fact, Francis (1961, 1962) showed that only the first column m_1 of M is necessary for determining the transformation which gives $A^{(p+2)}$ from $A^{(p)}$, if they both have the Hessenberg form.

Practically, the first part of the double iteration consists of the application of an initial transformation $N_1^*\,A^{(p)}\,N_1$ where N_1 is unitary and such that $N_1^*\,m_1 = \pm\,\|m_1\|\,e_1$. This leads to a matrix which no longer has the Hessenberg form.

Thus, the remaining part of the iteration will involve the application of (n-1) successive transformations, which have the same form as the initial one whose matrices N_i are such that the resulting matrix $A^{(p+2)}$ has the Hessenberg form.

This process can fail when a subdiagonal term of the given matrix is zero. In this case, the matrix can be split, and the iteration is performed on the lower main submatrix only.

In the subroutine, N_i are Householder's matrices.

2. Programming considerations

At each iteration, the latent roots x_1 and x_2 of the lower main submatrix of order 2 are computed. Then, the following situations can occur:

a. The term $a_{n-1,n-2}$ can be taken as zero. Then, x_1 and x_2 are eigenvalues of the original matrix, and the order of the matrix is reduced by 2. IANA(N) and IANA(N-1) are set to 0 and 2 respectively.

b. The term $a_{n,n-1}$ can be taken as zero. In this case, $a_{n,n}$ is an eigenvalue of the original matrix, and the order of the matrix is reduced by 1. IANA(N) is set to 1.

c. One of the last two subdiagonal terms is stable through one iteration. Then the smaller one is considered as zero. The corresponding components of IANA are set to 0, 1, or 2, according to a. or b.

d. The maximum number of iterations is reached. In this case, the smaller of the last two subdiagonal elements is taken as zero. The corresponding components of IANA are set to 0, 1, or 2, according to a. or b.

The user can check the results by inspecting the subdiagonal terms of the matrix on return from the subroutine, according to the vector IANA, in the following way:

If for each IANA(I) containing 1 or 2, $2 \le I \le M$,

$$\left|A(I,I-1)\right| \le 10^{-7}\left(\left|RR(I)\right|+\left|RI(I)\right|\right),$$

then RR(I) and RI(I) were computed with a satisfactory accuracy.

Subroutine HSBG

This subroutine reduces an n by n real matrix A by a similarity transformation to upper almost-triangular (Hessenberg) form. Each row is reduced in turn, starting from the last one, by applying a suitable right elimination matrix, and similarity is achieved by also applying the left inverse transformation. Thus the eigenvalues of A are preserved.

1. Mathematical background

Let $A^{(p)}$ denote the matrix obtained from $A^{(o)} = A$ after reducing rows $n, n-1, \ldots, n-p+1$. The similarity which transforms $A^{(p)}$ to $A^{(p+1)}$ is as follows:

a. First we determine a pivot element $a^{(p)}_{n-p,k}$ whose column subscript k is such that

$$\left| a^{(p)}_{n-p,k} \right| = \max_i \left| a^{(p)}_{n-p,i} \right| , i = 1, 2, \ldots, n-p-1$$

b. If the pivot element $a^{(p)}_{n-p,k} = 0$, no transformations are necessary; that is, the (p+1)th similarity is the identity transformation. Otherwise, if it is necessary ($k \neq n-p-1$), we interchange the kth and (n-p-1)th columns so that the pivot element is in the subdiagonal position. The same interchange is applied to the rows of $A^{(p)}$. The resulting matrix is similar to $A^{(p)}$, and, to ease the notation, we denote it by $A^{(p)}$.

c. Define multipliers

$$b^{(p)}_j = a^{(p)}_{n-p,j} / a^{(p)}_{n-p,n-p-1} \quad j=1,2,\ldots,n-p-2$$

Then the (p+1)th similarity is given by the following.

Right elimination:

$$\bar{a}^{(p)}_{ij} = a^{(p)}_{ij} - b^{(p)}_j \, a^{(p)}_{i,n-p-1}$$

$i=1,2,\ldots,n-p$
$j=1,2,\ldots,n-p-2$

$$\bar{a}^{(p)}_{ij} = a^{(p)}_{ij} \qquad \text{other indices}$$

Left inverse transformation:

$$a^{(p+1)}_{n-p-1,j} = \bar{a}^{(p)}_{n-p-1,j} + \sum_{i=1}^{n-p-2} b^{(p)}_i \, \bar{a}^{(p)}_{ij}$$

$$a_{ij}^{(p+1)} = \bar{a}_{ij}^{(p)} \qquad i \neq n-p-1$$

Finally, $A^{(n-2)}$ will have the upper almost-triangular form.

Subroutines PECN and DPECN

These subroutines perform the economization of a polynomial for symmetric range.

A given polynomial P(x) with coefficient vector $P = (p_1, \ldots, p_n)$, representing a function f(x) with a maximum error eps over the range (-bound, bound) -- that is, $\left| f(x) - \sum_{i=1}^{n} p_i x^{i-1} \right| \leqq \text{eps for} \left| x \right| \leqq$ bound -- is reduced to a shorter coefficient vector, if possible, representing f(x) over the same range with a maximal error absolutely less than tol by means of telescoping.

The Chebyshev polynomial $T_{n-1}(t)$ has 2^{n-2} as coefficient of t^{n-1}. As a consequence, t^{n-1} may be replaced by $T_{n-1}(t)/2^{n-2}$ plus a polynomial in t of degree n-2.

This means that the telescoped polynomial:

$$P_1(x) = \sum_{i=1}^{n} p_i x^{i-1} - (p_n \cdot \text{bound}^{n-1} / 2^{n-2}) \; T_{n-1}(x/\text{bound})$$

is of degree n - 2 representing f(x) over the range $|x| \leqq$ bound with a maximal error err absolutely less than $\text{eps}_1 = \text{eps} + |p_n| \cdot \text{bound}^{n-1}/2^{n-2}$, since $|T_{n-1}(t)| \leqq 1$ for $|t| \leqq 1$.

If eps_1 is less than the tolerance tol, the procedure may be repeated with P_1 instead of P, and eps_1 instead of eps.

This iterative scheme results in a polynomial approximation to f(x) which possibly consists of fewer terms and thus may allow the computation of f(x) with less effort than the original approximation P(x).

Naturally, tol should be greater than eps.

Subroutines PECS and DPECS

These subroutines perform the economization of a polynomial for unsymmetric range.

A given polynomial P(x) with coefficient vector $P = (p_1, \ldots, p_n)$, representing a function f(x) with a maximal error eps over the range (0, bound) -- that is, $\left| f(x) - \sum_{i=1}^{n} p_i x^{i-1} \right| \leqq$ eps for $0 \leqq x \leqq$ bound -- is reduced to a shorter coefficient vector, if possible, representing f(x) over the same range with a maximal error absolutely less than tol by means of telescoping.

The shifted Chebyshev polynomial $T^s_{n-1}(t) = T_{n-1}(2t - 1)$ has 2^{2n-3} as coefficient of t^{n-1}. As a consequence, t^{n-1} may be replaced by $T^s_{n-1}(t)/2^{2n-3}$ plus a polynomial in t of degree n - 2.

This means that the telescoped polynomial

$$P_1(x) = \sum_{i=1}^{n} p_i x^{i-1} - (p_n \cdot (\text{bound})^{n-1} / 2^{2n-3}) T^s_{n-1}(x/\text{bound})$$

is of degree n - 2 representing f(x) over the range $0 \leqq x \leqq$ bound with a maximal error err absolutely less than $\text{eps}_1 = \text{eps} + \left| p_n \right| \cdot \text{bound}^{n-1} / 2^{2n-3}$, since $\left| T^s_{n-1}(t) \right| \leqq 1$ for $0 \leqq t \leqq 1$.

If eps_1 is less than the tolerance tol, the procedure may be repeated with P_1 instead of P, and eps_1 instead of eps.

This iterative scheme results in a polynomial approximation to f(x) which possibly consists of fewer terms and thus may allow the computation of f(x) with less effort than the original approximation P(x).

Naturally, tol should be greater than eps.

Subroutine POLRT

This subroutine computes the real and complex roots of a real polynomial.

Given a polynomial

$$f(z) = \sum_{n=0}^{N} a_n z^n \qquad (1)$$

let

$Z = X + iY$ be a starting value for a root of f(z).

Then:

$$Z^n = (X + iY)^n \qquad (2)$$

Define X_n as real terms of expanded equation (2).

Define Y_n as imaginary terms of expanded equation (2).

Then for:

$n = 0$

$X_o = 1.0$

$Y_o = 0.0$

$n > 0$

$$X_n = X \cdot X_{n-1} - Y \cdot Y_{n-1} \qquad (3)$$

$$Y_n = X \cdot Y_{n-1} + Y \cdot X_{n-1} \qquad (4)$$

Let:

U be the real terms of (1)
V be the imaginary terms of (1)

Then:

$$U = \sum_{n=0}^{N} a_n X_n \qquad (5)$$

$$V = \sum_{n=0}^{N} a_n Y_n \qquad (6)$$

or:

$$U = a_o + \sum_{n=1}^{N} a_n X_n \qquad (7)$$

$$V = \sum_{n=1}^{N} a_n Y_n \qquad (8)$$

$$\frac{\partial U}{\partial X} = \sum_{n=1}^{N} n \cdot X_{n-1} \cdot a_n \qquad (9)$$

$$\frac{\partial U}{\partial Y} = -\sum_{n=1}^{N} n\, Y_{n-1}\, a_n \qquad (10)$$

Note that equations (3), (4), (7), (8), (9), and (10) can be performed iteratively for n = 1 to N by saving X_{n-1} and Y_{n-1}.

Using the Newton-Raphson method for computing ΔX, ΔY, the result is:

$$\Delta X = \left(V\frac{\partial U}{\partial Y} - U\frac{\partial U}{\partial X}\right) \Bigg/ \left[\left(\frac{\partial U}{\partial X}\right)^2 + \left(\frac{\partial U}{\partial Y}\right)^2\right] \qquad (11)$$

$$\Delta Y = -\left(U\frac{\partial U}{\partial Y} + V\frac{\partial U}{\partial X}\right) \Bigg/ \left[\left(\frac{\partial U}{\partial X}\right)^2 + \left(\frac{\partial U}{\partial Y}\right)^2\right] \qquad (12)$$

after applying the Cauchy-Riemann equations.

Thus, for the next iteration:

$$X' = X + \Delta X$$

$$Y' = Y + \Delta Y$$

Subroutines PRQD and DPRQD

These subroutines find the roots of a real polynomial by means of the QD-algorithm with displacement. The progressive QD-algorithm is a fast device for calculation of all roots of a polynomial P(x) with real coefficients when there are no approximations to the roots available.

The roots of P(x) = 0 are determined by solving for the poles of Q(x)/P(x) where Q(x) is some polynomial of smaller degree than P(x). In the following, n is used as the symbol for the degree of P(x). Using the derivative P'(x) for Q(x) has the advantage that the poles are simple even in case of multiple roots of P(x).

Start of the QD-algorithm requires the continued S-fraction:

$$\cfrac{c}{x-q_1 - \cfrac{1}{1-e_1 - \cfrac{1}{x-q_2 - \cfrac{1}{1- \ddots - \cfrac{q_n}{1}}}}} \quad \text{of } P'(x)/P(x)$$

This calculation is performed using the Euclidean algorithm. By means of normalization such that the highest coefficient is 1, $Q_0(x)$ is obtained from P(x), and $P_1(x)$ from P'(x). Then e_k and q_k are calculated from the iteration scheme:

$$q_k Q_k(x) = x \cdot P_k(x) - Q_{k-1}(x), \quad k = 1,2,\ldots,n \qquad (1)$$

$$e_k P_{k+1}(x) = Q_k(x) - P_k(x), \quad k = 1,2,\ldots,n-1 \qquad (2)$$

using the fact that all elements $Q_i(x)$ and $P_i(x)$ are normalized by definition.

The following example is an illustration for this iteration scheme:

$$P(x) = 1 + 3x + 3x^2 + x^3 \quad , n = 3$$

$$Q_0(x) = x^3 + 3x^2 + 3x + 1$$

$$P_1(x) = x^2 + 2x + 1 \quad , q_1 Q_1(x) = -x^2 - 2x - 1, \; q_1 = -1$$

$$Q_1(x) = x^2 + 2x + 1 \quad , e_1 P_2(x) = 0 \quad , e_1 = 0$$

where $Q_1(x)$ is a common divisor of $P'(x)/P(x)$ and $q_1 = -1$ is the value of the real root which factors out first.

The above iteration scheme breaks down if some intermediate value of q_1 with $0 < i < n$ is equal or approximately equal to zero. In this case an error code is set to 4, which indicates that no S-fraction exists for $P'(x)/P(x)$.

If Q_0 and P_1 have a common divisor of degree j, this common divisor is obtained as Q_{n-j}, and necessarily $e_{n-j} P_{n-j+1} = 0$.

Due to roundoff errors, all coefficients of $e_{n-j} P_{n-j+1}$ cannot be expected to vanish exactly; therefore, allowance is made for coefficients of small absolute value.

If the highest coefficient of $e_{n-j} P_{n-j+1}$ is small in absolute value but some lower coefficient is not, the error code is set to 4, and the subroutine is abandoned.

The coefficients e_k, q_k obtained by the Euclidean algorithm form the first row of the QD-array indicated by superscript 0.

e_0	q_1	e_1	q_2	e_2	...	q_m	e_m
0	$q_1^{(0)}$	$e_1^{(0)}$	$q_2^{(0)}$	$e_2^{(0)}$	...	$q_m^{(0)}$	$e_m^{(0)}$
0	$q_1^{(1)}$	$e_1^{(1)}$	$q_2^{(1)}$	$e_2^{(1)}$	...	$q_m^{(1)}$	$e_m^{(1)}$
. . . . .							

Normally m is equal to n but it may be smaller if a common factor exists.

The following rows are obtained by means of the relationships:

$$q_i^{(v+1)} = q_i^{(v)} + e_i^{(v)} - e_{i-1}^{(v+1)}, \quad i = 1, \ldots, m \tag{3}$$

$$e_i^{(v+1)} = \frac{e_i^{(v)} \cdot q_{i+1}^{(v)}}{q_i^{(v+1)}}, \quad i = 1, \ldots, m-1 \tag{4}$$

together with $e_0^{(v)} = e_m^{(v)} = 0$.

Let x_i denote the roots of P(x) ordered in decreasing absolute value. If P(x) has only roots of different absolute value, there is convergence of the q_k-column to the value x_k. Complex roots are indicated by oscillation of certain q-values.

If x_k and x_{k+1} are of equal absolute value, then the roots of

$$x^2 - (q_k^{(v+1)} + q_{k+1}^{(v)})\, x + q_k^{(v)} q_{k+1}^{(v)} = 0 \tag{5}$$

converge to x_k and x_{k+1}. The same reasoning applies if the relation $|x_k| = |x_{k+1}|$ holds only approximately.

The QD-algorithm in the form (3), (4) suffers from the fact that convergence is rather slow. By means of displacement of the origin a form is obtained which is asymptotically of quadratic convergence.

The strategy is as follows. Start with displacement $t = 0$.

I. As soon as convergence is indicated to a real root -- that is, $e_{m-1}^{(v)}$ is sufficiently small (internal test value 0.01) -- perform a displacement by the amount $q_m^{(v)}$.

Starting with $q_k^{(v)}$, $e_k^{(v)}$, use instead of (3), (4) the iteration scheme:

$$t = t + q_m^{(v)} \tag{6}$$

$$q_k^{(v+1)} = q_k^{(v)} + e_k^{(v)} - e_{k-1}^{(v+1)} - q_m^{(v)}$$

$$, \quad k = 1, 2, \ldots, m \tag{7}$$

$$e_k^{(v+1)} = q_{k+1}^{(v)} \cdot e_k^{(v)} \Big/ q_k^{(v+1)}$$

$$, \quad k = 1, 2, \ldots, m-1 \tag{8}$$

Values $e_0^{(v+1)}$ and $e_m^{(v)}$ are thereby set equal to zero.

II. If convergence is indicated to a root pair -- that is, $e_{m-2}^{(v)}$ is less than $e_{m-1}^{(v)}$ and sufficiently small (internal test value 0.01) -- calculate the discriminant of the quadratic equation (5):

$$D = p * p - q_m^{(v)} * q_{m-1}^{(v)}$$

with

$$P = 0.5\,(q_{m-1}^{(v)} + e_{m-1}^{(v)} + q_m^{(v)})$$

If D is positive, provide for a real displacement of amount $P - \sqrt{D}$ or $P + \sqrt{D}$, whichever has the smaller absolute value, and proceed according to (7), (8).

If D is negative, three complex displacements are applied in sequence: the first by amount $P + i\sqrt{|D|}$, the second by $-2i\sqrt{|D|}$, and the third by $V + i\sqrt{|D|}$, resulting in a total real displacement of amount P.

Instead of (6), (7), (8) the following iteration scheme is then obtained. Starting with:

$$t = t + P \tag{9}$$

$$q_1^* = q_1^{(v)} + e_1^{(v)} - P \tag{10}$$

$$P_1 = -D/q_1^{*2} \tag{11}$$

$$e_1^* = e_1^{(v)} q_2^{(v)} / \left[q_1^* (1 + p_1)\right] \tag{12}$$

$$q_1^{**} = q_1^* + e_1^* \tag{13}$$

calculate for $k = 2, 3, \ldots, m$:

$$q_k^* = q_k^{(v)} + e_k^{(v)} - e_{k-1}^* - P \tag{14}$$

$$e_{k-1}^{**} = e_{k-1}^* q_k^* / q_{k-1}^{**} \tag{15}$$

$$p_k = p_{k-1} (q_{k-1}^{**} / q_k^*)^2 \tag{16}$$

$$q_{k-1}^{(v+3)} = q_{k-1}^{**} + e_{k-1}^{**} - e_{k-2}^{(v+3)} \tag{17}$$

$$e_k^* = q_{k+1}^{(v)} e_k^{(v)} / \left[q_k^* (1+p_k)\right] \tag{18}$$

$$q_k^{**} = q_k^* + e_k^* - e_{k-1}^{**} \tag{19}$$

$$e_{k-1}^{(v+3)} = (e_{k-1}^{**} q_k^{**} / q_{k-1}^{(v+3)}) (1 + p_k) \tag{20}$$

Finally set:

$$q_m^{(v+3)} = q_m^{**} - e_{m-1}^{(v+3)} \tag{21}$$

Values $e_0^{(v+3)}$, $e_m^{(v)}$ and $q_{m+1}^{(v)}$ are thereby set equal to zero.

III. If none of the values $e_{m-1}^{(v)}$ and $e_{m-2}^{(v)}$ is sufficiently small, the relationship (3), (4) is used with no displacement at all.

Regarding termination of the iterative scheme given by I., II., III. there are two possibilities:

1. If $e_{m-1}^{(v)}$ is negligible (internal test value is 10^{-6} in single precision and 10^{-16} in double precision), a real root is factored out.

2. If $e_{m-2}^{(v)}$ is negligible (with the same internal test values), a pair of roots is factored out.

A maximum of ten times the number of coefficients using I., II. or III. is allowed. At every iteration step for one and the same root or root pair, the internal test value for convergence and the internal test value for acceptance of a displacement are increased by ten percent.

In case of convergence:

1. For a real root --
   real part of root = $t + q_m$
   complex part of root = 0
2. For a real root pair (characterized by $D > 0$) --
   real part of first root = $t + P + \sqrt{D}$
   complex part of first root = 0
   real part of second root = $t + P - \sqrt{D}$
   complex part of second root = 0
3. For a complex root pair (characterized by $D < 0$) --
   real part of first root = $t + P$
   complex part of first root = $\sqrt{-D}$
   real part of second root = $t + P$
   complex part of second root = $-\sqrt{-D}$

As soon as a root or root pair has been factored out, m is reduced by 1 or 2 respectively and the whole procedure I., II., III. is repeated with original values of internal test values, until m = 0 -- that is, all roots have been calculated -- or m = 1, when the last real root is factored immediately. If $P'(x)$, $P(x)$ have a common divisor, the whole process is repeated for this common divisor. Thus, the complete factorization of the original polynomial $P(x)$ is obtained.

Some remarks are in order:

1. The QD-algorithm is a nonlinear relationship and therefore sensitive to roundoff errors. Small intermediate q-values cause loss of accuracy. Therefore, all divisors are checked before division is actually performed. If a divisor is small in

absolute value due to loss of significant digits, the error parameter is set to 3 indicating possible instability of calculation, and further calculation is bypassed.

2. If a maximum of 10 * n iteration steps is insufficient for calculation of all roots, the error parameter is set to 1, indicating poor convergence. Further calculation is bypassed again.

3. If the original polynomial has a degree less than one, the error parameter is set to 2 indicating that no root exists.

4. If, in case of a complex displacement, q^{**}_{m-1} or q^{*}_{m} gets very small due to loss of significant digits, and the calculated $e^{(v+3)}_{m-2}$ is less than the internal test value TOL, a pair of roots is calculated from the quadratic equation:

$$x^2 - x\cdot(q^{**}_{n-1} + q^{*}_{n} - e^{(v+3)}_{n-2}) + (q^{**}_{n-1} - e^{*}_{n-1}) \left[q^{*}_{n} - e^{*}_{n-1}\,p_{n-1} - q^{*}_{n}\,\frac{e^{**}_{n-2}}{q^{(v+3)}_{n-2}}(1+p_{n-1})\right] \qquad (22)$$

which is easily obtained from (5).

5. A final test of accuracy is made after calculation of all roots of the given polynomial. The calculated roots are used for calculation of the corresponding coefficient vector. If this calculated coefficient vector has less than a specified number of correct digits (the maximal relative error must be less than TOL), the error parameter is set to -1 indicating that calculation of all roots was successful only with poor accuracy of results.

Subroutines PRBM and DPRBM

These subroutines compute the real and complex roots of a real polynomial

$$p(x) = c_1 + c_2 x + \ldots + c_{n+1} x^n$$

using Bairstow's iterative method of quadratic factorization.

1. Mathematical background

Every real polynomial of degree greater than one can be factored in the form $p(x) = q(x)r(x)$ where $q(x) = x^2 + q_2 x + q_1$ is quadratic. If q(x) is reducible, that is, if q(x) is a product of two real linear factors, p(x) has a pair of real roots; and if q(x) is irreducible, p(x) has a complex conjugate pair of roots. If r(x) has degree exceeding one, it too may be factored as above, and so on. The quadratic factors of p(x) are determined by subroutines PQFB and DPQFB. See those routines for a detailed description of Bairstow's method.

2. Programming considerations

The subroutines need only the coefficient vector $C = (c_1, \ldots, c_{IC})$ and the number of coefficients IC = n+1 as input. They give as output an error parameter IER, the number of computed roots IR, the real and complex parts of the computed roots in vectors RR and RC, and -- if all the roots have been computed -- the coefficients of the polynomial with the computed roots stored in the vector POL.

If p(x) is a constant, that is, if $c_2 = c_3 = \ldots = 0$, we set IR = 0, IER = 2, and return to the call program.

Otherwise, let $IR = \max \left\{ j \mid c_j \neq 0 \right\}$. Then we may write:

$$p(x) = c_{IR}\, \bar{p}(x)\, \bar{\bar{p}}(x)$$

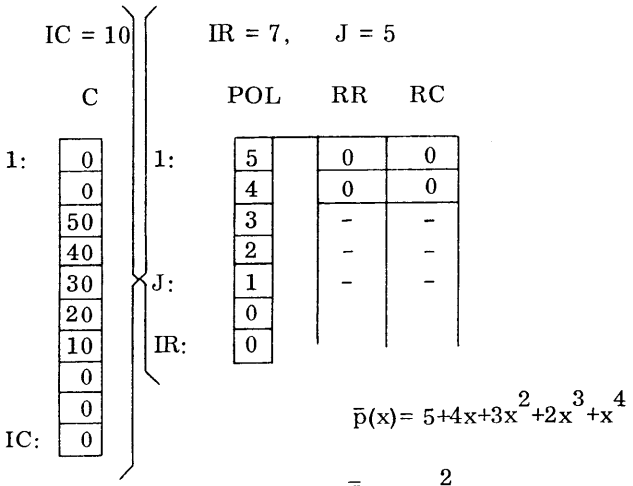
$$\bar{p}(x) = p_1 + p_2 x + \ldots + p_J x^{J-1}$$

$$\bar{\bar{p}}(x) = x^K$$

where $K \geq 0$, $J = IR - K$, and $p_j = c_{K+j}/c_{IR}$, $j = 1, 2, \ldots, J$, and $p_1 \neq 0$. The coefficients of $\bar{p}$ are stored in POL(1) up to POL(J) and POL(J+1) up to POL(IR) are initialized to zero. If an exponential overflow occurs during the calculation of the p_i we again set IR = 0, IER = 2 and return control to the calling program.

The following example illustrates the procedure so far:

$$p(x) = 0+0\cdot x+50\cdot x^2 + 40\cdot x^3 + 30\cdot x^4 + 20\cdot x^5 + 10\cdot x^6 + 0\cdot x^7 + 0\cdot x^8 + 0\cdot x^9$$



$$\bar{p}(x) = 5+4x+3x^2+2x^3+x^4$$

$$\bar{\bar{p}}(x) = x^2$$

3. The Bairstow iteration

Upon entering the main part of the routine we assume

$$p(x) = c_{IR}\,\bar{p}(x)\,\bar{\bar{p}}(x)$$

where

$$\bar{p}(x) = p_1 + p_2x + \ldots + p_jx^{j-1} \qquad (p_j = 1)$$

is the polynomial with the unknown roots, and

$$\bar{\bar{p}}(x) = p_{j+1} + p_{j+2}x + \ldots + p_{IR}x^{IR-j-1} + x^{IR-j}$$

is the polynomial generated from the computed roots. The coefficients $p_1, p_2, \ldots, p_{IR}$ are stored in POL(1), POL (2), . . ., POL(IR). Now there are three possibilities:

(1) j = 1. All the roots have been computed. IR is decreased by 1 in order to record the number of computed roots and control is passed on to the last phase of the subroutine (the appendix).

(2) j = 2. The last root is $x = -p_1$. This is recorded by setting $RR(IR - 1) = -p_1$ and $RC(IR - 1) = 0$. The polynomial $\bar{p}(x)$ is multiplied by the linear factor $x + p_1$, occupying after multiplication the locations POL(2) up to POL(IR). IR is decreased by 1, thus recording the number of computed roots, and control is passed on to the appendix.

(3) $j \geq 3$. In this case the polynomial $\bar{p}(x)$ is factored by means of subroutine PQFB or DPQFB, where the quadratic factor $q_1 + q_2x + x^2$ of the previous step is used as the initial guess (in the first factorization x^2 is used). If factorization is not successful, it is restarted with the initial guesses $-q_1+q_2x+x^2$, $-q_1-q_2x+x^2$ and $q_1-q_2x+x^2$. If none of these trials leads to a successful factorization, q_1 and q_2 are increased by 1 (at most nine times). If after a maximum of 40 trials factorization is still unsuccessful, IR is decreased by J, thus recording the number of computed roots, and the rest of the subroutine is bypassed giving the error message IER = 3.

If any one of these trials is successful, $\bar{p}(x)$ is divided by the determined quadratic factor, occupying after division the locations POL(1) up to POL (J-2). Then the polynomial $\bar{\bar{p}}(x)$ is multiplied by the same quadratic factor and occupies after multiplication the locations POL(J-1) up to POL(IR). At least the quadratic equation is solved, and the real and complex parts of the two roots are stored in the corresponding locations of RR and RC. After decreasing j by 2, the main part of the subroutine is reentered.

Assuming that all the roots of the polynomial have been computed, the coefficients of the polynomial $\bar{\bar{p}}(x)$ are shifted into the locations POL(1) up to POL(IR), and POL(IR+1) is set to 1 (IR is the number of computed roots).

Furthermore, the absolutely greatest error of the coefficients of the resulting polynomial is generated using the formula

$$a = \max_i |\,\delta_i\,|$$

where $\delta_i = \begin{cases} (p_i - c_i)/c_i & \text{if } c_i \neq 0 \\ p_i & \text{if } c_i = 0 \end{cases}$ $\quad i = 1, \ldots, IR$

The number a is stored in RR(IR+1) giving the user some indication of the accuracy reached by the subroutines. The warning IER = -1 is given if $a > \epsilon$ ($\epsilon = 10^{-3}$ in single precision and $\epsilon = 10^{-6}$ in double precision). The warning IER = -1 is overridden by the warning IER = 1, which is given if any quadratic factorization fails to converge. (See PQFB.)

Subroutines PQFB and DPQFB

These subroutines use Bairstow's iterative method to find an approximation to a quadratic factor of a given polynomial $p(x) = c_1+c_2x+\ldots+c_{n+1}x^n$ (deg $p(x) = n \geq 2$, c_i real).

1. Mathematical background

Let $Q(x) = x^2 + Q_2x+Q_1$ be any quadratic polynomial with real coefficients. Then $p(x) = R(x)Q(x) + B(Q_1, Q_2)x + C(Q_1, Q_2)$, where $C(Q_1, Q_2) = a_1$, $B(Q_1, Q_2) = a_2$, $R(x) = a_3+a_4x+\ldots+a_{n+1}x^{n-2}$, and

$$a_i = \begin{cases} 0 & \text{if } i > n+1 \\ c_i - Q_2 a_{i+1} - Q_1 a_{i+2} & \text{if } i=n+1,\ldots,2 \\ c_1 - Q_1 a_3 & \text{if } i=1 \end{cases}$$

Of course, if $q(x)=x^2 + q_2x+q_1$ is a factor of $p(x)$, then:

$$\left.\begin{aligned} C(q_1, q_2) &= 0 \\ \text{and} \\ B(q_1, q_2) &= 0 \end{aligned}\right\}$$

Suppose that $Q(x)$ is an approximation to $q(x)$; then Q_1 and Q_2 are approximations to q_1 and q_2 respectively, and if ΔQ_1 and ΔQ_2 are such that:

$$\left.\begin{aligned} q_1 &= Q_1 + \Delta Q_1 \\ \text{and} \\ q_2 &= Q_2 + \Delta Q_2 \end{aligned}\right\}$$

Then:

$$\left.\begin{aligned} C(Q_1 + \Delta Q_1, Q_2 + \Delta Q_2) &= 0 \\ \text{and} \\ B(Q_1 + \Delta Q_1, Q_2 + \Delta Q_2) &= 0 \end{aligned}\right\} \qquad (1)$$

Instead of solving (1) for ΔQ_1 and ΔQ_2, we solve:

$$\left.\begin{aligned} C(Q_1, Q_2) + \frac{\partial}{\partial Q_1} C(Q_1, Q_2)\,\Delta Q_1 \\ + \frac{\partial}{\partial Q_2} C(Q_1, Q_2)\,\Delta Q_2 = 0 \\ \text{and} \\ B(Q_1, Q_2) + \frac{\partial}{\partial Q_1} B(Q_1, Q_2)\,\Delta Q_1 \\ + \frac{\partial}{\partial Q_2} B(Q_1, Q_2)\,\Delta Q_2 = 0 \end{aligned}\right\} \qquad (2)$$

for ΔQ_1 and ΔQ_2. Equation (2) is the linearization of (1). To solve (2) we must find $\frac{\partial}{\partial Q_i} B(Q_1, Q_2)$ and $\frac{\partial}{\partial Q_i} C(Q_1, Q_2)$, $i = 1, 2$. To do this we define

$$r_i = \begin{cases} a_i & \text{if } i>1 \\ a_1 - Q_2 B & \text{if } i=1 \end{cases}$$

and then

$$s_i = \begin{cases} 0 & \text{if } i>n+1 \\ r_i - Q_2 s_{i+1} - Q_1 s_{i+2} & \text{if } i = n+1, n, n-1,\ldots,1 \end{cases}$$

Now:

$$\left.\begin{aligned} \frac{\partial r_i}{\partial Q_2} &= -r_{i+1} - Q_2 \frac{\partial r_{i+1}}{\partial Q_e} - Q_1 \frac{\partial r_{i+2}}{\partial Q_2} \\ \text{and} \\ \frac{\partial r_i}{\partial Q_1} &= -r_{i+2} - Q_2 \frac{\partial r_{i+1}}{\partial Q_1} - Q_1 \frac{\partial r_{i+2}}{\partial Q_1} \end{aligned}\right\}$$

By an easy induction on i it follows that:

$$\frac{\partial r_i}{\partial Q_2} = -S_{i+1} \quad \text{and} \quad \frac{\partial r_i}{\partial Q_1} = -S_{i+2}, \qquad i=1,\ldots,n+1$$

In particular:

$$\left.\begin{aligned} \frac{\partial B}{\partial Q_1} &= \frac{\partial a_2}{\partial Q_1} = \frac{\partial r_2}{\partial Q_1} = -S_4 \\ \frac{\partial B}{\partial Q_2} &= \frac{\partial a_2}{\partial Q_2} = \frac{\partial r_2}{\partial Q_2} = -S_3 \\ \frac{\partial C}{\partial Q_1} &= \frac{\partial a_1}{\partial Q_1} = \frac{\partial r_1}{\partial Q_1} + Q_2 \frac{\partial r_2}{\partial Q_1} = \\ & -S_3 - Q_2 S_4 \\ \frac{\partial C}{\partial Q_2} &= \frac{\partial a_1}{\partial Q_2} = \frac{\partial r_1}{\partial Q_2} + Q_2 \frac{\partial r_2}{\partial Q_2} + r_2 = \\ & -S_2 - Q_2 S_3 + r_4 \end{aligned}\right\}$$

and if we let:

$$\left.\begin{aligned} C_1 &= s_4 \\ B_1 &= s_3 \\ A_1 &= s_2 - r_2 \\ A &= r_1 \end{aligned}\right\}$$

then we can rewrite (2) as:

$$\left.\begin{aligned} (B_1 + Q_2 C_1)\,\Delta Q_1 + (A_1 + Q_2 B_1)\,\Delta Q_2 &= A + Q_2 B \\ C_1\,\Delta Q_1 + \qquad B_1\,\Delta Q_2 &= B \end{aligned}\right\}$$

which simplifies to:

$$\left.\begin{aligned} B_1\,\Delta Q_1 + A_1\,\Delta Q_2 &= A \\ C_1\,\Delta Q_1 + B_1\,\Delta Q_2 &= B \end{aligned}\right\} \qquad (3)$$

Solving (3) we find that:

$$\left.\begin{aligned} \Delta Q_1 &= \frac{A_1 B - B_1 A}{A_1 C_1 - B_1^2} \\ \Delta Q_2 &= \frac{C_1 A - B_1 B}{A_1 C_1 - B_1^2} \end{aligned}\right\}$$

We can now replace Q_i by $Q_i + \Delta Q_i$, $i = 1, 2$, and repeat the above procedure.

2. Programming considerations

The input consists of a vector C of polynomial coefficients (C(1) is the constant term), the dimension IC of C, a vector Q of dimension 4 with Q(1) and Q(2) containing initial guesses for the coefficients of a quadratic factor, and an upper bound LIM for the number of iterations to be performed.

First $J \le IC$ is determined such that $C(J) \neq 0$, $C(K) = 0$ for $K > J$. If $J \le 1$, there is no computation and the error parameter IER is set to -1. If $J > 1$, the polynomial is normalized by dividing all the coefficients of C by C(J), the coefficient of the leading term. If overflow occurs during the normalization, computation is terminated and IER is set to -1. If no overflow occurs, the degree (J-1) of the polynomial p(x) is tested; if p is of degree 1, there is no further computation and IER is set to -2; if p is of degree 2, Q(1) and Q(2) are set to C(1) and C(2) respectively, Q(3) and Q(4) are set to zero, IER is set to zero, and computation is terminated; if p is of degree greater than 2, the main part of the subroutine--the Bairstow iterative procedure--is entered.

Every approximation $Q(x) = x^2 + Q_2 x + Q_1$ to a quadratic factor of p has associated with it a constant CC, called the norm of the modified linear remainder and hereafter referred to as the norm. It is given by $CC = CA \cdot |A| + CB \cdot |B|$ where:

$$CA = \begin{cases} 1 & \text{if } |C(1)| \le |C(2)| \\ \left|\dfrac{C(2)}{C(1)}\right| & \text{if } |C(1)| > |C(2)| \end{cases}$$

and

$$CB = \begin{cases} \left|\dfrac{C(1)}{C(2)}\right| & \text{if } |C(1)| < |C(2)| \\ 1 & \text{if } |C(1)| \ge |C(2)| \end{cases}$$

Since there is no guarantee that the Bairstow method will converge, several accuracy tests are performed at the end of each iteration. Depending on the outcome of these tests, which in part involve CC, either the computation is terminated or another iteration is performed.

Letting:

$$EPS = \begin{cases} 10^{-6} & \text{in single precision} \\ 10^{-14} & \text{in double precision} \end{cases}$$

and:

$$EPS1 = \begin{cases} 10^{-3} & \text{in single precision} \\ 10^{-16} & \text{in double precision} \end{cases}$$

the tests are described below.

a. If $|A| \le EPS^* |C(1)|$ and $|B| \le EPS^* |C(2)|$, or if $|\Delta Q_1| \le EPS^* |Q_1|$ and $|\Delta Q_2| \le EPS^* |Q_2|$, computation is terminated after setting IER = 0, $Q(1) = Q_1$, $Q(2) = Q_2$, Q(3) = A, and Q(4) = B.

b. If $|\Delta Q_1| \le EPS1^* |Q_1|$ and $|\Delta Q_2| \le EPS1^* |Q_2|$, and if $|\Delta Q_1/Q_1|$ or $|\Delta Q_2/Q_2|$ is not smaller than its value for the previous iteration (this is generally due to roundoff errors), computation is terminated after setting IER = 0, $Q(1) = QQ_1$, $Q(2) = QQ_2$, Q(3) = AA, and Q(4) = BB where QQ_1, QQ_2, AA, and BB are the values of Q_1, Q_2, A, and B belonging to

a previous iteration--the iteration with the smallest norm.

c. If no convergence occurs within LIM iterations and if the last norm is not greater than CD/10, where CD is the norm associated with the quadratic factor x^2, results are generated as in b. with the exception that IER is set to 1. If the last norm is greater than CD/10:

(1) If the initial guess for the quadratic factor was x^2, the results are generated as in b. with the exception that IER is set to -3.

(2) If the initial guess for the quadratic factor was not x^2, the subroutine restarts with x^2 as the initial guess.

d. If exponential overflow or division by 0 occurs during any iteration, results are generated as in b. with the exception that IER is set to -3.

Subroutines CNP and DCNP

These subroutines compute the values of the Chebyshev polynomials for a given argument x and orders zero up to N. The Chebyshev polynomial $T_n(x)$ satisfies the recurrence equation

$$T_{n+1}(x) = 2x \cdot T_n(x) - T_{n-1}(x)$$

with starting values $T_0(x) = 1$, $T_1(x) = x$. From this equation it follows immediately that roundoff errors grow at worst linearly under the tacit assumption that the argument has an absolute value less than one.

If e_{n+r} is the error in $T_{n+r}(x)$ due to a single roundoff error e in $T_n(x)$:

$$e_{n+r+1} = 2x \cdot e_{n+r} - e_{n+r-1}$$

with initial conditions $e_n = e$, $e_{n-1} = 0$.

The solution of this difference equation has its maximum for $|x| = 1$:

$$e_{n-1} = 0,\ e_n = e,\ \left|e_{n+1}\right| = 2e, \ldots, \left|e_{n+r}\right| = (r+1)e$$

The order is assumed to be zero for negative values of N.

Subroutines CNPS and DCNPS

These subroutines compute the value of a series expansion in Chebyshev polynomials. The Chebyshev polynomial $T_n(x)$ satisfies the recurrence equation

$$T_{n+1}(x) = 2x \cdot T_n(x) - T_{n-1}(x)$$

with starting values $T_0(x) = 1$, $T_1(x) = x$.

An n-term expansion in Chebyshev polynomials with coefficient vector $C = (c_1, \ldots, c_n)$ is evaluated by means of a backward iteration scheme:

$$\text{Arg} = 2x,\ H_1 = 0,\ H_0 = 0$$

$$\left.\begin{aligned} H_2 &= H_1 \\ H_1 &= H_0 \\ H_0 &= \text{Arg} \cdot H_1 - H_2 + c_{n-i+1} \\ Y &= (c_1 - H_2 + H_0)/2. \end{aligned}\right\} \text{ for } i = 1, \ldots, n$$

This gives result $Y(x) = \sum_{i=1}^{n} c_i T_{i-1}(x)$.

Calculation is bypassed in case of a nonpositive value of the dimension n.

Subroutines TCNP and DTCNP

These subroutines transform a given series expansion in Chebyshev polynomials to a polynomial. The independent variable x of the given expansion is thereby substituted by the independent variable z of the resulting polynomial using the linear transformation $x = A * z + B$ or $z = (x - B)/A$.

This means:
$$\sum_{i=1}^{N} C_i * T_{i-1}(A * z + B)$$

$$= \sum_{i=1}^{N} POL_i * z^{i-1}$$

Calculation is bypassed in case of a nonpositive value of the dimension N.

The range (-1, +1) in x is transformed to the range (z_l, z_r) in z with $z_l = -(1+B)/A$ and $z_r = (1-B)/A$, or vice versa, $A = 2/(z_r - z_l)$ and $B = -(z_r + z_l)/(z_r - z_l)$.

The Chebyshev polynomial $T_n(x)$ satisfies the recurrence equation

$$T_{n+1}(x) = 2x \cdot T_n(x) - T_{n-1}(x)$$

with starting values $T_0(x) = 1$, $T_1(x) = x$. The transformation is performed by means of a forward iteration scheme:

1. The coefficient vector of the Chebyshev polynomial $T_i(x)$ is calculated from the coefficient vectors of $T_{i-1}(x)$, $T_{i-2}(x)$ using the recurrence equation, for i = 3, ..., N.

2. The resulting polynomial coefficient vector is obtained by summation of c_i times coefficient vector of $T_{i-1}(x)$ over i, for i = 1, ..., N.

Subroutines CSP and DCSP

These subroutines compute the values of the shifted Chebyshev polynomials for a given argument x and orders zero up to N. The shifted Chebyshev polynomial satisfies the recurrence equation.

$$T^S_{n+1}(x) = 2\ (2\ x-1)\ T^S_n(x) - T^S_{n-1}(x)$$

with starting values $T^S_0(x) = 1$, $T^S_1(x) = 2 \cdot x - 1$. From this equation, it follows immediately that roundoff errors grow at worst linearly under the tacit assumption that the argument values are between zero and one.

If e_{n+r} is the error in $T^S_{n+r}(x)$ due to a single rounding error e in $T^S_n(x)$:

$$e_{n+r+1} = 2\ (2\ x-1)\ e_{n+r} - e_{n+r-1}$$

with initial conditions $e_n = e$, $e_{n-1} = 0$.

The solution of this difference equation has its maximum for x = 1 or x = 0.

$$e_{n-1} = 0,\ e_n = e,\ \left|e_{n+1}\right| = 2e,\ \ldots,\ \left|e_{n+r}\right|$$

$$= (1 + r)\ e.$$

The order is assumed to be zero for negative values of N.

Subroutines CSPS and DCSPS

These subroutines compute the value of a series expansion in shifted Chebyshev polynomials. The shifted Chebyshev polynomial $T^S_n(x)$ satisfies the recurrence equation

$$T^S_{n+1}(x) = 2\,(2x-1)\,T^S_n(x) - T^S_{n-1}(x)$$

with starting values $T^S_0(x) = 1$, $T^S_1(x) = 2x - 1$.

An n-term expansion in shifted Chebyshev polynomials with coefficient vector $C = (c_1, \ldots, c_n)$ is evaluated by means of a backward iteration scheme:

$$\text{Arg} = 4x - 2,\quad H_1 = 0,\quad H_0 = 0$$

$$\left.\begin{aligned} H_2 &= H_1 \\ H_1 &= H_0 \\ H_0 &= \text{Arg} \cdot H_1 - H_2 + c_{n-i+1} \\ Y &= (c_1 - H_2 + H_0)/2. \end{aligned}\right\} \text{ for } i = 1, \ldots, n$$

This gives the result $Y(x) = \sum_{i=1}^{n} c_i\, T^S_{i-1}(x)$.

Calculation is bypassed in case of a nonpositive value of the dimension n.

Subroutines TCSP and DTCSP

These subroutines transform a given series expansion in shifted Chebyshev polynomials to a polynomial. The independent variable x of the given expansion is thereby substituted by the independent variable z of the resulting polynomial using the linear transformation x = A * z + B or z = (x - B)/A.

This means:
$$\sum_{i=1}^{N} C_i * T^S_{i-1}(A * z + B)$$
$$= \sum_{i=1}^{N} POL_i * z^{i-1}$$

Calculation is bypassed in case of a nonpositive value of the dimension N.

The range (0, +1) in x is transformed to the range (z_l, z_r) in z with $z_l = -B/A$ and $z_r = (1-B)/A$ or vice versa, $A = 1/(z_r - z_l)$ and $B = -z_l/(z_r - z_l)$.

The shifted Chebyshev polynomial $T^S_n(x)$ satisfies the recurrence equation

$$T^S_{n+1}(x) = 4 \times T^S_n(x) - 2\, T^S_n(x) - T^S_{n-1}(x)$$

with starting values $T^S_0(x) = 1$, $T^S_1(x) = 2 x - 1$. The transformation is performed by means of a forward iteration scheme:

1. The coefficient vector of the shifted Chebyshev polynomial $T^S_i(x)$ is calculated from the coefficient vectors of $T^S_{i-1}(x)$, $T^S_{i-2}(x)$ using the recurrence equation, for i = 3, ..., N.

2. The resulting polynomial coefficient vector is obtained by summation of c_i times $T^S_{i-1}(x)$ over i, for i = 1, ..., N.

Subroutines HEP and DHEP

These subroutines compute the values of the Hermite polynomials for a given argument x and orders zero up to N. The Hermite polynomial $H_n(x)$ satisfies the recurrence equation

$$H_{n+1}(x) = 2\,(x \cdot H_n(x) - n \cdot H_{n-1}(x))$$

with starting values $H_0(x) = 1$, $H_1(x) = 2\,x$.

The order is assumed to be zero for negative values of N.

Subroutines HEPS and DHEPS

These subroutines compute the value of a series expansion in Hermite polynomials. The Hermite polynomial $H_n(x)$ satisfies the recurrence equation

$$H_{n+1}(x) = 2\,(x \cdot H_n(x) - n \cdot H_{n-1}(x))$$

with starting values $H_0(x) = 1$, $H_1(x) = 2x$.

An n-term expansion in Hermite polynomials with coefficient vector $C = (c_1, \ldots, c_n)$ is evaluated by means of a forward iteration scheme:

$$\left.\begin{aligned} Y &= c_1,\ H_0 = 1,\ H_1 = 2 \cdot x \\ H_2 &= x \cdot H_1 - (i-1)\,H_0 \\ H_0 &= H_1 \\ H_1 &= H_2 + H_2 \\ Y &= Y + c_i \cdot H_0 \end{aligned}\right\} \quad \text{for } i = 2, \ldots, n$$

This gives the result $Y(x) = \sum_{i=1}^{n} c_i \cdot H_{i-1}(x)$.

Calculation is bypassed in case of a nonpositive value of the dimension n.

Subroutines THEP and DTHEP

These subroutines transform a given series expansion in Hermite polynomials to a polynomial. The independent variable x of the given expansion is thereby substituted by the independent variable z of the resulting polynomial using the linear transformation x = A * z + B or z = (x-B)/A.

This means:
$$\sum_{i=1}^{N} C_i * H_{i-1}(A * z + B)$$
$$= \sum_{i=1}^{N} POL_i * z^{i-1}$$

Calculation is bypassed in case of a nonpositive value of the dimension N.

The range (-c, + c) in x is transformed to the range (z_l, z_r) in z with $z_l = -(c + B)/A$ and $z_r = (c-B)/A$, or vice versa, $A = 2c/(z_r - z_l)$ and $B = -c(z_r + z_l)/(z_r - z_l)$.

The Hermite polynomial $H_n(x)$ satisfies the recurrence equation

$$H_{n+1}(x) = 2(x \cdot H_n(x) - n \cdot H_{n-1}(x))$$

with starting values $H_0(x) = 1$, $H_1(x) = 2x$.

The transformation is performed by means of a forward iteration scheme:

1. The coefficient vector of the Hermite polynomial $H_i(x)$ is calculated from the coefficient vectors of $H_{i-1}(x)$, $H_{i-2}(x)$ using the recurrence equation, for i = 3, . . ., N.

2. The resulting polynomial coefficient vector is obtained by summation of c_i times coefficient vector of $H_{i-1}(x)$ over i, for i = 1, . . ., N.

Subroutines LAP and DLAP

These subroutines compute the values of the normalized Laguerre polynomials for a given argument x and orders zero up to N. The polynomial $L_n(x)/n!$, termed $L_n(x)$ below, satisfies the recurrence equation

$$L_{n+1}(x) = \left[(2n + 1 - x)\, L_n(x) - n\, L_{n-1}(x)\right]/(n+1)$$

with starting values $L_0(x) = 1$, $L_1(x) = 1 - x$.

For reasons of economy and numerical stability the recurrence equation is used in the form

$$L_{n+1}(x) = L_n(x) - L_{n-1}(x) + L_n(x)$$

$$-\left[(1+x)\, L_n(x) - L_{n-1}(x)\right]/(n+1).$$

For large values of n the last term is negligible, giving the approximation

$$L_{n+1}(x) = 2\, L_n(x) - L_{n-1}(x).$$

This form shows that roundoff errors grow at worst linearly as long as x is small compared to n.

If e_{n+r} is the error in $L_{n+r}(x)$ due to a single rounding error e in $L_n(x)$, the approximation is:

$$e_{n+r+1} = 2 \cdot e_{n+r} - e_{n+r-1}$$

with initial conditions $e_n = e$, $e_{n-1} = 0$. This implies:

$$e_{n+1} = 2e,\ e_{n+2} = 3 \cdot e,\ \ldots,\ e_{n+r} = (r+1)e$$

The order is assumed to be zero for negative values of N.

Subroutines LAPS and DLAPS

These subroutines compute the value of a series expansion in normalized Laguerre polynomials. The polynomial $L_n(x)/n!$, termed $L_n(x)$ below, satisfies the recurrence equation

$$L_{n+1}(x) = 2 \cdot L_n(x) - L_{n-1}(x) - \left[(1 + x) \cdot L_n(x) - L_{n-1}(x)\right] /(n+1)$$

with starting values $L_0(x) = 1$, $L_1(x) = 1 - x$.

An n-term expansion in Laguerre polynomials with coefficient vector $C = (c_1, \ldots, c_n)$ is evaluated by means of a forward iteration scheme:

$$Y = c_1,\ H_0 = 1,\ H_1 = 1 - x,\ T = 1 - x$$

$$\left.\begin{aligned} H_2 &= H_1 - H_0 + H_1 - (T \cdot H_1 - H_0)/i \\ H_0 &= H_1 \\ H_1 &= H_2 \\ Y &= Y + c_i \cdot H_0 \end{aligned}\right\} \text{ for } i = 2, \ldots, n$$

This gives the result $Y(x) = \sum_{i=1}^{n} c_i \cdot L_{i-1}(x)$.

Calculation is bypassed in case of a nonpositive value of the dimension n.

Subroutines TLAP and DTLAP

These subroutines transform a given series expansion in Laguerre polynomials to a polynomial. The independent variable x of the given expansion is thereby substituted by the independent variable z of the resulting polynomial using the linear transformation $x = A * z + B$ or $z = (x-B)/A$.

This means: $$\sum_{i=1}^{N} C_i * L_{i-1}(A * z + B)$$

$$= \sum_{i=1}^{N} POL_i * z^{i-1}$$

Calculation is bypassed in case of a nonpositive value of the dimension N.

The range (0, c) in x is transformed to the range (z_l, z_r) in z with $z_l = -B/A$ and $z_r = (c - B)/A$, or vice versa, $A = c/(z_r - z_l)$ and $B = -c * z_l/(z_r - z_l)$.

The Laguerre polynomial $L_n(x)$ satisfies the recurrence equation

$$L_{n+1}(x) = x/(n+1) \cdot L_n(x) + \left[2 - 1/(n+1)\right] L_n(x) - \left[1 - 1/(n+1)\right] L_{n-1}(x)$$

with starting values $L_0(x) = 1$, $L_1(x) = 1 - x$.

The transformation is performed by means of a forward iteration scheme:

1. The coefficient vector of the Laguerre polynomial $L_i(x)$ is calculated from the coefficient vectors of $L_{i-1}(x)$, $L_{i-2}(x)$ using the recurrence equation, for i = 3, ..., N.
2. The resulting polynomial coefficient vector is obtained by summation of c_i times $L_{i-1}(x)$ over i, for i = 1, ..., N.

Subroutines LEP and DLEP

These subroutines compute the values of the Legendre polynomials for a given argument x and orders zero up to N. The Legendre polynomial $P_n(x)$ satisfies the recurrence equation

$$P_{n+1}(x) = ((2n+1) \cdot x \cdot P_n(x) - n \cdot P_{n-1}(x))/(n+1)$$

with starting values $P_0(x) = 1$, $P_1(x) = x$.

For reasons of economy and numerical stability the recurrence equation is used in the form:

$$P_{n+1}(x) = x \cdot P_n(x) - P_{n-1}(x) + x \cdot P_n(x) - (x \cdot P_n(x) - P_{n-1}(x))/(n+1)$$

For large values of n the last term is negligible, giving the approximation:

$$P_{n+1}(x) = 2 \cdot x \cdot P_n(x) - P_{n-1}(x)$$

This form shows that roundoff errors grow at worst linearly, assuming that the argument x is absolutely less than one.

If e_{n+r} is the error in $P_{n+r}(x)$ due to a single rounding error e in $P_n(x)$, the approximation is

$$e_{n+r+1} = 2x \cdot e_{n+r} - e_{n+r-1}$$

with initial conditions $e_n = e$, $e_{n-1} = 0$. The solution of this difference equation has its maximum for $|x| = 1$:

$$e_{n-1} = 0,\ e_n = e,\ |e_{n+1}| = 2e,\ \ldots,\ |e_{n+r}| = (r+1)e$$

The order is assumed to be zero for negative values of N.

Subroutines LEPS and DLEPS

These subroutines compute the value of a series expansion in Legendre polynomials. The Legendre polynomial $P_n(x)$ satisfies the recurrence equation

$$P_{n+1}(x) = 2x \cdot P_n(x) - P_{n-1}(x) - (x \cdot P_n(x) - P_{n-1}(x))/(n+1)$$

with starting values $P_0(x) = 1$, $P_1(x) = x$.

An n-term expansion in Legendre polynomials with coefficient vector $C = (c_1, \ldots, c_n)$ is evaluated by means of a forward iteration scheme:

$$Y = c_1,\ H_0 = 1,\ H_1 = x$$

$$\left.\begin{aligned} H_2 &= x \cdot H_1 \\ H_2 &= H_2 - H_0 + H_2 - (H_2 - H_0)/i \\ H_0 &= H_1 \\ H_1 &= H_2 \end{aligned}\right\} \quad \text{for } i = 2, \ldots, n$$

$$Y = Y + c_i \cdot H_0$$

This gives the result $Y(x) = \sum_{i=1}^{n} c_i \cdot P_{i-1}(x)$.

Calculation is bypassed in case of a nonpositive value of the dimension N.

Subroutines TLEP and DTLEP

These subroutines transform a given series expansion in Legendre polynomials to a polynomial. The independent variable x of the given expansion is thereby substituted by the independent variable z of the resulting polynomial using the linear transformation $x = A * z + B$ or $z = (x - B)/A$.

This means:

$$\sum_{i=1}^{N} C_i * P_{i-1}(A * z + B)$$

$$= \sum_{i=1}^{N} POL_i * z^{i-1}$$

Calculation is bypassed in case of a nonpositive value of the dimension N.

The range (-1, +1) in x is transformed to the range (z_1, z_r) in z with $z_1 = -(1 + B)/A$ and $z_r = (1 - B)/A$, or vice versa, $A = 2/(z_r - z_1)$ and $B = -(z_r + z_1)/(z_r - z_1)$.

The Legendre polynomial $P_n(x)$ satisfies the recurrence equation

$$P_{n+1}(x) = x\left[2-1/(n+1)\right] P_n(x) - \left[1-1/(n+1)\right] P_{n-1}(x)$$

with starting values $P_0(x) = 1$, $P_1(x) = x$.

The transformation is performed by means of a forward iteration scheme:

1. The coefficient vector of the Legendre polynomial $P_i(x)$ is calculated from the coefficient vectors of $P_{i-1}(x)$, $P_{i-2}(x)$ using the recurrence equation, for i = 3, ..., N.

2. The resulting polynomial coefficient vector is obtained by summation of c_i times coefficient vector of $P_{i-1}(x)$ over i, for i = 1, ..., N.

Roots of Nonlinear Equations

Subroutines RTWI and DRTWI

These subroutines refine the initial guess x_0 of a root of the general nonlinear equation $x = f(x)$. Wegstein's iteration scheme is used in order to get accelerated convergence in case of a function f (x), which has at least continuous first derivative in the range in which iteration moves.

Following Figure 14, set $x_1 = y_0 = f(x_0)$ and $y_1 = f(x_1)$.

Refinement of x_1 is done by determination of the intersection of the linear function $y = x$ and the secant through the points (x_0, y_0) and (x_1, y_1), thus getting:

$$x_2 = x_1 + \frac{\dfrac{x_1 - x_0}{x_0 - y_0}}{\dfrac{x_1 - y_1}{x_1 - y_1}} - 1$$

and $y_2 = f(x_2)$

The next step is done by starting at (x_2, y_2) and setting:

$$x_3 = x_2 + \frac{\dfrac{x_2 - x_1}{x_1 - y_1}}{\dfrac{x_2 - y_2}{x_2 - y_2}} - 1$$

$$y_3 = f(x_3)$$

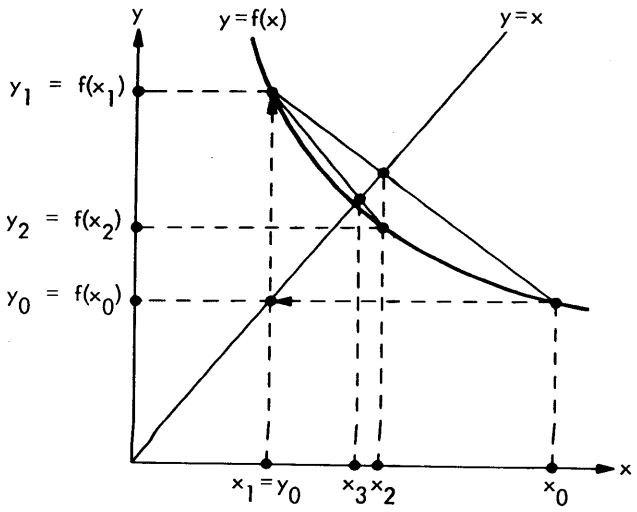

Figure 14. Wegstein's iterative method

It is easily seen that this determines the intersection between y = x and the secant through the points (x_1, y_1) and (x_2, y_2). Therefore Wegstein's iteration scheme is often called the secant modification of the normal iteration scheme $x_{i+1} = f(x_i)$.

Repeating these steps, the result is the iteration scheme:

$$\left.\begin{aligned} x_{i+1} &= x_i + \frac{x_i - x_{i-1}}{\dfrac{x_{i-1} - y_{i-1}}{x_i - y_i} - 1} \\ y_{i+1} &= f(x_{i+1}) \end{aligned}\right\} (i = 1, 2, \ldots) \quad (1)$$

Each step requires one evaluation of f(x).

This iterative procedure is terminated if the following two conditions are satisfied:

$$\delta_1 \leqq \varepsilon \quad \text{and} \quad \delta_2 \leqq 10 \cdot \varepsilon$$

with

$$\delta_1 = \begin{cases} \left| \dfrac{x_{i+1} - x_i}{x_{i+1}} \right| & \text{in case of } |x_{i+1}| > 1 \\ |x_{i+1} - x_i| & \text{in case of } |x_{i+1}| \leqq 1, \end{cases} \quad (2)$$

$$\delta_2 = \begin{cases} \left| \dfrac{x_{i+1} - y_{i+1}}{x_{i+1}} \right| & \text{in case of } |x_{i+1}| > 1 \\ |x_{i+1} - y_{i+1}| & \text{in case of } |x_{i+1}| \leqq 1 \end{cases}$$

and tolerance ε given by input.

The procedure described above may not converge within a specified number of iteration steps. Reasons for this behavior, which is indicated by an error message may be:

1. Too few iteration steps are specified.
2. The initial guess x_0 is too far away from any root.
3. The tolerance ε is too small with respect to roundoff errors.
4. The root to be determined is of multiplicity greater than one.

Furthermore, the procedure fails if at any iteration step the denominator of equation (1) becomes zero. This is also indicated by an error message. This failure may have two reasons:

1. The secant has the slope 1, either exactly or due to roundoff errors. In both cases it is probable that there is at least one point ξ in the range in which iteration moves with $f'(\xi) = 1$.

2. $x_i = x_{i-1}$ and $x_i \neq y_i = f(x_i)$. This case is possible due to roundoff errors or to a very steep slope of the secant.

Subroutines RTMI and DRTMI

These subroutines determine a root of the general nonlinear equation $f(x) = 0$ in the range of x from x_{li} up to x_{ri} (x_{li}, x_{ri} given by input) by means of Mueller's iteration scheme of successive bisection and inverse parabolic interpolation. The procedure assumes $f(x_{li}) \cdot f(x_{ri}) \leqq 0$.

Starting with $x_l = x_{li}$ and $x_r = x_{ri}$ and following Fig. 15, one iteration step is described.

First, the middle of the interval $x_l \ldots x_r$ is computed:

$$x_m = \frac{1}{2}(x_l + x_r).$$

In case $f(x_m) \cdot f(x_r) < 0$, x_l and x_r are interchanged to ensure that $f(x_m) \cdot f(x_r) > 0$.

In case

$$2 f(x_m)\,[f(x_m)-f(x_l)] - f(x_r)\,[f(x_r) - f(x_l)] \geqq 0 \quad (1)$$

x_r is replaced by x_m and the bisection step is repeated. If, after a specified number of successive bisections, inequality (1) is still satisfied, the procedure is bypassed and an error message is given.

In Fig. 15, the second bisection step leads to a configuration which does not satisfy inequality (1). Thus by inverse parabolic interpolation:

$$\Delta x = f(x_l)\,\frac{x_m - x_l}{f(x_m)-f(x_l)}$$

$$\left\{1 + f(x_m)\,\frac{f(x_r) - 2 f(x_m) + f(x_l)}{[f(x_r)-f(x_m)]\,[f(x_r)-f(x_l)]}\right\} \quad (2)$$

$$\text{and } x = x_l - \Delta x$$

and x is sure to be situated between x_l and x_m.

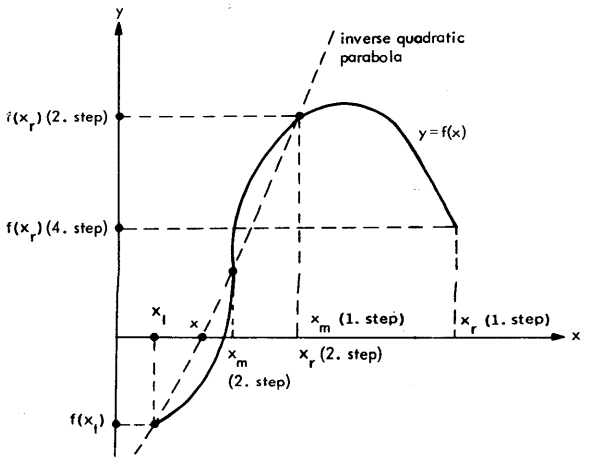

Figure 15. Mueller's iterative method

Now, for the next iteration step, x becomes x_1 and x_m becomes x_r if $f(x) \cdot f(x_1) > 0$, or x becomes x_r if $f(x) \cdot f(x_1) < 0$.

Convergence is either quadratic or linear if the multiplicity of the root to be determined is equal to one or greater than one respectively, and if f(x) can be differentiated continuously at least twice in the range $x_{1i} \cdots x_{ri}$. Each iteration step requires two evaluations of f(x).

This iterative procedure is terminated if either the two conditions (checked in bisection loop)

$$\left.\begin{aligned} |x_r - x_1| &\leq \varepsilon \cdot \max(1, |x_r|) \\ |f(x_r) - f(x_1)| &\leq 100 \cdot \varepsilon \end{aligned}\right\} \quad \text{and} \qquad (3)$$

or the two conditions (checked after inverse parabolic interpolation)

$$\left.\begin{aligned} |\Delta x| &\leq \varepsilon \cdot \max(1, |x|) \\ |f(x)| &\leq 100 \cdot \varepsilon \end{aligned}\right\} \quad \text{and} \qquad (4)$$

are satisfied, where tolerance ε is given by input.

The procedure described above may not converge within a specified number of iteration steps followed by the same number of successive bisections. Reasons for this behaviour, which is indicated by an error message, may be:

1. Too few iteration steps are specified.
2. The initial interval $x_{1i} \cdots x_{ri}$ is too long.
3. The tolerance ε is too small with respect to roundoff errors.

Furthermore, the procedure is bypassed, also giving an error message, if the basic assumption $f(x_{1i}) \cdot f(x_{ri}) \leq 0$ is not satisfied.

Subroutines RTNI and DRTNI

These subroutines refine the initial guess x_0 of a root of the general nonlinear equation $f(x) = 0$. Newton's iteration scheme is used in the following form:

$$x_{i+1} = x_i - \frac{f(x_i)}{f'(x_i)} \qquad (i = 0, 1, 2, \ldots) \qquad (1)$$

Convergence is quadratic or linear if the multiplicity of the root to be determined is equal to one or greater than one respectively, and if f(x) can be differentiated continuously at least twice in the range in which iteration moves. Each iteration step requires one evaluation of f(x) and one evaluation of $f'(x)$.

This iterative procedure is terminated if the following two conditions are satisfied:

$$\delta \leqq \varepsilon \text{ and } |f(x_{i+1})| \leqq 100 \cdot \varepsilon$$

with

$$\delta = \left\{ \begin{array}{ll} \left| \dfrac{x_{i+1} - x_i}{x_{i+1}} \right| & \text{in case of } |x_{i+1}| > 1 \\ |x_{i+1} - x_i| & \text{in case of } |x_{i+1}| \leqq 1 \end{array} \right\} \qquad (2)$$

and tolerance ε given by input.

The procedure described above may not converge within a specified number of iteration steps. Reasons for this behaviour, which is indicated by an error message, may be:

1. Too few iteration steps are specified.
2. The initial guess x_0 is too far away from any root.
3. The tolerance ε is too small with respect to roundoff errors.
4. The root to be determined is of multiplicity greater than one.

Furthermore, the procedure fails and is bypassed if at any iteration step the derivative $f(x_i)$ becomes zero. This is also indicated by an error message.

Extremum of Functions

Subroutines FMFP and DFMFP

These subroutines perform the calculation of an unconstrained minimum of a function of several variables using a method proposed by Davidon. The underlying method is described in the article by R. Fletcher and M.J.D. Powell, "A Rapidly Convergent Descent Method for Minimization", Computer Journal, vol. 6, iss. 2, 1963, pp. 163 - 168.

It is assumed that the function f of the n variables $x_1, \ldots, x_n$ (abbreviated as argument vector x) may be computed together with its gradient vector g(x) for any point x. The generalized Taylor expansion for functions of several variables is

$$f(x+u) = f(x) + g(x) \cdot u + \frac{1}{2} u^T G(x) u + \text{higher terms}$$

where g is the gradient vector and G the matrix of second order partial derivatives. Vectors are assumed to be column vectors; u^T means transpose of vector u. It is assumed that in the neighborhood of the required minimum x_{min} the function is approximated closely by the first three terms of its Taylor expansion, giving

$$f(x) = f(x_{min}) + \frac{1}{2} (x - x_{min})^T G(x_{min}) (x - x_{min})$$

since $g(x_{min}) = 0$. Then the gradient is seen to be approximately $g(x) = G(x_{min}) (x - x_{min})$.

Assume now that the symmetric matrix G is positive definite. Then the following equation holds true:

$$x - x_{min} = G^{-1} (x_{min}) \cdot g(x)$$

which would allow x_{min} to be calculated in one step if $G^{-1} (x_{min})$ were available.

To approach $G^{-1} (x_{min})$, a method of successive linear searches in G-conjugate directions is used. Starting with the identity matrix $G^{(0)} = I$, a sequence of symmetric matrices $G^{(i)}$ is generated which tends to G^{-1}. At the $(i+1)^{st}$ iteration step a linear search is made in direction $h^{(i)} = -G^{(i)} g^{(i)}$, where $g^{(i)}$ is an abbreviation for $g(x^{(i)})$. By means of the linear search the minimum of $y(t) = f(x^{(i)} + t \cdot h^{(i)})$ is determined, giving argument $x^{(i+1)} = x^{(i)} + t_i \cdot h^{(i)}$.

The argument of the minimum $x^{(i+1)}$ on the line through $x^{(i)}$ in direction $h^{(i)}$ is determined by the relation that scalar product $(g^{(i+1)}, h^{(i)}) = 0$.

Now:
$$x^{(n)} = x^{(j)} + \sum_{i=j}^{n-1} t_i h^{(i)}$$

and:
$$g^{(n)} = g^{(j)} + \sum_{i=j}^{n-1} t_i G h^{(i)}$$

Therefore:

scalar product
$$(g^{(n)}, h^{(j)}) = \sum_{i=j+1}^{n-1} t_i (G h^{(i)}, h^{(j)})$$

Suppose now that the vectors $h^{(0)}, h^{(1)}, \ldots, h^{(n-1)}$ are G-conjugate, satisfying $(G h^{(i)}, h^{(j)}) = 0$ for $i \neq j$. Then $(g^{(n)}, h^{(j)}) = 0$, and since $h^{(0)}, h^{(1)}, \ldots, h^{(n-1)}$ form a basis, $g^{(n)} = 0$ and $x^{(n)} = x_{min}$. This shows that the minimum is located at the n^{th} iteration for a quadratic function when using successive linear searches for G-conjugate directions.

For the generation of G-conjugate directions, start with $h^{(0)} = -g^{(0)}$ and calculate successive directions $h^{(i)}$ by means of $h^{(i)} = -G^{(i)}g^{(i)}$, where $G^{(i)}$ is modified to $G^{(i+1)}$ so that $h^{(i)}$ is an eigenvector of the matrix $G^{(i+1)}$ G with eigenvalue 1. This ensures that $G^{(i)}$ approaches G^{-1} as $x^{(i)}$ approaches x_{min}. An easy calculation shows:

$$G^{(i+1)} = G^{(i)} + \frac{dx \cdot dx^T}{dx^T \cdot dg} - \frac{G^{(i)} dg \cdot dg^T G^{(i)}}{dg^T G^{(i)} dg}$$

with $dg = g^{(i+1)} - g^{(i)}$

$dx = x^{(i+1)} - x^{(i)}$

where all vectors are regarded as column vectors, and superscript T means transpose of column vector--that is, row vector.

The strategy adopted for termination of the successive linear searches is as follows:

1. If the function value has not decreased in the last iteration step, the search for the minimum is terminated provided the gradient is already sufficiently small; otherwise, the next step is in the direction of steepest descent.

2. If the argument vector and the direction vector change by very small amounts, and at least n iterations are performed, the minimization is terminated again.

3. If the number of iterations exceeds an upper bound furnished by the user, further calculation is bypassed, and an error code is set to 1 indicating poor convergence.

4. If one of the successive linear searches indicates that no constrained minimum exists, further calculation is bypassed again, and the error code is set to 2 indicating that it is likely that no minimum exists.

The i^{th} term $G^{(i)}$ is reset to the identity matrix if there is indication that the current $G^{(i)}$ is not positive definite, or if the formula for $G^{(i+1)}$ breaks down due to zero divisors.

The linear search technique used in subroutines FMFP and DFMFP is as follows. For a given argument vector x and vector h, defining a direction through x, a local minimum of the function $y(t) = f(x+th)$ must be found. This means that a value t_m must be determined for which

$$y'(t_m) = \text{scalar product } (g(x+t_m h), h) = 0$$

From $y'(0) = (g(x), h) < 0$ it is evident that a minimum $y(t_m) < y(0)$ should be found for positive values of t.

The calculation of the minimum is in three stages. The first estimates the magnitude of t_m, the second determines an interval containing t_m, and the third interpolates the value of t_m.

An estimate of the step-size may be obtained, assuming that the true value of the constrained minimum is equal to the estimated value EST of the unconstrained minimum and that y (t) is closely represented by a quadratic polynomial passing through (x, y(0)) with derivative y'(0):
step = 2 (EST - y(0))/y'(0).

This equation tends to overestimate the step-size, since the unconstrained minimum will normally not lie on the line through x with direction h. Therefore, step is taken as step-size s only if it is positive and less than one. Otherwise, s = 1 is taken as step-size.

At the second stage y(t) and y'(t) are examined at the points $t = s, 2s, 4s, \ldots, s_1, s_2$, where successive values are obtained by doubling the step-size.

This search is terminated at $t = s_2$ if:

$$y'(s_2) = 0, \text{ or } y'(s_2) > 0, \text{ or } y(s_2) \geq y(s_1)$$

$$\text{or if } s_2 \cdot \left(\sum_{i=1}^{n} |h_i| \right) > 10^{10}.$$

The last case (search argument runs out of range) is interpreted as an indication that no local minimum exists on the given line. In this case, the error indicator is set to (2) and further calculation is bypassed.

In case $y'(s_2) = 0$, t_m is set to s_2 and $x_m = x = s_2 h$ is used as the argument of a constrained minimum on the line through x with direction h.

In the second and third case ($y'(s_2) > 0$ and/or $y(s_2) \geq y(s_1)$) a minimum lies necessarily between s_1 and s_2. Its argument value gets approximated using cubic interpolation.

The extrema of the cubic interpolation passing through (s_1, $y_1 = y(s_1)$, $y'_1 = y'(s_1)$) and (s_2, $y_2 = y(s_2)$, $y'_2 = y'(s_2)$) are given by solving a quadratic equation. The solution s_3 can be expressed as $s_3 = s_1 + (1-\alpha)(s_2 - s_1) = s_2 - \alpha(s_2 - s_1)$ with

$$\alpha = \frac{y'_2 - z + w}{y'_2 - y'_1 + 2W} = \frac{y'_2 + z - w}{y'_2 + y'_1 + 2z},$$

$$0 < \alpha < 1, \text{ and } z = y'_1 + y'_2 - 3\frac{y_2 - y_2}{s_2 - s_1},$$

$$w = \pm (z^2 - y'_1 y'_2)^{1/2}.$$

The conditions on the problem guarantee a real value of w. The sign of w is so chosen that s_3 is in the interval (s_1, s_2). If this condition is satisfied for the two possible values of s_3, the value closer to s_1 is retained.

As written above, two equivalent formulas can provide α. The choice is based on numerical stability considerations.

If $y(s_3) \leq y(s_1)$ and $y(s_3) \leq y(s_2)$, then t_m is set equal to s_3 and $x_m = x + t_m \cdot h$ is used as argument of the desired minimum along the given line. Otherwise, the interval (s_1, s_2) is reduced by replacing s_1 by s_3 if $y(s_3) \leq y(s_1)$ and $y'(s_3) < 0$ and by replacing s_2 by s_3 in all other cases. The interpolation process is repeated for this new reduced interval.

Subroutines FMCG and DFMCG

These subroutines perform the calculation of an unconstrained minimum of a function of several variables using conjugate gradients. The underlying method is described in the article by R. Fletcher and C. M. Reeves, "Function minimization by conjugate gradients", Computer Journal, vol. 7, no. 2, 1964, pp. 149-154.

It is assumed that the function f(x) of the n variables $x_1, \ldots, x_n$ may be computed, together with its gradient g(x) for any point $x = \begin{pmatrix} x_1 \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{pmatrix}$. In the neighborhood of the required minimum x_{min} the function f(x) is approximated closely by the first three terms of its Taylor expansion, giving

$$f(x) = f(x_{min}) + \frac{1}{2}(x - x_{min})^T G(x_{min})(x - x_{min})$$

since $g(x_{min}) = 0$. The quantity $G(x_{min})$ means the matrix of second-order partial derivatives taken at the point x_{min}.

From the Taylor expansion, the gradient is seen to be approximately:

$$g(x) = G(x_{min}) \cdot (x - x_{min})$$

The condition for the gradient to vanish is:

$$G(x_{min}) \cdot x = G(x_{min}) \cdot x_{min}$$

For solution of these equations, directions $h^{(0)}$, $h^{(1)}$, ... are generated such that $h^{(i+1)}$ is a linear combination of $-g^{(i+1)}(x^{(i+1)})$ and $h^{(0)}$, $h^{(1)}$, ..., $h^{(i)}$, so that G-orthogonality is satisfied, that is, $h^{(i)T} Gh^{(j)} = 0$ for $i \neq j$.

An easy calculation gives the following results. If a sequence of successive linear searches in directions $h^{(0)} = -g^{(0)}$, $h^{(i+1)} = -g^{(i+1)} + \beta_i \cdot h^{(i)}$ is performed with:

$$\beta_i = \frac{(g^{(i+1)}, g^{(i+1)})}{(g^{(i)}, g^{(i)})}, \quad x^{(i+1)} = x^{(i)} + t_i h^{(i)} \quad \text{and}$$

$$(g^{(i+1)}, h^{(i)}) = 0$$

then this process is guaranteed to locate the minimum of a quadratic function in n iterations at most. For general functions the process is iterative rather than n-step. (This is true even for quadratic functions due to roundoff errors.)

Strategy for termination of the successive linear searches is as follows:

1. If the change of the argument is very small, and at least n + 1 iterations have been performed, the search for the minimum is terminated.

2. If the function value has not decreased in the last linear search, the minimization is terminated.

3. If the number of iterations exceeds an upper bound furnished by the user, further calculation is bypassed, and an error code is set to 1 indicating poor convergence.

4. If one of the successive linear searches indicates that no constrained minimum exists, further calculation is bypassed, and the error code is set to 2 indicating that it is likely that no minimum exists.

5. After each cycle of n + 1 iterations, the next iteration is in the direction of steepest descent.

The linear search technique used in subroutines FMCG and DFMCG is described in the writeup for subroutines FMFP and DFMFP.
