With both multiprocessors, many algorithms were implemented. Encouraging results [4-6] demonstrate that EGPA computers are well-suited for a broad spectrum of applications. One area is the numerical simulation of phenomena in physics, chemistry etc. As a rule, the corresponding mathematical models use partial differential equations. In order to find a good solution of such an equation, the discretization must be fine and as a consequence, the required computer performance in FLOPS is very high. The emergence of multigrid methods and the advance of vector-processors dramatically improved the situation. Suddenly, many but not all phenomena can be successfully investigated by simulation. A lot of supercomputer applications have emerged, and a worldwide interest in multigrid algorithms and their implementation is rapidly growing.

Since the main objective of multiprocessors is high speed computation, such a system must be suitably structured to fit these algorithms. In chapter IV we present a general method for mapping multigrid algorithms onto EGPA systems. A simple example, the Poisson-Equation is used in chapter V to demonstrate in more detail the implementation technique and related problems. The measured speedups for this type of equation together with the results for the more complicated Steady Stokes Equations are discussed. Some reasons for the loss in relation to the theoretically maximal values are given.

In the last chapter we give a short survey of our recent research.

## EGPA systems:

EGPA systems form a subclass of multiprocessors with the following features [ 3 ]:

Tight coupling: The architecture consists of processor-memory-modules (PMM) which are connected in two-dimensional orthogonal grid-like structures. Each processor has access to the memories of the four adjacent PMMs (bidirectional connections) and each memory can be accessed by neighbouring processors through a multiport control device.

Restricted neighbourhood: By coupling each PMM with four neighbours the local complexity remains constant throughout the processor plane, whereas the global complexity grows proportionally to the number of PMMs in the system. The principle of constant local complexity and linearly growing global complexity can be realized in various size independent topologies.

Regularity and homogeneity: In most cases a rectangular array of processors is most appropriate, as it can be derived from many algorithmic schemes from relaxation methods. Regularity regarding the interconnection structure, and homogeneity regarding the PMM-structure are mainly directed to the requirements of data-exchange in multiprocessors.

Hierarchy: Two or more arrays of PMMs constitute a hierarchical system through "vertical" connections. Each processor (master) - except those at the lowest level - has access to the memories of four subordinated PMMs (slaves, unidirectional connections).

For larger systems it is unnecessary to have many hierarchical layers. Therefore a possible EGPA computer may have the following structure (s. fig. 1a):

0190-3918/86/0000/0799 $01.00 © 1986 IEEE

- The number of PMMs in the lowest layer is four times larger than the number of PMMs in the second layer. Each PMM in the second layer is connected to a disk via I/O and has access to the memories of the slaves.
- The number of PMMs in the third layer will decrease more strongly to produce for instance a tapering ratio of 1:16. Then for hardware reasons, buscoupling should be preferred memory coupling.

In such a system there is a functional partitioning. The lowest layer is the main worker layer. The next layer has to perform mainly operating system functions, e.g. to manage the data swapping from or to the disks. The processor (or processors) in the top layer constitute an interface to a host (or a workstation). All the upper layers are used for broadcasting (or collecting) data or programs.

### The EGPA system built with DIRMU modules

DIRMU (DIstributed Reconfigurable MUltiprocessor) is a kit for building multiprocessors. The basic element, a PMM consists of two subunits: the P-sub-module (8086/87 with 320 kB private memory and 8 exit-ports) and the M-sub-module (64 KByte 8-port memory). Two PMMs can be connected by plugging a cable into an exit-port of the first module and into a memory port of the other module. Therefore, every combination of memory coupled processors is possible, whereby each processor can have up to seven neighbours (1 exit-port and 1 memory port are used to allow the P-sub-module access its own multiport memory). One possible architecture is the EGPA system shown in fig. 1b.

This system was used for the implementation - among others - of the multigrid algorithms described in the following. The DIRMU kit and the measured results are presented in several papers [5-7] in more detail. For a better understanding the following describes briefly the addressing technique. In this case we want to build the 3-processor-system shown in fig. 2 top. The corresponding DIRMU systems looks like fig. 2 bottom and the addressing is explained in fig. 3.

### General Multigrid Approach on EGPA systems

Let us assume that we are searching for a solution u ($\underline{x}$) of

$$L^u = f, \underline{x} \in B,$$
$$C (u), \underline{x} \in \partial B,$$

where L is a (not necessarily) linear differential operator and f is a function defined on the region B contained in $R^d$. C stands for a condition which u has to fulfil at the boundary of B. Henceforth. We assume that B is (or is almost) the unit cube. Where necessary, this can be achieved by a suitable transformation of the equations [8].

Such equations are usually solved by discretization. For this purpose we choose a grid G with mesh size h. Then we solve the approximate system by relaxation

$$L_h u_h = f_h, \underline{x} \in B \cap G$$

If h is small enough and the relaxation process is executed sufficiently often, then the approximate solution $u_h$ is a good approximation of u. The main problem is that the rate of convergence decrease strongly with decreasing h for all known relaxation methods.

The situation can be essentially improved by using multi grids $G_i$, with $h = 2^{-i}$. A multigrid procedure is given by a predefined sequence of operations of the type R, E, L, $I_1$, $I_2$. The following rules must be obeyed:

- Besides $G_1$, each grid under treatment is relaxed by operation R.
  In $G_1$ the equations are solved exactly (operation type E)
- In case of a transition from $G_i$ to $G_j$, then $i = j \pm 1$.
- In case of a transition from $G_{i-1}$, the residues $(f_h - L_h U_h)$ are restricted (operation L).
- In case of a transition from $G_i$ to $G_{i+1}$:
  a) if $G_{i+1}$ was already used, corrections must be interpolated and added to the existing approximations of the discrete n-values.
  b) if $G_{i+1}$ was not yet used, then the corresponding u-values must be interpolated (operation $I_2$).

There are many possible orders through which the grids can be passed. One example is the V-cycle shown in fig. 4a) and a full multigrid cycle based on V-cycles (fig. 4b).

Multigrid methods are well-suited to EGPA systems because all the operations are homogeneous and local. Thus, a general approach for mapping such an algorithm onto an EGPA system can be given.

We assume an EGPA system with 1<m layers $L_1$ (top), $L_2$, $L_3$, ..., $L_e$ (bottom). Mapping the algorithm onto the computer will be effected in the following way:

- Assign each grid to the finest of all layers which possesses no more modules than the grid has points. This rule avoids situations where, for a calculation, a processor needs data which it can not access directly. Another consequence is that as many grids as possible can be computed by the processors in the lowest layer - so that the computing power is used very efficiently (see fig. 5).
- If the problem is 2-dimensional, each grid plane is partitioned and the parts are assigned to the modules of the corresponding processor layer in a natural way (fig. 6a). Partitioning is achieved in a load balancing manner. This means that all parts should be as equal as possible. Only parts with points of the boundary should be smaller to compensate higher computation load. Three dimensional grids are projected into a 2-dimensional grid which is divided and assigned to processors in the same manner as described before. Each processor manipulates the 3-dimensional column of grid points projected onto the assigned part (see fig. 6 b). In any case, each processor has direct access to all needed data (fig. 6a).

It should be mentioned that the influence of the boundary must be estimated by the programmer. Automatic partitioning methods are not known at present. The computational efficiency can be improved only by analysing execution times obtained with test data.

At runtime, each processor executes a program which differs from the mono-program only in index boundaries and in additional synchronisation parts. If all is correctly implemented the behaviour of the multiprocessor program is completely equivalent to that of the monoprocessor program. How such a correct program can look will be shown in the next chapter.

## An implementation example

In the following, we only discuss the parts of the program which differ from that known from monoprocessors. For demonstration purposes we chose the relatively simple Poisson equations with Dirichlet conditions.

$$\frac{\partial^2}{\partial^2} u(x,y) - \frac{\partial^2}{\partial x^2} u(w,y) = f(x,y),(x,y)\varepsilon(0,1)^2=G,$$

$$u(x,y) = g(x,y),(x,y)\varepsilon\partial G.$$

Let for $h = 2^{-k}$

$$G_h = (x_i,y_j),\ x_i = ih;Y_j = jh;i,j = 0,1...,2^k,$$

A possible discretization of the equation is

$$(4\ u_{i,j} - u_{i,j-1} - u_{i,j+1} - u_{i-1,j} - u_{i+1,j})/h^2=f_{i,j}$$

where

$u_{ij} = u(x_i,y_j)$ and $f_{i,j} = f\ (x_i,\ y_j)$.

We parallelize a full multigrid algorithm (s. fig. 4b) implemented by Witsch [9] with the following operations:

Relaxation: Each grid point is relaxed in red black order

with $u_{i,j} = (h^2 f_{i,j}+u_{i,j-1}+u_{i,j+1}+u_{i-1},+u_{i+1,j})/4$

Red black order means: All grid points are coloured red or black so that the whole grid looks like a checkerboard. All red points are relaxed before all black points. The main advantage is that it is unimportant in which order the reds or the blacks are relaxed. The reason is that the new red values depend only on black values and vice versa.

Restriction: full injection
Interpolation 1: bilinear
Interpolation 2: of 4th order.

We now explain the control flow of the user program for solving Poisson equation. For sake of simplicity we assume that exactly one grid level is manipulated by a processor layer. The following control variables are used

$$\text{deep} = \begin{cases} 0 & \text{grid level is reached for the first time, e.g. position ✱ in fig. 4} \\ 1 & \text{grid level is reached for the second time, e.g. position ▲ in fig. 4} \\ 2 & \text{otherwise} \end{cases}$$

$$\text{deepest} = \begin{cases} \text{true} & \text{finest grid} \\ \text{false} & \text{otherwise.} \end{cases}$$

$$\text{end} = \begin{cases} \text{true} & \text{stop} \\ \text{false} & \text{go on} \end{cases}$$

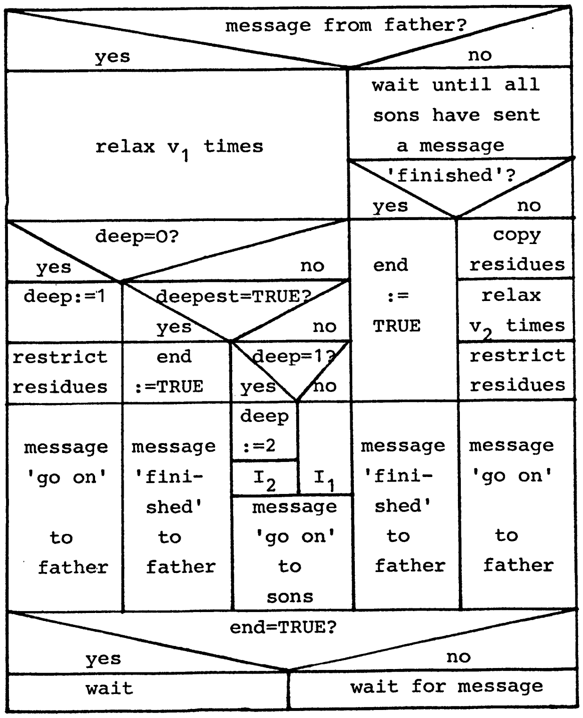
top processor:

The corresponding process is initialized by the system. This process initializes the son processes at each of its slave processors. Then the following loop is executed:

```
exact solution in G1;
interpolate into son memories;
messages to sons,
wait for messages from all sons,
if message = "finished" then stop;
end loop.
```

All other processors execute the same program:

```
Initialisation: deep: = 0; deepest: = true/false
                V1:  = number of relaxation steps
                       befor interpolation
                V2:    number of relaxation steps
                       after restriction,
                initialize sons.
```



Although the above diagram is self-explaining, we have to clarify some features.

The interpolations $I_1$ and $I_2$ produce data, which have only effects on the contents of the memories of the next deeper PMM layer. In the first case the corrections are added to the existing values of the grid points, in the other case the grid is generated for the first time. In contrast to that, the restriction operation writes the residues into the memories of the same layer, since the processors of a layer have no direct access to the memories in the next higher layer. Therefore, the PMMs of the higher layer first have to copy the data into their memories.

While the above diagram shows synchronisation between layers, the following program demonstrates synchronisation between processors of the same level.

We only look at the procedure "relax" which is always called $V_1$ ($V_2$) times in sequence.

```
BEGIN
   WHILE  blackrel & north ≠ blackrel OR
          blackrel & west  ≠ blackrel OR
          blackrel & south ≠ blackrel OR
          blackrel & east  ≠ blackrel

   DO wait (t) OD;
   relaxed;
   redrel: = redrel + 1;
   WHILE redrel & north ≠ redrel OR
         redrel & west  ≠ redrel OR
         redrel & south ≠ redrel OR
         redrel & east  ≠ redrel
   DO wait (t) OD;
   relaxblack;
   blackrel: = blackrel + 1
   END
```

To understand the routine we have to remember that this program is running at any processor. This is the reason why we write relative programs (relative to an assumed PMM location within the system). We achieve this by using variables with relative names. Two examples are "blackrel" and "redrel". "redrel" ("blackrel") is the name of a set of variables. In each PMM, there is an incarnation of "redrel" located in the multiport memory. Such a set is relatively addressed. Each processor writes or reads the incarnation into its multiport memory by using the name "redrel". The corresponding incarnation of the western neighbour (according to the gridlike interconnection structure) is accessed by "redrel & west". With DIRMU (fig. 3) we explain these facts from a hardware point of view. Let us assume that the connection from a processor to the multiport memory of its western neighbour is plugged into exitport 3 and its own multiport memory is accessible by addresses of port 0. Furthermore we assume that "redrel" has the address 8·64 K+d. Then the address of "redrel & west" is 11·64 K+d. This address is transformed to 8·64 K+d by the multiport of the western PMM and this is the address of the variable "redrel" from the point of view of the western processor.

In the above routine the variables "redrel" respectively "blackrel" indicate how often the redpoints resp. the blackpoints were relaxed. Therefore this variables are set to zero during the initialisation. The first WHILE guarantees that the data needed for relaxing the red points already exists in the adjacent PMMs. The second WHILE is necessary to be sure that for the relaxation of the black points all needed red points being in the PMMs of the neighbours are updated.

Now we discuss an improvement of the main routine given by the diagram. The synchronization between layers is achieved by messages. In the implemented program we realy used spinlocks, because this technique is much quickier than message passing (μsec in comparison to msec). This technique we illustrate for the synchronisation between layers (grids).

For controlling the states of the sons and of the neighbours, we introduce the variables.

```
 an = activity number
lan:= last activity number
```

A father-process signals the next activity to the sons by incrementing their activity number

```
an & sons + : = 1
```

(we use this as abbreviation for the real statements

```
an & son 1: = an & son 1 + 1;
       .
       .
       .
an & son 4: = an & son 4 + 1;).
```

(Here we address the incarnations of "an" laying in the memories of the slaves by adding & son i equivalent to the technique how we select the incarnation in the memories of the neighbours. It is also a kind of relatively programming.)

Now let us assume that the sons have copied the last value of "an" into "lan". If a son-process is ready for a new activity, he executes a waiting-loop

```
WHILE an = lan DO wait (t) OD;.
```

After incrementing "an" by the father the processor executes the next statement after this WHILE. For instance, he can control the states of the neighbours by another waiting-loop:

```
WHILE an & neighbours ≠ an DO wait (t) OD
      (an & neighbours stands for
       an & NORTH ≠ an OR ... OR an&WEST≠an)
```

There are a few possibilities for upwards-synchronization (from son to father).

If the process terminates the current activity, he can e.g. change the sign of "an" (an:=-an). Then the father asks for the values of "an" in the sons memories.

```
WHILE an & sons > o DO wait (t) OD;
```

The father process leaves this waiting-loop only in the case, that all son-processes have been carried out the requested activity.

In such a way we synchronize within most of our programs. We found this time saving technique very good and all users preferred it. There is one disadvantage in comparison to message passing: there is no system control of the synchronization. To overcome this we used hardware monitors for tracing. Finally we want to emphasize one fact in context with our Poisson program. No matter which technique we use, only local synchronization takes place. This is important, because a global synchronization would be much more time-consuming.

The possibility to synchronize locally (practiced in most of our programs) and the possibility to program relatively are two very important features of our system.

## Some results

We implemented two multigrid algorithms on the EGPA system build with 21 PMMs (see fig. 1b) [12,13]. In both cases, the processor at the top operates only on grid 0 and the four processors of the middle layer manipulate grid 1. All other grids were assigned to the 16 processors of the bottom layer. The results are given in table 1.

### Some comments to the results:

With increasing number of grids the speedup increases, since the synchronization and communication part of the program decreases in comparison to the calculation part. If the problem is too small, it will make no sense to use such an multiprocessor. Some lower bounds for the size, which a problem should have, are given by Mierendorff and Kolp [11] They showed that in case of a 3 dimensional multigrid algorithm the problem size has to be O ($p^3$); when $p^2$ is the number of processors in the lowest layer. The results for the Steady State Stokes Equation are better than those for Poisson, since in the former case there is more work to do.

Since not all processors are always busy - only one layer is working at a time - the maximal speedup cannot be equal to the number of processors. The ideal speedup gives the upper bound which can maximally be achieved under ideal circumstances. The difference between measured speedup and ideal speedup reflects the loss.

This loss is not effected by the time for the proper synchronization action but by the waiting times. These periods of idleness are caused by unbalanced load, which is obtaind by the fact that it is impossible to divide the used grids into parts with equal load.

## Future work

We introduced EGPA systems. We demonstrated the programming of such systems.

For two multigrid algorithms the speedups measured at our 21-processor system were given. Together with former enjoying results in context with many other problems we were encouraged to continue the investigation of such systems.

In order to increase the performance of the DIRMU-PMM we decided to improve the hardware by adding a powerful coprocessor. First measurements with a first prototype yielded speedups of more than 100 in comparison to the existing system. In the next time we will test whether this good results can be generalized to a whole system [7].

In this context we will investigate the I/O-problem which will occur if the data to be handled are too many and swapping algorithms have to be used. Provided that our theoretical estimations are correct and we believe this, then we will be able to manage this problem with additional hardware without slowing our system down.

# CONSTRUCTING THE VORONOI DIAGRAM ON A MESH-CONNECTED COMPUTER

Mi Lu

Department of Electrical and Computer Engineering
Rice University

## Abstract

In this paper, we present a Mesh-Connected Computer algorithm to construct the Voronoi diagram of a set of planar points. Given a set of $n$ planar points, our algorithm constructs a Voronoi diagram on an $O(\sqrt{n}\times\sqrt{n})$ MCC with constant storage per processer in $O(\sqrt{n}\log n)$ time. Using the Voronoi diagram, the problem of determining the nearest neighbor between two sets and constructing the Euclidean minimum spanning trees can be solved with the same time complexity on the MCC. The best sequential algorithms for constructing the Voronoi diagram have an optimal $O(n\log n)$ time complexity. Previous known parallel algorithm for this problem requires $O(\log^3 n)$ time on a Parallel Random Access Machine and $O(\log^4 n)$ time on the Cube-Connected-Cycles with $O(\log n)$ storage per PE.

## I. Introduction

Voronoi diagrams (also called Thiessen diagrams) of a set $S$ of $n$ points is a well known structure which makes explicit some proximity information about $S$. In the Voronoi diagram [1], each point is surrounded by a convex polygon enclosing that territory which is closer to the surrounded point than to any other point in the set. Shamos [2] applied two-dimensional Voronoi diagrams to obtain elegant solutions in computational geometry, such as finding the nearest neighbor, construction of minimum spanning tree, etc. Generalizations of the Voronoi diagram were considered by several authors. Shamos [3] describes an $O(n\log n)$ time sequential algorithm to construct the planar Voronoi diagram for a set of planar points. The strategy used in the serial algorithm is divide-and-conquer. In the merging step the Voronoi edges are generated in a "zigzag" sequential manner which seems difficult to parallelize.

Our algorithm is based on Brown's [4] approach which transforms the problem of constructing a planar Voronoi diagram for an $n$-point set to the construction of a convex hull of $n$ points in three dimensional space. Chow [5] worked on parallelizing the algorithm to solve this problem. Using the shared memory machine (SMM) with $n$ processors, the time performance of her algorithm is $O(\log^3 n\log\log n)$. A recent paper [6] presented an $O(\log^3 n)$ time algorithm to solve this problem with $O(n\log n)$ space. An $O(\log^4 n)$ time algorithm for the construction of Voronoi diagram on Cube-Connected-Cycles with $O(\log n)$ storage per processor, was also proposed in [5] with $O(\log^4 n)$ time complexity. Our algorithm has $O(\sqrt{n}\log n)$ time complexity, and is performed on an $O(\sqrt{n}\times\sqrt{n})$ MCC with constant storage per PE which is a simpler model than the SMM. It needs to be pointed out that $\sqrt{n}\log n < \log^4 n$ for practical $n$.

In the MCC, identical processors are connected via simple and regular communication paths to form a two dimensional array, each with a constant number of registers. It is a single-instruction-stream, multiple-data-stream (SIMD) computer. (For other geometric algorithm on MCCs, see [7-9].)

Several well know MCC algorithm such as Sorting [10], and performing a Random Access Write(RAW) and a Random Access Read(RAR) [11] will be used in our paper. Section II describes the algorithm for constructing the Voronoi diagram, and section III provides some applications of the Voronoi diagram. A summary will be given in section IV.

## II. Constructing Voronoi Diagram

Given two points $p_i$ and $p_j$ in the plane, the set of points closer to $p_i$ than $p_j$ is the half-plane containing $p_i$ that is bounded by the perpendicular bisector of $p_i$ and $p_j$. Denote this half-plane by $H(p_i,p_j)$. Given a set $S$ of $n$ points in the plane, the locus of points in the plane that are closer to $p_i$ than to any other point is a convex polygon (maybe unbounded). It is known as the Voronoi polygon and denoted by $V_i$.

$$V_i = \bigcap_{j\neq i} H(p_i,p_j).$$

The Voronoi diagram is then composed of the $n$ polygons $V(i)$ (see Figure 1). The vertices of the diagram are called Voronoi points and the line segments are Voronoi edges.

To construct a 2-dimensional Voronoi diagram, Brown [4] used a technique called inversion to transform the planar points to 3-dimensions. Given an inversion center $P_0$ and an inversion radius $r$, we can transform point $Q$ to point $Q'$ by inversion, where $\overrightarrow{P_0Q'}$ is in the same direction as $\overrightarrow{P_0Q}$, and $|\overrightarrow{P_0Q'}| = r^2/|\overrightarrow{P_0Q}|$. The inversion has the following properties:

1. An inversion transforms a plane which does not pass through the inversion center to a sphere which passes through the inversion center, and vice versa. Denote the former type of transformation as a *plane→sphere* transform and the latter as a *sphere→plane* transform.
2. The interior of the sphere corresponds to one of the half spaces bounded by the plane and the exterior of the sphere corresponds to the other half space.
3. The inversion is involutory, i.e. application of inversion twice yields the original point.

Given a set of $n$ points on the $xy$ plane, we examine the inversion of three of them with respect to an inversion center $P_0$, not in the $xy$ plane. We can consider the inversion as a *plane→sphere* transform such that the three points are on the $xy$ plane originally and their images are on a sphere passing through inversion center $P_0$. On the other hand, we can consider the inversion as a *sphere→plane* transform in which the three points are originally on a sphere passing through their circumcircle on $xy$ plane and $P_0$ out of $xy$ plane, and their images are on a plane. In this case, if the other $n-3$ points are in the exterior of the circumcircle, then due to property 2, their images are in one half space bounded by the plane decided by the images of those three points (see Figure 2). So, the problem of determining for each set of three points whether their circumcircle excludes all other points becomes that of determining for each face if it is a convex face. Note that the number of the faces $\leq 2n-4$ for a hull with $n$ vertices.

The method used to construct a Voronoi diagram will be presented in a top-down manner below.

This research was partially supported by an IBM Faculty Development Award.

*Algorithm Voronoi*:

*input*: A set of $n$ points represented by their Cartesian coordinates $(x_i,y_i)$. They are distributed on a $\sqrt{n}\times\sqrt{n}$ Mesh-Connected Computer, one point per PE.

*output*: A set of Voronoi edges contained in the mesh.

1. Perform the inversion for each point. For simplicity, choose point (0,0,1) as the inversion center and choose r=1. See Figure 3. Let $(x'_i,y'_i,z'_i)$ be the coordinates of the inversed image of a point, i.e. $x' = x/(x^2+y^2+1)$; $y' = y/(x^2+y^2+1)$; $z' = (x^2+y^2)/(x^2+y^2+1)$.
2. Construct the 3-dimension convex hull $CH$ for the set of image points. This is done by algorithm *Convex Hull* which will be described latter in this section. At the end of this step, each convex face $F_i$ represented by three points through which it passes, is stored in a PE with the flag of this face *extn*=1. The addresses (i.e. PE indices) and the PEs in which its adjacent faces are present are also known by the PE. If we exclude degeneracies, each convex face is a triangle and has three adjacent faces.
3. Each PE performs the "reinversion" for the three points on each convex face it contains. The image $(x'',y'',z'')$ of a point $(x',y',z')$ on the face $F_i$ is given by $x''=x'/(1-z')$; $y''=y'/(1-z')$. Find the center of the circumcircle of the three points corresponding to each face $F_i$. Let $C_i$ denote the center of this circle. If $P_0$ and the $CH$ are at the same side of $F_i$, set $v_i$ to 1. $C_i$ is a Voronoi point.
4. Each PE containing $C_i$ with $v_i$=1 does RAR of $v_j$ from the PE containing $F_j$ such that $F_j$ is an adjacent face of $F_i$ in $CH$.
   If $v_j$=1, $(C_i,C_j)$ is a Voronoi edge.
   Else $C_i$ starts a ray in the $\overrightarrow{C_iC_j}$ direction.

**End** of algorithm *Voronoi*

**Theorem:** Algorithm *Voronoi* finds the Voronoi diagram for a set of $n$ planar points in $O(\sqrt{n}\log n)$ time on an $O(\sqrt{n}\times\sqrt{n})$ Mesh-Connected Computer.

**Proof:** We give this proof with the assumption that the algorithm *Convex Hull* is correct and takes $O(\sqrt{n}\log n)$ time. (This will be justified once we describe algorithm *Convex Hull* later in this section.) Steps 1 and 3 can be done in constant time. Step 4 involves at most three RARs and needs $O(\sqrt{n})$ time. Thus algorithm *Voronoi* has $O(\sqrt{n}\log n)$ time performance, subject to the assumption about algorithm *Convex Hull* to be presented. □

The rest of this section deals with the description of algorithm *Convex Hull*. The strategy we used is divide-and-conquer based on [4]. Given two set of faces each belonging to a convex hull, we need to first decide for each face if it is an external face. We then remove the faces which are not external. Finally we add new faces along the "circuit" which is shared by pairs of faces consisting of an external face and a non-external face.

To judge if a face is external, we need to test if the two convex hulls to be merged, say convex hull $A$ and $B$, are in the same half space bounded by the face. Let the face to be judged be $F_i^A$ in convex hull $A$. Denote all the faces in convex hull $B$ as $F_j^{B\prime}$s. Instead of testing all the $F_j^B$ with $F_i^{A\prime}$s, we only test two representatives $F_r^B$ and $F_{r'}^B$ such that if they are in the same half space as convex hull $A$, every face in $B$ is. When we refer to a face, we indicate it by three points and define each point by its coordinates $(x_i,y_i,z_i)$. The equation of the plane can be expressed as follows:

$$\begin{vmatrix} x & y & z & 1 \\ x_1 & x_2 & x_3 & 1 \\ y_1 & y_2 & y_3 & 1 \\ z_1 & z_2 & z_3 & 1 \end{vmatrix} = 0.$$

The general form of the above equation is $\alpha_i x + \beta_i y + \gamma_i z + \delta_i = 0$. The details of algorithm *Convex Hull* are as follows:

*Algorithm Convex Hull*:

*input*: A set of points represented by their coordinates $(x_i,y_i,z_i)$. They are distributed on a $\sqrt{n}\times\sqrt{n}$ Mesh-Connected Computer, one point per PE.

*output*: A set of convex faces where each face is represented by three points; a flag indicating whether the face corresponds to a Voronoi point and the index of the PEs where the information about the adjacent faces are present.

2.1 Sort the $n$ points by $x$-coordinates into non-decreasing order in shuffled row major.

2.2 Recursively solve the convex hull problem in parallel on each block of the mesh where a block consists of $2^k$ PEs in the $k$-th iteration.

2.3 Combine two convex hulls each generated in a submesh. (Fig. 4(a) is a reference.)

2.3.1 Decide for each face $F_i$ if it is an external face, and indicate if so by setting the flag *extn* to 1, as described below.

Each PE which contains a face of convex hull $A$, $F_i^A$, performs the following actions:

Find the two representative faces of convex hull $B$, $F_r^B$ and $F_{r'}^B$; (This is done by invoking the algorithm *Represent* which will be presented later.)

Test if $F_r^B$ and $F_{r'}^B$ and convex hull $A$ are in the same half space bounded by $F_i^A$.

If it is, set flag *extn* to 1.

PEs containing faces of convex hull $B$ performs similar actions independently and simultaneously, with $A$ and $B$ reversed.

2.3.2 Find the circuit edges.

The PE which contains $F_i^A$ and has set $extn_i$=1 does a RAR from the PE where $F_k^A$, an adjacent face of $F_i^A$, lies. If $extn_k = 0$, mark the points shared by $F_i^A$ and $F_k^A$. (They form a circuit edge.) All above is repeated three times, once for an adjacent face of $F_i^A$.

(Do the same thing for the PEs containing $F_j^{B\prime}$s in parallel.)

To order the edges in the circuit, independently and concurrently sort all the marked points $p'$s in $A$ and in $B$ by $cos^{-1}\ y/\sqrt{y^2+z^2}$, which is the angle between $op'$ and the $y$ axis where $p'$ is the projection of $p$ on $yz$ plane and $o$ is the origin.

2.3.3 Find the new convex faces between the circuit in $A$ and the circuit in $B$.

*comment*: Each face is decided by an edge $E_i^A$ in circuit $A$ (respectively $E_j^B$ in circuit $B$) and a vertex in circuit $B$ (respectively $A$). Using the method in [5], we need to find for each $E_i^A$ ($E_j^B$ respectively) a vertex from all the vertices in circuit $B$ ($A$ respectively) to form a convex face. Once a vertex, say $p_j$ is chosen, it divides the vertices in circuit $B$ into two subsets. Those edges with index smaller(respectively grater) than $E_i^A$ need only search among the vertices with index smaller (greater respectively) than $p_j$. Here is the implementation. (See Fig. 4(b).)

Originally all the edges in circuit $A$ forms a set and all the PEs containing points in circuit $B$ (marked points) are the submesh associated with the set. Do the following recursively:

(**) Choose an edge with the middle index in each set and broadcast its record to its associated submesh.

For each associated submesh concurrently, do the comparison in each row of the submesh in parallel and in the right most column of the submesh afterward.

Thus the vertex to form the convex face can be found by the criterion in [5]. Denote the index of the PE containing it as $\text{PE}_m$.

Let the edges with index smaller (greater respectively) than or equal to the middle be a set, the PEs with index smaller (greater respectively) than or equal to $\text{PE}_m$ be the associated mesh of the set. (For simplicity, assume the submesh is a rectangular block, since the points in a incomplete row may be distributed to the PEs in the regular block with at most constant increases in the number of points handled per PE. See Fig. 5.) **go to** the line marked "**".

For each new face, set *extn* to 1.

**End** of algorithm *Convex Hull*

**Theorem**: Algorithm *Convex Hull* finds for a set of $n$ points its convex hull in $O(\sqrt{n}\log n)$ time on an $O(\sqrt{n}\times\sqrt{n})$ Mesh-Connected Computer.

**Proof**: Sorting in step 2.1 takes $O(\sqrt{n})$ time. Denote the running time of algorithm *Convex Hull* as $T(n)$. $T(n)$ can be expressed by the recurrence equation $T(n) = T(n/2) + M(n)$. To find $M(n)$, assume algorithm *Represent* in step 2.3.1 is correct and has $O(\sqrt{n}\log n)$ time complexity. (This will be shown after the description of algorithm *Represent*.) Step 2.3.2 involves a constant number of the RARs and sorting steps; therefore $O(\sqrt{n})$ time is sufficient. In step 2.3.3, broadcast, and comparison in each row or column takes $O(\sqrt{n})$ time respectively. Step 2.3.3 needs to be repeated for $\log n$ iterations, thus takes $O(\sqrt{n}\log n)$ time in total. Since $M(n) = O(\sqrt{n}\log n)$, we have $T(n) = O(\sqrt{n}\log n)$. A convex hull with $n$ vertices has at most $3n$–6 edges and $2n$–4 faces. We can distribute the elements on the Mesh-Connected Computer of size $\sqrt{n}\times\sqrt{n}$, with a constant number of points, edges or faces per PE. The proof is complete subject to the correctness of the assumption about algorithm *Represent* which will be shown as follows. □

The representative face of $F_i^A$ is the face $F_r^B$ in $CH(B)$ such that angle$(F_i^A, F_r^B)$ is the smallest. Let the normal vectors of faces $F_i^A$ and face $F_j^B$ be $<a_i,b_i,c_i>$ and $<a_j,b_j,c_j>$ respectively.

$$\cos angle(F_i^A, F_j^B) = <a_i,b_i,c_i>\cdot<a_j,b_j,c_j> = (a_ia_j + b_ib_j + c_ic_j)$$

If angle$(F_i^A, F_j^B)$ is the smallest, $a_ia_j+b_ib_j+c_ic_j$ is the greatest when $0 \le angle \le \pi$. Investigate the distance between point $p_i$ with coordinate$(a_i,b_i,c_i)$ and point $p_j$ with coordinate$(a_j,b_j,c_j)$.

$$distance\ (p_i,p_j) = \sqrt{2(1-(a_ia_j+b_ib_j+c_ic_j))}$$

We can see if $a_ia_j+b_ib_j+c_ic_j$ is the greatest, $distance\,(p_i,p_j)$ is the smallest. To find for $F_i^A$ with normal vector $<a_i,b_i,c_i>$ the face $F_r^B$, we need only to find for point $p_i$ with coordinate $(a_i,b_i,c_i)$ its nearest neighbor among all the points $p_j$, with coordinates $(a_j,b_j,c_j)$ where $<a_j,b_j,c_j>$ is the normal vector of $F_j^B$.

All the points $p_j$ corresponding to faces of $CH(B)$ are on the unit sphere and we can construct a spherical Voronoi diagram for them by projecting onto the sphere the edges of the circumscribing polyhedron which is formed by the planes tangent to the sphere at $p_j$'s [4]. Performing point location for query point $p_i$, we can find its nearest neighbor. Observe the Voronoi diagram in Figure 1, we can find that it is composed by a set of broken line generated at different levels of the merging step, when the Voronoi diagram is being constructed by a divide-and-conquer approach. In Figure 6(a), the bold broken line was generated in the final ($\log n$–1 level) merge step. The fine broken line was generated one step earlier and the dashed broken line was generated two steps earlier. If we sort all the points, on whose Voronoi diagram we are locating the query point, by their $x$-coordinates in non-decreasing order so that their binary indices are $b_{\log n}\cdots b_1b_0$, each segment in the $i$-th level broken line is a perpendicular bisector of two points such that the most significant bit different between their indices are the $i$-th bit. To locate the query point $p_i$, we first want to decide whether it falls in the left half or right half of the Voronoi polygons. Then find which quarter it falls in, and so on. For the example of Fig. 6(a), we first want to decide which side of the bold broken line the query point $p_i$ lies on. Then find which side of the fine broken line it lies on and so on. To decide which side of the broken line a point lies on, first we divide the plane into horizontal slabs each containing one segment (see Fig. 6(b)). Once we find the slab the point falls in, it becomes very easy to examine which side of the segment, and thus of the broken line, point $p_i$ lies. The point location on the spherical Voronoi diagram is similar. The MCC algorithm is as follows:

*Algorithm Represent*

*input*: Two sets of faces belonging to the convex hull of $A$ and $B$ respectively, where face $F_i$ is represented by the equation $\alpha_ix + \beta_iy + \gamma_iz + \delta_i = 0$. The faces are distributed one per PE.

*output*: For each convex face in $A$ two representative convex faces in $B$, (the PE which contains a face in $A$ will have at the end of the algorithm the indices of the PEs which contain the later), and for each convex face in $B$ two representative convex faces in $A$.

2.3.1.1 A PE which contains a face $F_i^A$ ($F_j^B$ respectively) finds its normal vectors $<a_i,b_i,c_i>$ and $<-a_i,-b_i,-c_i>$ ($<a_j,b_j,c_j>$ and $<-a_j,-b_j,-c_j>$ respectively) where

$$a_i = \frac{\alpha_i}{\sqrt{\alpha_i^2+\beta_i^2+\gamma_i^2}}$$

$$b_i = \frac{\beta_i}{\sqrt{\alpha_i^2+\beta_i^2+\gamma_i^2}}$$

$$c_i = \frac{\gamma_i}{\sqrt{\alpha_i^2+\beta_i^2+\gamma_i^2}}$$

The following steps find for each point $p_i(a_i,b_i,c_i)$ and $p_{i'}(-a_i,-b_i,-c_i)$ in $A$ ($B$ respectively), its nearest neighbor among $p_j(a_j,b_j,c_j)$'s in $B$ ($A$ respectively). (They are all on the unit sphere.)

2.3.1.2 Construct the spherical Voronoi diagram for the points in $A$ and $B$ respectively. We describe the steps for the points in $A$. Steps for the points in $B$ are similar.

(a) Find for all the points $p_i$ $(a_i,b_i,c_i)$ corresponding to face $F_i^A$ the planes tangent to the unit sphere at that point. These planes will form a circumscribing polyhedron of the unit sphere. Each PE which contains a face $F_i^A$ generates the equation of the plane $a_ix + b_iy + c_iz = 1$.

(b) To find the edge in the circumscribing polyhedron, each PE containing $F_i^A$ does a RAR from the PE which contains an adjacent face $F_j^A$. The intersection of these planes

$$\begin{cases} a_ix + b_iy + c_iz = 1 \\ a_jx + b_jy + c_jz = 1 \end{cases}$$

decides an edge of the circumscribing polyhedron.

(c) By examining in convex hull $A$ all the faces adjacent to $F_i^A$ of $CH(A)$, we can determine the vertex of the circumscribing polyhedron $t_i(u_i,v_i,w_i)$'s.

(d) Find the Voronoi point $\lambda_i(\xi_i,\eta_i,\zeta_i)$ and Voronoi arc $e_i$ of the spherical Voronoi diagram. Each PE computes

$$\xi_i \leftarrow \frac{u_i}{\sqrt{u_i^2+v_i^2+w_i^2}}$$

$$\eta_i \leftarrow \frac{v_i}{\sqrt{u_i^2+v_i^2+w_i^2}}$$

$$\zeta_i \leftarrow \frac{w_i}{\sqrt{u_i^2+v_i^2+w_i^2}}$$

$$e_i \leftarrow \begin{cases} x^2+y^2+z^2=1 \\ \begin{vmatrix} \eta_1\zeta_1 \\ \eta_2\zeta_2 \end{vmatrix} \mathrm{x} - \begin{vmatrix} \xi_1\zeta_1 \\ \xi_2\zeta_2 \end{vmatrix} \mathrm{y} + \begin{vmatrix} \xi_1\eta_1 \\ \xi_2\eta_2 \end{vmatrix} \mathrm{z} = 0 \end{cases}$$

Each Voronoi arc "remembers" the two points with which it is associated.

2.3.1.3 Mark the levels for the Voronoi arcs in the spherical Voronoi diagram, as described below.

Sort all the points $p_i$'s (the points surrounded by the Voronoi arcs) by $\theta_i = x_i/\sqrt{x_i^2+y_i^2}$. Each point has its binary index.

Each PE which contains a Voronoi arc $e_i$ does a RAR to get the index of the pair of points it is associated with.

Find the "bit exclusive or", say $\Psi$, of the binary index of each pair of points associated with $e_i$. The level of $e_i$, $l_i$, can be found by $l_i = \lfloor \log\Psi \rfloor$. $[(2's\ complement(2^{l_i}) - 2^{l_i}) \wedge (index\ of\ e_i's\ associated\ point)]/2^{l_i+1}$ is the index of the chain to which $e_i$ belongs. For an example, if $e_i$ is associated with point 0010 and 0101, "bit exclusive or" of 0010 and 0101 is 0111, $\lfloor \log 0111 \rfloor = (2)_{10}$, so $e_i$ is of level 2. Furthermore, $2's\ complement(2^2) - 2^2 = 2's\ complement(0100) - 0100 = 1100 - 0100 = 1000$. $(1000 \wedge 0010)$ (or $1000 \wedge 0101$) $= 0$; so $e_i$ is indexed as 0 in the chains of level 2.

2.3.1.4 **From** level $i = \log n - 1$, $i = i - 1$, **until** $i = 0$,

each PE containing an unlocated query point in subset $j$ checks which side of the Voronoi arc chain $j$ of level $i$ it lies at.

(a) Sort all the points in the chain using the chain index as the major key and their $y$-coordinates as the minor key together with the query points using the index of the subset they belong as the major key and their $y$-coordinates as the minor key. Each query points records the index of the PE which it is in as *global_rank*.

(b) Sort the query points only, using the same key described above. Each query point records the index of the PE which it is in as *local_rank* and calculates

$$dest = global\_rank - local\_rank - 1.$$

Then sort all the points in the Voronoi arc chain only, using the same key described above.

(c) Each PE containing the query point does a RAR from the PE with index *dest* to get the equation of the Voronoi arc and the two points associated with it. Decide whether the Voronoi arc lies to the left/right side of the query point and record it as $bound_L/bound_R$.

(d) If a query point has $bound_L$ and $bound_R$ bounding the same region, i.e. has the same associated point, the query point has been located. Record the index of the PE in which the "owner" point of the region lies.

Let all the unlocated query points on the left/right sides of the Voronoi chain of level i be a subset whose index is $b_{\log n}\cdots b_i\cdots b_1 b_0$ with $b_i$ equal to 0/1.

*comment*: In a sorted list, the rank of an element is the number of the elements before it in the list. Given two sets $P\{p_i\}$ and $Q\{q_j\}$, if they are sorted together, *global_rank* of an element indicates the sum of the number of $p_i$'s and $q_j$'s previous to it. Its *local_rank* indicates the number of $q_i$'s previous to it only. So the *global_rank* – *local_rank* indicates the number of $p_i$'s previous to it, and the one closest to it has its own *local_rank* equal to *global_rank* – *local_rank* – 1. For the details, see [8].

**End** of algorithm *Represent*

**Theorem**: Algorithm *Represent* finds for each face in $A$ the representative faces in $B$ in $O(\sqrt{n}\log n)$ time on an $O(\sqrt{n}\times\sqrt{n})$ mesh.

**Proof**: Step 2.3.1.1 needs only constant time. In step 2.3.1.2, step (a), (c) and (d) each takes constant time and (b) needs $O(\sqrt{n})$ time for RAR. Thus step 2.3.1.2 uses $O(\sqrt{n})$ time to finish the construction of the spherical Voronoi diagram. Step 2.3.1.3 involves a sort and a RAR each requiring $O(\sqrt{n})$ time. For step 2.3.1.4, sorting in (a) and (b) each takes $O(\sqrt{n})$ time; RAR in (c) takes $O(\sqrt{n})$ time and (d) needs constant time only. Step 2.3.1.4 will be executed for $\log n$ iterations, thereby requiring $O(\sqrt{n}\log n)$ time. Thus the time complexity of algorithm *Represent* is $O(\sqrt{n}\log n)$. The number of the edges in a Voronoi diagram constructed for $n$ points is $O(n)$. If there are $k$ Voronoi arc chains of level $i$ each with $O(n)$ arcs, there will be $2k$ of Voronoi arc chains of level $i-1$ each with $O(n/2)$ arcs. So we can always distribute the $O(n)$ vertices or arcs in the Voronoi chain together with $O(n)$ query points on an $O(\sqrt{n}\times\sqrt{n})$ mesh, such that each PE has only a constant number of arcs (vertices).

We have presented an algorithm to construct the Voronoi diagram for a set of $n$ planar points on a $\sqrt{n}\times\sqrt{n}$ MCC with constant storage per PE, and proved that its time performance is $O(\sqrt{n}\log n)$.

## III. Applications of the Voronoi Algorithm

The Voronoi diagram can be used to solve many geometrical problems such as finding the nearest neighbors between two sets and constructing the minimum spanning trees.

Given two sets $P$ and $Q$ with $p$ and $q$ points respectively, the problem of all nearest neighbors between two sets is to find for each point in $Q$ its nearest neighbor in $P$. To solve this problem on MCC, we first construct the Voronoi diagram for points in $P$, which takes $O(\sqrt{p}\log p)$ time. Then we perform point location for each point in $Q$ using the same method described in algorithm *Represent*. The nearest neighbor of each point in $Q$ can be found in $O(\sqrt{p+q}\log p)$ time.

Given a set of points in the plane, the minimum spanning tree of it is a subgraph of the Voronoi dual [2]. Based on a Voronoi diagram, the Voronoi dual can be constructed in constant time on the $(\sqrt{n}\times\sqrt{n})$ mesh by joining each pair of points which are associated with a Voronoi edge. The dual is a planar graph. Using, for instance, the mesh algorithm proposed in [12], the minimum spanning tree for a planar graph can be constructed in $O(\sqrt{n}\log n)$ time. Thus the time complexity of the algorithm solving the Euclidean minimum spanning tree problem on a $\sqrt{n}\times\sqrt{n}$ mesh is $O(\sqrt{n}\log n)$.

## IV. Summary

We have presented the algorithm for constructing the Voronoi diagram of a set of planar points on a Mesh-Connected Computer having constant number storage per PE. Given a set of $n$ planar points distributed on an $O(\sqrt{n}\times\sqrt{n})$ Mesh-Connected Computer, our algorithm can find the Voronoi diagram for the set in $O(\sqrt{n}\log n)$ time.

We have also discussed some geometrical problems which can be solved on the Mesh-Connected Computer once the Voronoi diagram has been determined. The problem of determining the nearest neighbors between two sets and constructing Euclidean minimum spanning trees can also be solved with the same time complexity.

# OPTIMAL ALGORITHMS FOR MESH-CONNECTED PARALLEL PROCESSORS WITH SERIAL MEMORIES*

by

Joseph Ja'Ja' and Robert Michael Owens†

Department of Electrical Engineering and Institute For Advanced Computer Studies
University of Maryland
College Park, Maryland 20742

Abstract -- We examine the problems of computing the discrete Fourier transform and performing matrix multiplication on an array of processors, where each processor consists of an ALU, a constant($\leq 3$) number of storage registers, and has a single serial memory attached to it. We show that the discrete Fourier transform can be computed optimally on one or two-dimensional arrays with $p$ processors in time $\Theta(n + \frac{n^2}{p^2})$ and $\Theta(\frac{n}{\sqrt{p}} + \frac{n^2}{p^2})$ respectively. For the problem of multiplying two $n \times n$ matrices, we show the optimal bound of $\Theta(n^2 + \frac{n^4}{p^2})$ for a linear array of $p$ processors and a lower bound of $\Omega(\frac{n^2}{\sqrt{p}} + \frac{n^4}{p^2})$ and an upper bound of $O(\frac{n^3}{p} + \frac{n^4}{p^2})$ for a $\sqrt{p} \times \sqrt{p}$ array of processors. We also settle the case of multiplying a matrix by a vector in time $\Theta(\frac{p}{n} + \frac{n^2}{p})$. Optimal bounds are also established for the corresponding bit model. Our lower bound techniques use a combination of crossing sequence and communication complexity arguments.

## 1. Introduction

In an attempt to achieve the maximum possible speedups, researchers have studied various architectures and examined their suitability to solve different classes of problems. Many schemes for specific problems have been developed and have been shown to achieve optimal speeds on these architectures. However almost all of these designs require that the number of processing elements must grow linearly with the size of the problem, a condition that makes the hardware cost too high.

We examine, in this paper, a simple array architecture (one and two-dimensional) with a fixed number of processors such that a serial memory is attached to each processor. Serial memories appear in magnetic disk, magnetic bubble, charge coupled devices, and even VLSI shift registers. Because of their high information density and low cost, serial memories seem to be quite attractive for use in applications requiring the processing of a large amount of data. However, their overall performance seems to be severely limited due to the fact that the elements can be only accessed in one particular order. A similar model has been studied by several authors ([BL], [BW], [CLW], [CW], [MTW], [OJ], [TW], [WC], [W]). In particular, it was shown in ([OJ]) that sorting $n$ numbers on a linear array of $p$ processors (comparators) can be done in time $\Theta(n + \frac{n^2}{p^2})$, and in time $\Theta(\frac{n}{\sqrt{p}} + \frac{n^2}{p^2})$ on a $\sqrt{p} \times \sqrt{p}$ array of processors. These results show that the performance of serial memories is comparable to that of random access memories whenever $p$ is large enough. In this paper, we consider numerical problems that have high computational requirements. Assuming that each processor is an ALU, we show that computing the discrete Fourier transform on $n$ points requires $\Theta(n + \frac{n^2}{p^2})$ steps in the word model, and $\Theta(n\,q + \frac{n^2q^2}{p^2})$ in the bit model, where each number consists of $q$ bits. For the case of a $\sqrt{p} \times \sqrt{p}$ array of processors, we show the optimal bounds of $\Theta(\frac{n}{\sqrt{p}} + \frac{n^2}{p^2})$ and $\Theta(\frac{nq}{\sqrt{p}} + \frac{n^2q^2}{p^2})$ for the word and bit models respectively. The lower bound techniques use a combination of crossing sequence and communication complexity arguments. We also consider the problem of multiplying two $n \times n$ matrices and exhibit matching upper and lower bounds of $\Theta(n^2 + \frac{n^4}{p^2})$ for a linear array of $p$ processors, and a lower bound of $\Omega(\frac{n^2}{\sqrt{p}} + \frac{n^4}{p^2})$ and an upper bound of $O(\frac{n^3}{p} + \frac{n^4}{p^2})$ for a $\sqrt{p} \times \sqrt{p}$ array of processors. The problem of multiplying a matrix by a vector is shown to require $\Theta(\frac{p}{n} + \frac{n^2}{p})$ steps.

The rest of the paper is organized as follows. The formal model is introduced in the next section, while the upper and lower bounds for the discrete Fourier transform are presented in section 3. The matrix multiplication problem is considered in section 4 and the last section is devoted to the problem of multiplying a matrix by a vector.

## 2. The Model

We will consider a network of $p$ interconnected processors, where each processor $\mathbf{P}_i$, $0 \leq i < p$, consists of one ($\mathbf{R}_i$ in the case of the discrete Fourier transform) or more ($\mathbf{A}_i$, $\mathbf{B}_i$, and $\mathbf{C}_i$ in the case of matrix multiplication) storage registers and an ALU capable of adding, subtracting, and multiplying numbers. A single $q$ bit number can be stored in each

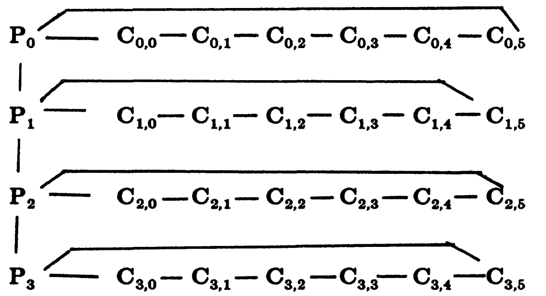
storage register. Attached to each processor $\mathbf{P}_\mathbf{i}$ is a single serial memory $\mathbf{S}_\mathbf{i}$. Each serial memory $\mathbf{S}_\mathbf{i}$ consists of a linearly connected array of storage cells $\mathbf{C}_{\mathbf{i},\mathbf{j}}$, $0 \leq j < l$. Either a single $q$ bit number (the *word* model) or a bit (the *bit* model) can be stored in each cell $\mathbf{C}_{\mathbf{i},\mathbf{j}}$. The length of each serial memory $\mathbf{S}_\mathbf{i}$ is $l$.

When a serial register $\mathbf{S}_\mathbf{i}$ is clocked, the content of cell $\mathbf{C}_{\mathbf{i},\mathbf{j}}$, $1 \leq j < l$, is transferred to cell $\mathbf{C}_{\mathbf{i},\mathbf{j}-1}$. Furthermore, the input to serial memory $\mathbf{S}_\mathbf{i}$ is transferred to cell $\mathbf{C}_{\mathbf{i},\mathbf{l}-1}$ and, hence, to the serial memory itself. The output of the serial memory is the content of cell $\mathbf{C}_{\mathbf{i},0}$.

Suppose processor $\mathbf{P}_\mathbf{i}$ is connected to processors $\mathbf{P}_{\mathbf{i}_j}$, $0 \leq j < n_i$. Then, at the beginning of each step, processor $\mathbf{P}_\mathbf{i}$ has available to it the contents of the storage register(s) of processors $\mathbf{P}_{\mathbf{i}_j}$ $0 \leq j < n_i$, the contents of its own storage register(s), and the output of its serial memory. At the end of each step, each processor is expected to supply a number to its serial memory and possibly change the contents of its storage registers.

In this paper we will consider two particular interconnections. In the first case, the processors are interconnected to form a linear array of length $p$ ( *linear* model). Figure 2.1 illustrates this configuration for $p = 4$ and $n = 24$.



$P_0$
$C_{0,0}$ — $C_{0,1}$ — $C_{0,2}$ — $C_{0,3}$ — $C_{0,4}$ — $C_{0,5}$
$P_1$
$C_{1,0}$ — $C_{1,1}$ — $C_{1,2}$ — $C_{1,3}$ — $C_{1,4}$ — $C_{1,5}$
$P_2$
$C_{2,0}$ — $C_{2,1}$ — $C_{2,2}$ — $C_{2,3}$ — $C_{2,4}$ — $C_{2,5}$
$P_3$
$C_{3,0}$ — $C_{3,1}$ — $C_{3,2}$ — $C_{3,3}$ — $C_{3,4}$ — $C_{3,5}$

Figure 2.1 Linearly Connected Array.

In the second, the processors are interconnected to form a $\sqrt{p} \times \sqrt{p}$ array ( *two-dimensional* model).

Our model is consistent with most of the architectures which have used serial memories as the principal storage memory. In particular the model is consistent with most architectures which use rotating magnetic disks, charge coupled devices, bubble memories, and equal length VLSI shift registers.

## 3. The Discrete Fourier Transform

The Discrete Fourier Transform, DFT, of $n$ points $x_0$, $x_1$, $\cdots$, $x_{n-1}$ is given by:

$$y_i = \sum_{j=0}^{n-1} w^{ij} x_j, \quad 0 \leq i < n, \qquad <DFT(n)>,$$

where $w$ is a primitive $n$'th root of unity. In matrix form,

$$\mathbf{y} = \mathbf{W}\mathbf{x},$$

where $\mathbf{x} = \left[x_i, 0 \leq i < n\right]^T$, $\mathbf{y} = \left[y_i, 0 \leq i < n\right]^T$, and $\mathbf{W} = \left[w^{ij}, 0 \leq i, j < n\right]$.

In this section we will show that $DFT(n)$ can be computed in time $\Theta(n + \frac{n^2}{p^2})$ on a linear array of $p$ processors and $\Theta(\frac{n}{\sqrt{p}} + \frac{n^2}{p^2})$ on a $\sqrt{p} \times \sqrt{p}$ array of processors. In both cases, a serial memory of length $l = \frac{n}{p}$ is attached to each processor. To establish the upper bound for the case of a linear array, we will do the following:

1) show how $DFT(n)$ can be computed on a $p \times \frac{n}{p}$ array of processors using $O(n)$ steps; and

2) show how each step of the array can be emulated using $\frac{n}{p}$ steps on our linear model.

The fast Fourier transform (decimation in frequency scheme [BB]) can be computed on a $p \times \frac{n}{p}$ array of processors in time $O(p + \frac{n}{p})$. In this case $p$ and $n$ are assumed to be both powers of two. From [JO2], we see that this algorithm consists of $\log n$ steps. Step $i$, $1 \leq i < \log p$, involves a column shuffle of length $\frac{p}{2^i}$, the evaluation of expressions of the form $a\,x + b\,y$ at each processor, and a column unshuffle of length $\frac{p}{2^i}$. Step $i$, $\log p \leq i < \log n$, involves a row shuffle of length $\frac{n}{2^i}$, the evaluation of expressions of the form $a\,x + b\,y$ at each processor, and a row unshuffle of length $\frac{n}{2^i}$. From figure 3.1, we see that a column[row] shuffle/unshuffle of two sequences of length $i$ can be performed using $i - 1$ column[row] exchange operations in a rectangular array.

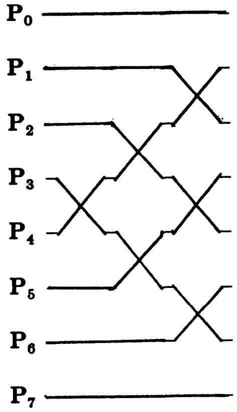


Figure 3.1 Shuffling.

Hence, $DFT(n)$ can be computed on a rectangular array using $O(p + \frac{n}{p})$ steps.

We now consider the emulation of a $p \times \frac{n}{p}$ rectangular array on our model. To emulate the array, we use a linear array of $p$ processors. A shift register of length $\frac{n}{p}$ is attached to each processor. In the emulation the contents of storage cell $\mathbf{C}_{\mathbf{i},\mathbf{j}}$, $0 \leq i < p$, $0 \leq j < \frac{n}{p}$ represent the state of processor $\mathbf{P}_{\mathbf{i},\mathbf{j}}$ of the array being emulated. From [OJ], we see that each step on the rectangular array can be emulated using $O(\frac{n}{p})$ steps on our linear model by shifting the contents of all the shift registers through the processors once. Hence, the discrete Fourier transform of $n$ points can be computed using $O((p + \frac{n}{p})\frac{n}{p}) = O(n + \frac{n^2}{p^2})$ steps on our linear model.

The weights used in the algorithm can either be serially supplied to the processors or computed. Computing the weights requires doubling the length of the serial memories and adding another storage register to each processor ([JO2]).

In the case of the two-dimensional array, it is straightforward to show a bound of $O((\sqrt{p} + \frac{n}{p})\frac{n}{p}) = O(\frac{n}{\sqrt{p}} + \frac{n^2}{p^2})$ steps using an emulation of an algorithm for a $\sqrt{p} \times \sqrt{p} \times \frac{n}{p}$ three dimensional array of processors.

Note that if we assume that a RAM is attached to each processor, we can obtain the bounds of $O(n)$ (linear array) and $O(\frac{n}{\sqrt{p}})$. Hence, if at least $\Omega(\sqrt{n})$ (linear array) or $\Omega(n^{\frac{2}{3}})$ (two-dimensional array) processors are used, a RAM based architecture is not superior to a serial memory based architecture.

To establish the lower bounds, we will elaborate on the basic model. We state precisely the conditions we need for the proof.

(1) Each serial memory $\mathbf{S}_l$ contains $\frac{n}{p}$ numbers, where $2p$ evenly divides $n$. The numbers are initially assumed to be stored in a predetermined order independent of their values.

(2) Each number consists of $q$ bits and each step operates on a number as a single entity.

(3) The serial memories are unidirectional.

(4) A general step of the algorithm at processor $\mathbf{P}_l$ consists of:

   (a) computing two quantities $\alpha_i$ and $\beta_i$ that depend only on the output of $\mathbf{S}_l$, $\mathbf{R}_l$, $\mathbf{R}_{l-1}$, and $\mathbf{R}_{l+1}$.

   (b) updating $\mathbf{R}_l$ with $\alpha_i$ and shifting $\beta_i$ into $\mathbf{S}_l$.

(5) The steps of all the serial memories are synchronous.

(6) The output numbers will reside in the serial memories in a predetermined order independent of their values.

We will call a *cycle* a set of $\frac{n}{p}$ consecutive shifts. Without loss of generality, we assume that the output is generated after precisely $c$ cycles, i.e., after $c\,\frac{n}{p}$ steps, for some positive integer $c$.

Theorem 3.1: Under assumptions (1) - (6), computing the discrete Fourier transform of $n$ points on $p$ linearly connected processors with serial memories requires $\Omega(\frac{n^2}{p^2} + n)$ steps. For a $\sqrt{p} \times \sqrt{p}$ array of processors, we need at least $\Omega(\frac{n^2}{p^2} + \frac{n}{\sqrt{p}})$ steps.

Proof: With each set of input values, we associate two sequences of $p$-tuples which we call *cycle sequences*. The first sequence can be defined as the contents $< \alpha_1^{(i)}, \alpha_2^{(i)}, \cdots, \alpha_p^{(i)} >$ of the R registers (of the processors) at the steps $\frac{n}{2p} + i\frac{n}{p}$, $0 \leq i < c$, where $c$ is the number of cycles as defined above. The second sequence is the contents $< \beta_1^{(i)}, \beta_2^{(i)}, \cdots, \beta_p^{(i)} >$ of the R registers at steps $i\frac{n}{p}$, $1 \leq i < c$. Note that the number of possible distinct cycle sequences is $2^{2qpc}$. We will next establish a lower bound on this quantity.

Recall that the $n$-point discrete Fourier transform of $\mathbf{x}$ is given by

$$\mathbf{y} = \mathbf{W}\mathbf{x}$$

Let $\mathbf{x} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix}$ be such that $\mathbf{x}_1$ is the length $\frac{n}{2}$ vector corresponding to the contents of the lower half of the serial memories and $\mathbf{x}_2$ is the length $\frac{n}{2}$ vector corresponding to the contents of the upper half of the serial memories. Similarly, we can define the two vectors (again each of length $\frac{n}{2}$) $\mathbf{y}_1$ and $\mathbf{y}_2$ which form the output vector. We can reorder the rows and columns of $\mathbf{W}$ to obtain a matrix $\overline{\mathbf{W}}$ such that

$$\begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{bmatrix} = \overline{\mathbf{W}} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} = \begin{bmatrix} \overline{\mathbf{W}}_{1,1} & \overline{\mathbf{W}}_{1,2} \\ \overline{\mathbf{W}}_{2,1} & \overline{\mathbf{W}}_{2,2} \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix}$$

Let $\mathbf{x} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix}$ and $\bar{\mathbf{x}} = \begin{bmatrix} \bar{\mathbf{x}}_1 \\ \bar{\mathbf{x}}_2 \end{bmatrix}$ be two input vectors which have the same cycle sequences. Let $\mathbf{y} = \begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{bmatrix}$ and $\bar{\mathbf{y}} = \begin{bmatrix} \bar{\mathbf{y}}_1 \\ \bar{\mathbf{y}}_2 \end{bmatrix}$ be the corresponding output vectors. Let's examine the output vector corresponding to the input vector $\begin{bmatrix} \mathbf{x}_1 \\ \bar{\mathbf{x}}_2 \end{bmatrix}$

For the first $\frac{n}{2p}$ steps, the algorithm works exactly as in the case of the input $\mathbf{x}$. At the beginning of the $(\frac{n}{2p} + 1)$'th step, the situation is identical to the beginning of the $(\frac{n}{2p} + 1)$'th step on input $\bar{\mathbf{x}}$ since $\mathbf{x}$ and $\bar{\mathbf{x}}$ have same cycle sequences. Hence, the algorithm behaves exactly as in the case of the input $\bar{\mathbf{x}}$ for the next $\frac{n}{2p}$ steps. Again, at the $(\frac{n}{p} + 1)$'th step, the situation is identical to that of input $\mathbf{x}$ at the $(\frac{n}{p} + 1)$'th step, and so on. Therefore, the output will be $\begin{bmatrix} \mathbf{y}_1 \\ \bar{\mathbf{y}}_2 \end{bmatrix}$, i.e., we have

$$\begin{bmatrix} \mathbf{y}_1 \\ \bar{\mathbf{y}}_2 \end{bmatrix} = \begin{bmatrix} \overline{\mathbf{W}}_{1,1} & \overline{\mathbf{W}}_{1,2} \\ \overline{\mathbf{W}}_{2,1} & \overline{\mathbf{W}}_{2,2} \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \bar{\mathbf{x}}_2 \end{bmatrix}$$

It follows that

$$\mathbf{y}_1 = \overline{\mathbf{W}}_{1,1}\mathbf{x}_1 + \overline{\mathbf{W}}_{1,2}\mathbf{x}_2 = \overline{\mathbf{W}}_{1,1}\mathbf{x}_1 + \overline{\mathbf{W}}_{1,2}\bar{\mathbf{x}}_2$$

$$\bar{\mathbf{y}}_1 = \overline{\mathbf{W}}_{2,1}\bar{\mathbf{x}}_1 + \overline{\mathbf{W}}_{2,2}\bar{\mathbf{x}}_2 = \overline{\mathbf{W}}_{2,1}\mathbf{x}_1 + \overline{\mathbf{W}}_{2,2}\bar{\mathbf{x}}_2$$

But this implies that

$$\overline{\mathbf{W}}_{1,2}(\mathbf{x}_2 - \overline{\mathbf{x}}_2) = 0$$

$$\overline{\mathbf{W}}_{2,1}(\mathbf{x}_1 - \overline{\mathbf{x}}_1) = 0 \qquad (*).$$

Let $rank(\overline{\mathbf{W}}_{1,2}) = \mu$ and $rank(\overline{\mathbf{W}}_{2,1}) = \lambda$. We know that ([T]) $\mu + \lambda \geq \frac{n}{2}$, regardless of how $\mathbf{W}$ is partitioned. Hence, $range\,\{\overline{\mathbf{W}}_{1,2}\,\mathbf{u}\}$ has $2^{\mu q}$ distinct points, say $\{\,\overline{\mathbf{W}}_{1,2}\,\mathbf{u}_1, \overline{\mathbf{W}}_{1,2}\,\mathbf{u}_2, \cdots, \overline{\mathbf{W}}_{1,2}\,\mathbf{u}_l, \cdots\,\}$ and $range\,\{\overline{\mathbf{W}}_{2,1}\,\mathbf{v}\}$ has $2^{\lambda q}$ distinct points, say $\{\,\overline{\mathbf{W}}_{2,1}\,\mathbf{v}_1, \overline{\mathbf{W}}_{2,1}\,\mathbf{v}_2, \cdots, \overline{\mathbf{W}}_{2,1}\,\mathbf{v}_l, \cdots\,\}$. Consider the input vectors $\begin{bmatrix}\mathbf{v}_j\\ \mathbf{u}_l\end{bmatrix}$ and $\begin{bmatrix}\hat{\mathbf{v}}_j\\ \hat{\mathbf{u}}_l\end{bmatrix}$ such that $(j, i) \neq (\hat{j}, \hat{i})$. In this case (*) does not hold. Hence any two such vectors must have two distinct cycle sequences. The number of such vectors is at least $2^{q\frac{n}{2}}$. Therefore we must have

$$2^{2pcq} \geq 2^{q\frac{n}{2}}$$

Hence, $c \geq \frac{n}{4p}$. >From this it follows that $T = \Omega(\frac{n^2}{p^2})$.

We now show that in the case of a linear array $\Omega(n)$ steps are required no matter how large $p$ is. Let's look at the link between processor $\mathbf{P}_{\frac{p}{2}}$ and processor $\mathbf{P}_{\frac{p}{2}+1}$. Half the input numbers are to the left of that link and the rest are to the right. Computing $DFT(n)$ requires $\Omega(n)$ communication between these two halves. Therefore, $\Omega(n)$ steps are required. The same argument will give $\Omega(\frac{n}{\sqrt{p}})$ for a $\sqrt{p} \times \sqrt{p}$ array of processors. □

Note that if we assume that RAM's are attached to the processors, we get the lower bounds of $\Omega(n)$ and $\Omega(\frac{n}{\sqrt{p}})$ for the linear and two-dimensional arrays respectively.

We can also establish similar lower bounds even if we assume that each number need not be treated as an atomic unit. We modify assumptions (1), (2), and (6) as follows.

(1') Each serial memory $\mathbf{S}_l$ contains $\frac{nq}{p}$ bits of the input, where $2p$ evenly divides $nq$. The bits are stored in a predetermined order independent of their values.

(2') Each step operates on single bits.

(6') The bits of the output will reside in the serial memories in a predetermined order independent of their values. The bits of an output number are stored in consecutive locations in a single serial memory.

We now define a *cycle* to be a set of $\frac{nq}{p}$ consecutive steps.

Theorem 3.2: Under the modified assumptions, computing the discrete Fourier transform of $n$ points, each consisting of $q$ bits, on $p$ linearly connected processors with serial memories requires $\Omega(\frac{n^2q^2}{p^2} + nq)$ steps. Under the same assumptions, we have the lower bound $\Omega(\frac{n^2q^2}{p^2} + \frac{nq}{\sqrt{p}})$ for a $\sqrt{p} \times \sqrt{p}$ array of processors.

Proof: The proof is similar to that of theorem 1.1 with the following modifications. Partition the elements of $\mathbf{x}$ into two subsets $\mathbf{L}$ and $\mathbf{U}$ such that $|\mathbf{U}|, |\mathbf{L}| \geq \frac{n}{3}$ and $x_i \in \mathbf{L}$ ($x_i \in \mathbf{U}$) implies that at least $\frac{1}{4}$ of the bits of $x_i$ are initially stored in the lower (upper) half of the serial memories.

Now let $\mathbf{x} = \begin{bmatrix}\mathbf{x}_1\\ \mathbf{x}_2\end{bmatrix}$ be such that $\mathbf{x}_1$ and $\mathbf{x}_2$ are the vectors corresponding to the elements in $\mathbf{L}$ and $\mathbf{U}$ respectively. Let $\mathbf{y} = \begin{bmatrix}\mathbf{y}_1\\ \mathbf{y}_2\end{bmatrix}$ be defined as before. We thus have

$$\begin{bmatrix}\mathbf{y}_1\\ \mathbf{y}_2\end{bmatrix} = \begin{bmatrix}\overline{\mathbf{W}}_{1,1} & \overline{\mathbf{W}}_{1,2}\\ \overline{\mathbf{W}}_{2,1} & \overline{\mathbf{W}}_{2,2}\end{bmatrix} \begin{bmatrix}\mathbf{x}_1\\ \mathbf{x}_2\end{bmatrix}$$

after reordering the rows and columns of the matrix $\mathbf{W}$. Notice that the bits of $\mathbf{x}_1$ are not necessarily stored initially in the lower half of the serial memories. However, we know that at least $\frac{q}{4}$ bits of each element of $\mathbf{x}_1$ are initially stored in the lower half of the serial memories. Consider all the possible input values for which all the bits of any element of $\mathbf{x}_1$, not in the lower half of the serial memories, are set to zero, and all the bits of any element of $\mathbf{x}_2$, not in the upper half, are set to zero. The number of such input values is at least $2^{\frac{nq}{4}}$. We now follow the same argument as in theorem 3.1 in identifying those values which yield identical cycle sequences.

Notice that if $rank(\overline{\mathbf{W}}_{2,1}) = \mu$, then there exists nonsingular matrices $\mathbf{P}$ and $\mathbf{Q}$ such that

$$\mathbf{P}\,\overline{\mathbf{W}}_{2,1}\,\mathbf{Q} = diag\,\{1, 1, \cdots, 1, 0, 0, \cdots, 0\}\ ,$$

where the number of 1's is equal to $\mu$. Hence, if $\mathbf{u}$ and $\mathbf{v}$ have different first $\mu$ entries, then

$$\mathbf{P}\,\overline{\mathbf{W}}_{2,1}\,\mathbf{Q}\,\mathbf{u} \neq \mathbf{P}\,\overline{\mathbf{W}}_{2,1}\,\mathbf{Q}\,\mathbf{v}$$

But this implies that $\overline{\mathbf{W}}_{2,1}(\mathbf{Q}\,\mathbf{u}) \neq \overline{\mathbf{W}}_{2,1}(\mathbf{Q}\,\mathbf{v})$ and thus $range\,(\overline{\mathbf{W}}_{2,1}\mathbf{u})$ contains at least $2^{\frac{\mu q}{4}}$ points in this case.

## 4. Matrix Matrix Multiplication

The product of two $n \times n$ matrices $\mathbf{A} = \left[a_{i,j},\, 0 \leq i, j < n\right]$ and $\mathbf{B} = \left[b_{i,j},\, 0 \leq i, j < n\right]$ is given by:

$$\mathbf{C} = \left[c_{i,j} = \sum_{k=0}^{n} a_{i,k}\, b_{k,j},\, 0 \leq i, j < n\right]$$

In this section we will show that this product can be computed in time $\Theta(n^2 + \frac{n^4}{p^2})$ on a linear array of $p$ processors and in time $O(\frac{n^3}{p} + \frac{n^4}{p^2})$ on a $\sqrt{p} \times \sqrt{p}$ array of processors. In both cases, a serial memory of length $l = \frac{n^2}{p}$ is attached to each processor. To establish the upper bound for the case of a linear array, one can do the following:

1) present an algorithm which computes the product of two $n \times n$ matrices on an $n \times n$ cyclic square array (an array with cyclic end around connections) using $O(n)$ steps;

2) show how each step on the square array can be emulated using $O(\frac{p}{n} + \frac{n}{p})$ steps on a $p \times l$ cyclic rectangular array;

3) show how each step on the rectangular cyclic array can be emulated using $O(1)$ steps on a rectangular noncyclic array; and

4) show how each step on a rectangular noncyclic array can be emulated using $O(\frac{n^2}{p})$ steps on our model.

We leave the details of steps 1-4 to the reader.

We now establish the lower bounds.

Theorem 4.1: Under the assumptions (1)-(6) of section 3, multiplying two $n \times n$ matrices on $p$ linearly connected processors with serial memories requires $\Omega(n^2 + \frac{n^4}{p^2})$ steps. For a $\sqrt{p} \times \sqrt{p}$ array of processors, we have the lower bound of $\Omega(\frac{n^2}{\sqrt{p}} + \frac{n^4}{p^2})$.

Proof: We actually prove a slightly stronger result by establishing the lower bounds for the problem of matrix squaring. The main strategy is similar to that of theorem 4.1. We show that the number of cycle sequences must be large.

Let $\mathbf{X}$ be an $n \times n$ matrix such that each entry consists of $q$ bits and let $\mathbf{Y} = \mathbf{X}^2$. Let $\mathbf{X} = \mathbf{X}_l + \mathbf{X}_u$, where $\mathbf{X}_l$ and $\mathbf{X}_u$ correspond to the entries initially stored in the lower and upper halves respectively of the serial memories. Suppose that $\overline{\mathbf{X}} = \overline{\mathbf{X}}_l + \overline{\mathbf{X}}_u$ generates the same set of cycle sequences as $\mathbf{X}$. If $\mathbf{Y}_l$ and $\mathbf{Y}_u$ denote the output arrays corresponding respectively to the lower and upper halves of the serial memories, then it is easy to see that we have the following:

$$\mathbf{Y}_l + \mathbf{Y}_u = \left(\mathbf{X}_l + \mathbf{X}_u\right)^2 = \mathbf{X}_l^2 + \mathbf{X}_u^2 + \mathbf{X}_l\mathbf{X}_u + \mathbf{X}_u\mathbf{X}_l$$

$$\overline{\mathbf{Y}}_l + \overline{\mathbf{Y}}_u = \left(\overline{\mathbf{X}}_l + \overline{\mathbf{X}}_u\right)^2 = \overline{\mathbf{X}}_l^2 + \overline{\mathbf{X}}_u^2 + \overline{\mathbf{X}}_l\overline{\mathbf{X}}_u + \overline{\mathbf{X}}_u\overline{\mathbf{X}}_l$$

$$\mathbf{Y}_l + \overline{\mathbf{Y}}_u = \left(\mathbf{X}_l + \overline{\mathbf{X}}_u\right)^2 = \mathbf{X}_l^2 + \overline{\mathbf{X}}_u^2 + \mathbf{X}_l\overline{\mathbf{X}}_u + \overline{\mathbf{X}}_u\mathbf{X}_l$$

$$\overline{\mathbf{Y}}_l + \mathbf{Y}_u = \left(\overline{\mathbf{X}}_l + \mathbf{X}_u\right)^2 = \overline{\mathbf{X}}_l^2 + \mathbf{X}_u^2 + \overline{\mathbf{X}}_l\mathbf{X}_u + \mathbf{X}_u\overline{\mathbf{X}}_l.$$

It is easy to deduce from the above equations the following identity:

$$\left(\mathbf{X}_l - \overline{\mathbf{X}}_l\right)\left(\mathbf{X}_u - \overline{\mathbf{X}}_u\right) + \left(\mathbf{X}_u - \overline{\mathbf{X}}_u\right)\left(\mathbf{X}_l - \overline{\mathbf{X}}_l\right) = 0 \; (*)$$

But in [JK] it was shown that $\Omega(2^{\alpha n^2 q})$ matrices exist such no pair of which satisfy (*), where $\alpha > 0$ is some constant. Therefore the number of cycle sequences must be at least as large, i.e.,

$$2^{2cpq} \geq 2^{\alpha n^2 q}$$

and hence $T = \Omega(\frac{n^4}{p^2})$. The rest of the proof follows as before.

Note that as in the case of theorem 3.2, we can establish similar results for the bit model. Moreover, it is worth mentioning that, for the case of a $\sqrt{p} \times \sqrt{p}$ array of processors, the bounds are optimal if $p \leq n$ or $p = \Theta(n^2)$. On the other hand, if $1 \leq p \leq n^2$ and only the semiring operations of addition and multiplication are allowed, then some processor will have to perform $\Omega(n^3/p)$ operations and hence we have the lower bound of $\Omega(\frac{n^3}{p} + \frac{n^4}{p^2})$ which matches the upper bound.

## 5. Matrix Vector Multiplication

The product of a $n \times n$ matrix $\mathbf{A} = \left[a_{i,j}, 0 \leq i, j < n\right]$ by a $n$ vector $\mathbf{b} = \left[b_i, 0 \leq i < n\right]^T$ is given by:

$$\mathbf{c} = \left[c_i = \sum_{j=0}^{n} a_{i,j}\, b_j, 0 \leq i < n\right]^T$$

In this section we will show that this product can be computed in time $\Theta(\frac{p}{n} + \frac{n^2}{p})$ on a linear array of $p$ processors and $\Theta(\sqrt{\frac{p}{n}} + \frac{n^2}{p})$ on a $\sqrt{p} \times \sqrt{p}$ array of processors. In both cases, a serial memory of length $l = \frac{n^2}{p}$ is attached to each processor. To establish the upper bound, we will do the following:

1) show how this product can be computed on a $p \times l$ array of processors using $O(n)$ steps; and

2) show how this product can be computed on our linear model using $O(\frac{p}{n} + \frac{n^2}{p})$ steps.

We will first consider the case where $p = n$. The algorithm for a $n \times n$ array begins with the storage registers $\mathbf{A}_{i,j}$, $\mathbf{B}_{i,j}$, and $\mathbf{C}_{i,j}$ of processor $\mathbf{P}_{i,}$, $0 \leq i, j < n$ containing $a_{i,j}$, $b_j$, and 0 respectively. Note that the elements of $\mathbf{b}$ are replicated. Figure 5.1 illustrates this initial configuration.

**A** storage registers

| | | | |
|---|---|---|---|
| $a_{0,0}$ | $a_{0,1}$ | $\cdots$ | $a_{0,n-1}$ |
| $a_{1,0}$ | $a_{1,1}$ | $\cdots$ | $a_{1,n-1}$ |
| $\cdots$ | $\cdots$ | $\cdots$ | $\cdots$ |
| $a_{n-1,0}$ | $a_{n-1,1}$ | $\cdots$ | $a_{n-1,n-1}$ |

**B** storage registers

| | | | |
|---|---|---|---|
| $b_0$ | $b_1$ | $\cdots$ | $b_{n-1}$ |
| $b_0$ | $b_1$ | $\cdots$ | $b_{n-1}$ |
| $\cdots$ | $\cdots$ | $\cdots$ | $\cdots$ |
| $b_0$ | $b_1$ | $\cdots$ | $b_{n-1}$ |

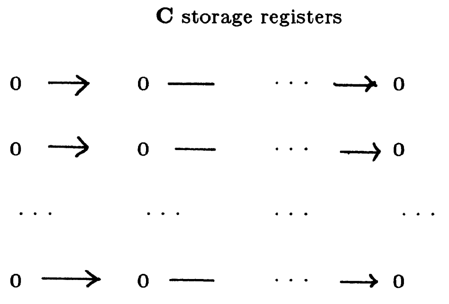

Figure 5.1 Initial Configuration for $p = n$.

The algorithm consists of $n$ steps. At the $k$'th step,

1) the contents of the $\mathbf{C}$ storage registers are shifted rightward as indicated in figure 5.1, i.e., the contents of $\mathbf{C}_{i,k-1}$, $0 \leq i < n$, $1 \leq k < n$, or 0, $0 \leq i < n$, $k = 0$ are transferred to $\mathbf{C}_{i,k}$; and
2) the content of $\mathbf{C}_{i,k}$, $0 \leq i < n$, is replaced by $\mathbf{A}_{i,k}\,\mathbf{B}_{i,k} + \mathbf{C}_{i,k}$.

It is clear that this algorithm can be emulated on our model in only $O(n)$ steps.

We now consider the case where $p < n$. In this case, we assume that $p$ evenly divides $n$. The algorithm for a $p \times n$ array begins with the storage registers $\mathbf{A}_{i,j}$, $\mathbf{B}_{i,j}$, and $\mathbf{C}_{i,j}$ of processor $\mathbf{P}_{i,j}$, $0 \leq i, j < n$ containing $a_{\hat{i},\hat{j}}$, $b_{\hat{j}}$, and 0 respectively, where $\hat{i}=\lfloor i\frac{p}{n}\rfloor$ and $\hat{j}=j+l \; mod(i,\frac{n}{p})$. The algorithm consists of $\frac{n^2}{p}$ steps. At the $k$'th step,

1) the contents of $\mathbf{C}_{i,k-1}$, $0 \leq i < n$, $0 \neq mod(k,n)$ or 0, $0 \leq i < n$, $0 \equiv mod(k,n)$ are transferred to $\mathbf{C}_{i,k}$; and
2) the content of $\mathbf{C}_{i,k}$, $0 \leq i < n$, is replaced by $\mathbf{A}_{i,k}\,\mathbf{B}_{i,k} + \mathbf{C}_{i,k}$.

It is clear that this algorithm can be emulated on our model in only $O(\frac{n^2}{p})$ steps.

We now consider the case where $p > n$. In this case, we assume that $n$ evenly divides $p$. The algorithm for a $p \times n$ array begins with the storage registers $\mathbf{A}_{i,j}$, $\mathbf{B}_{i,j}$, and $\mathbf{C}_{i,j}$ of processor $\mathbf{P}_{i,j}$, $0 \leq i, j < n$ containing $a_{\hat{i},\hat{j}}$, $b_{\hat{j}}$, and 0 respectively, where $\hat{i}=\lfloor i\frac{p}{n}\rfloor$ and $\hat{j}=j+l \; mod(i,\frac{n}{p})$. Clearly, in this case, the product can be computed in $O(\frac{n^2}{p} + \frac{p}{n})$ steps. Taking all the above facts together, we get that the product of a matrix by a vector can be computed in $O(\frac{p}{n} + \frac{n^2}{p})$ steps on our linear model.

The algorithm for a $\sqrt{p} \times \sqrt{p}$ array follows from that of the linear array. The difference being that the product can be computed in only $O(\frac{n^2}{p} + \sqrt{\frac{p}{n}})$ steps instead of $O(\frac{n^2}{p} + \frac{p}{n})$ steps, if $p > n$.

It is obvious that these bounds are optimal even if RAM's are used.

# AN EFFICIENT EMBEDDING OF LARGE TREES IN PROCESSOR GRIDS*

*Duane A. Bailey*

## Abstract

Programming for parallel architectures often includes the specification of a *process embedding* in which logical processes and their interconnections are mapped onto physical processor elements and their connecting links, respectively. Few parallel programming environments provide assistance in performing this embedding. We are investigating the use of grammar-based descriptions of embeddings and we report here on a specific grammar that we have developed for generating embeddings of arbitrarily large, complete binary trees in square processor arrays. The embedding has an efficient processor utilization and it is easily automated. Further, if the number of logical processes exceeds the number of physical processors, our embedding has a simple contraction which yields an optimal, near-uniform distribution of computation and communication tasks.

## Introduction

Within the next decade, parallel architectures composed of a thousand or more processing elements will be commercially available. As the number of processors grows, however, their programming will become an increasingly cumbersome task. This is especially apparent in the activity of *program embedding* in which logical processes and their interconnections are mapped onto physical processing arrays. Aspects of this mapping problem have received significant amounts of attention, yet current parallel programming environments have been able to provide only limited support. We are investigating the use of grammar-based graph descriptions in the development of a strategy for program embedding, and we report here on the characteristics of a specific embedding that we have found for mapping arbitrarily deep, complete binary trees in square grid processor arrays.

Previous embeddings of binary trees into rectangular arrays have been of two types: hand embeddings and recursive embeddings. Hand embeddings[8] have optimal processor utilization but they will not be feasible for the huge numbers of processing elements that we anticipate in future machines. Recursive embeddings[4]-[5] can be automated but they have so far failed to achieve the efficiency of hand embeddings. The Hyper-H embedding, for example, is a useful method for laying out the tree for VLSI but its processor utilization is not optimal. Our strategy, based on specialized *shape grammars*[6], automatically generates optimal embeddings for arbitrarily large trees – even in the case where the number of logical nodes exceeds the number of available processors.

In the next section, we describe the embedding of a $2n$-level complete binary tree in a $2^n \times 2^n$ processor arrays with an interconnection network of the CHiP computer[8]. In following section, we describe the mapping of such a tree onto a smaller grid. And finally, in the last section, we draw some conclusions on extending this program embedding strategy to other regular structures.

## The Tree Embedding

In this section we describe a technique for performing tree embeddings for the CHiP architecture[8]. A CHiP machine (Figure 1) consists of a $2^n \times 2^n$ array of processors with local memory. *Corridors* of switches are located horizontally and vertically between rows of processor elements. We require that each switch have degree 8 and a crossover level of 3, allowing it to host three simultaneous communication paths.

Our tree embedding technique uses a two-phase shape grammar[1] to determine the node assignments and switch settings. In the first phase, processes are embedded into the processor array. For this we use a type of parallel shape grammar, called a *template grammar*, in which derivations are constrained to rewrite the entire sentential shape at each step; that is, the left-hand sides of the set of productions applied must be a minimal set covering the sentential form. In the second phase, communication channels are routed. For this we use a type of sequential shape grammar, called a *ruler grammar*, in which scaling transformations are not allowed.

The template grammar for the first phase of our tree embedding is shown in Figure 2. The letters that appear on the shapes are not actually part of the shapes – they are simply coordinate labels; non-terminal shapes contain an arrow, while terminal shapes do not. A sample derivation is shown in Figure 3. Because the entire shape must be rewritten in every step, all successful derivations in this grammar have the same form: first odd numbered productions are applied for an arbitrary number of steps and then even numbered productions are applied for a single step. The very first production divides the processor array into quadrants. The root of the tree will be located in the quadrant labeled $P$ and it's left and right children will be located in the quadrants labeled $L$ and $R$ respectively. The single unassigned, "orphan processor" will be located in the upper right quadrant, labeled $O$. To embed the remainder of the tree, the array is recursively subdivided into quadrants which will host lower level subtrees. In the final step, processor

*Much of this work was supported by the Office of Naval Research under contract N000014-84-K-0647. Duane Bailey was supported under an American Electronics Association Fellowship from ComputerVision.

[1] A shape grammar operates on shapes in much the same way that a conventional grammar operates on strings: the portion of a sentential form that matches the left-hand side of a production is replaced by its right-hand side. Unlike string grammars, however, the productions of a shape grammar may undergo arbitrary Euclidean transformations before matching [6].

nodes and "buds" for their communication channels are laid down, all of the nonterminal shapes are removed, and we are left with a start shape for the second phase of the grammar.

A ruler grammar for the channel embedding phase is given in Figure 4. In this case, the letters are again used for labels but their positioning is significant. The grammar works by "growing" the channels from the buds left by first phase in such a way that no two channels share a common wire. Figure 5 shows several steps in a sample derivation. Derivations which erroneously create channels that are not part of our embedding will fail to rewrite all non-terminal markers[1]. Final embeddings produced by our grammar for a 63 node tree in an $8 \times 8$ grid and a 255 node tree in a $16 \times 16$ grid are shown in Figure 1. Note the symmetry of the embeddings and that the $8 \times 8$ embedding, rotated by $180^o$, is found in the upper right quadrant of the $16 \times 16$ embedding.

## Contractions Induced by Tree Embeddings

When the number of logical processes exceeds the number of physical processors, it is necessary to contract the logical structure to fit the array. The contraction must map sets of processes to processors while preserving their connectivity. Fishburn and Finkel[3] have suggested using *quotient maps* to generate equivalence classes of processes which may be multitasked on a processor. If the cardinality of each equivalence set is the same, the contraction is said to be *computationally uniform*. A quotient map also induces a set of equivalence classes on the logical communication channels and, if every physical channel emulates the same number of logical channels, it is said to be *exchange uniform*. If a contraction is exchange and computationally uniform, it is said to be *totally uniform*.

Berman and Snyder[2] have suggested the quotient map shown in Figure 6 in which the depth of the tree has been reduced by one, the left and right subtrees of the root have been identified, and the root has been grouped with its two children. Further contractions would be accomplished by iterating this procedure. Repeated coallessing of the root, however, makes this contraction unattractive: it is not computationally uniform because the equivalence class of the root must always contain nearly twice the number of processes found in any other class.

Quotient maps for grids, however, contract more uniformly. Figure 7 details such a contraction. If the grid is folded like a napkin – horizontally and vertically – groups of four nodes are identified to form a smaller grid of equivalence classes. This contraction is totally uniform. It might be expected, therefore, that embeddings of trees that take advantage of grid contractions may yield more uniform distribution of computation and communication. We have found this to be true.

Any embedding of a contracted binary tree in a square grid can off-load extra processes from the root to the unused processor, provided it is possible to route a channel between them. Our embedding assures that the orphan processor is always located horizontally opposite the root, easily accessible to such a channel. We call a complete binary tree in which an extra process has been attached to the root in this way an *augmented tree*.

Extending our grammar to augmented trees in the obvious way produces an embedding with quadrants that are identical under vertical and horizontal flips and can thus be folded into a contraction. This contraction identifies nodes and channels in much same way as Berman's quotient map except in its use of the extra processor. It off-loads nearly half the processes that would otherwise be located at the root, making it exchange uniform and as computationally uniform as possible. Our strategy of first mapping the tree onto a large *logical* processor grid, and then contracting it to an augmented tree embedding of the correct size is conceptually distinct from the contract-then-map paradigm and yields a more uniform distribution of the computation and communication.

## Conclusions

Because shape-related information is often important to the embedding process, we have investigated the use of shape grammars for describing layouts of regular process structures. The strategy we have developed first recursively assigns processes to localities and then routes their interconnections. Using it, we have been able to create efficient embeddings of arbitrarily large, complete binary trees in a square grid. We expect that this strategy will be useful in creating layouts for other regular structures and we are now concentrating on the development of tools to automate some aspects of these grammatical descriptions. In addition, we have found that our tree embedding permits contractions induced by quotient maps of square grids, resulting in a uniform distribution of tasks and communication. We expect that this embed-then-contract approach will also be useful in producing uniform maps of other recursively described structures and we are investigating the extent to which it too can be automated.

# OPTIMAL COMMUNICATION NEIGHBORHOODS

(Preliminary Version)

**L.V. Kalé**

Department of Computer Science
University of Illinois at Urbana–Champaign

**Abstract** — An important consideration while designing a large-scale parallel processing system is whether it provides adequate bandwidth to sustain its communication requirements. We show that for a major class of topologies, if global communication is allowed, the communication requirements increase more rapidly than the bandwidth with increasing number of PEs. We explore the strategy of restricting the communication neighborhood of PEs. We give a method for maximizing the neighborhood while satisfying the bandwidth constraints for the point-to-point topologies and bus topologies, and demonstrate the advantages of bus topologies.

## 1 Introduction

Massive parallel processing systems, with tens of thousands of processors, are feasible with current and foreseeable hardware technologies and costs. An important concern while designing such systems is their *scalability*. A system is scalable if one can add an arbitrary amount of hardware and get a corresponding increase in performance.

In this paper, we first prove that any multi-processor interconnection scheme that allows communication between arbitrary pairs of PEs cannot be scalable. A possible solution is to restrict the maximum communication distance of each PE. For many reasons, including the desirability of uniform load distribution, we wish to maximize the number of PEs reachable in that distance from an individual PE. The problem is that of maximizing this *neighborhood* without sacrificing scalability.

For point–to–point topologies, this problem can be solved by choosing the largest communication distance that is consistent with the bandwidth requirements. Bus–based topologies are more interesting in this context because they provide an additional degree of freedom for the designer: namely, the number of PEs connected by each bus.

In the next section, we show why global–communication schemes are not scalable. Section 3 enunciates the strategy of restricted communication neighborhoods. In Section 4, we apply this strategy to point–to–point topologies. Section 5 develops a method for determining the optimal communication neigborhoods for bus topologies, and applies it to some specific topologies. Section 6 summarizes the results.

## 2 Global Communication is Not Scalable

**Theorem:** *Any topology that connects a number of PEs with uniformly distributed communication requirements without using additional switching elements is not arbitrarily scalable.*

'Uniformly distributed communication requirements' means that both the source and destination of the messages are found with equal probability from any of the PEs of the system. The intuitive idea behind the proof is simple: as the number of PEs in a network increase, so does the number of communication channels, thus creating a balance between message data generated per unit time and the total communication bandwidth. But each message now has to traverse more channels than before, and so the communication requirement eventually catches up with the available bandwidth.

Let $B_a$ and $B_r$ be the available and the required bandwidth of a network as whole, respectively. The available bandwidth can be written as: $B_a = channels(p) B$ (1)
where $B$ is the bandwidth of an individual communication channel and $channels(p)$ is the number of communication channels available in a topology with $p$ PEs. Each PE must have connection to a bounded number of channels to be scalable. Let that bound be $c$. Assuming each channel connects $w$ PEs ($w \geq 2$), $channels(p) = pc/w$ (2)
Then, $B_a = Bpc/w$ (3)

The required bandwidth depends on two factors, the message data generated by each PE, say $m$ bytes/sec, and the average number of channels that each message has to travel, say hops(p). $B_r = m\ p\ hops(p)$ (4)

Given that the number of connections per PE is bounded, the average number of hops must increase with p. To ensure that the system always provides the required bandwidth, we must have $B_a \geq B_r$. However:
$B_a \geq B_r \ \rightarrow\ Bpc/w \geq mp\ hops(p) \ \rightarrow\ Bc/(mw) \geq hops(p)$
The left hand side is constant, while the right hand side increases with $p$, and so there exists a $p$ beyond which this requirement can not be satisfied. □

The preceding theorem has to be understood in proper perspective. It does not preclude global communication altogether: The constant factors may require an unreasonably large number of PEs before the communication stagnation occurs. Communication strategies may bias the probability distribution of the PEs involved in a message towards shorter paths so that even though the length of the longest path increases with $p$, the average path–length does not. Decomposition strategies may increase the grain–size along with the number of PEs, thus reducing the overall communication need.

The result applies to a variety of topologies including the shuffle–exchange, the cube–connected cycles (CCC), and the grid of PEs. For example, in CCC, each PE is connected to 3 channels, and so the number of channels is $(3/2)p$. So if we have designed a CCC system with 384 PEs ($2^6.6$) with well–matched processor speed and communication bandwidth, then the theorem guarantees that for the next possible CCC, which has 896 PEs, communication stagnation is bound to occur. The boolean hypercube escapes this fate because the number of channels in it increases as $p \log p$ while the $hops(p)$ is at most $\log p$. However, it achieves this by increasing the number of connections per PE: there are $\log p$ connections/PE. This is inconsistent with our scalability requirement.

The result does not apply to systems with switching networks because the channels within the switching network provide the required bandwidth. For example, the omega network has $p \log p$ communication channels. In this paper we confine ourselves to topologies without additional switching elements.

## 3 Restricted Communication Neighborhoods

The theorem of last section points to a fundamental limitation of global communication. A system designer has two approaches for dealing with its consequences.

1. Allow global communication and accept the concommitant limit on the maximum size of the system. This is the only possible approach when the application critically depends on global communication. That is a reason why Ullman [1] suggests this approach for fast sorting on multi-processors.

2. In many application domains, global communication is not *necessary*. So, it is feasible to limit the communication neighborhood of each PE and still retain the scalability of the system. Such domains include parallel execution of functional and logic programs. Here, the sub-computations can be contracted out to *any* PE, and in particular to a PE within the neighborhood. Considerations such as uniform load-distribution dictate that the neighborhoods be as large as possible. Finding the largest neighborhood while satisfying the bandwidth constraints is the topic of the rest of the paper.

## 4 The point-to-point Topologies

Let us consider the point-to-point topologies to begin our analysis. For these, $w=2$, i.e. each channel connects only 2 PEs. Let there be $p$ processors, each generating $m$ bytes/sec. Let $d$ be the (average) distance each message is allowed to go. Then, the required bandwidth of the whole system, $B_r = pmd$. By eqn. (3), the total available bandwidth is: $B_a = (pc/2)B$, where B is the bandwidth of an individual channel. For maximum communication distance $d_{\max}$, we equate the required bandwidth with the available bandwidth, to get: $pmd_{\max}=(pc/2)B$. So, $d_{\max}=(cB/2m)$.

Notice that $d_{\max}$ is the bound on the *average* communication distance. It is possible to design communication strategies that allow different communication distances, including those larger than $d_{\max}$, with varying probability so that the average is $d_{\max}$. Here we consider a simpler, more conservative strategy: restrict each message to travel *at most* $d_{\max}$ hops.

Let the number of PEs reachable in $d$ hops be $nbrhood_r(d)$ for a given topology $r$. Then the maximum communication neighborhood for $r$ is $nbrhood_r(d_{\max})$. As an example, consider the 2-dimensional grid of PEs. Here, $nbrhood_r(d)=2d^2+2d+1$. Let the bandwidth of each channel be 100K bytes/sec. and each PE generate a communication load of 10K bytes/sec. Each PE is connected to 4 channels ($c=4$), so $d_{\max} = (4\times100)/(2\times10) = 20$ and the maximum communication neighborhood includes $2\times20^2+2\times20+1 = 841$ PEs.

## 5 Bus Topologies

A *bus* is a communication channel that connects 2 or more PEs. A bus topology is an interconnection scheme that uses a number of buses. A few bus-topologies have been reported in the literature [2-5]. The number of PEs on each bus is called the *width* of the bus, and denoted by $w$. We assume that all the buses in any specific instance of a scheme have the same width. An interconnection scheme may organize a given number of PEs using a variety of bus-widths. Thus $w$ is available as a design parameter that can be chosen with some flexibility. This flexibility makes the problem of finding the optimal communication neighborhoods interesting.

We use the notation defined in Section 4. In addition, let $b$ be the total number of buses in the system. Equation (2) can then be re-written as:

$$pc = bw \qquad (5)$$

Intuitively, the total number of 'wires' coming out of the PEs must equal the total number of connections available on the buses. As before: The required bandwidth, $B_r=pmd$

The available bandwidth, $B_a=bB=(pc/w)B$ (by eqn. 5).

Equating $B_r$ and $B_a$, $pmd = (pc/w)B$.

Therefore:

$$wd = cB/m=w_0 \qquad (6)$$

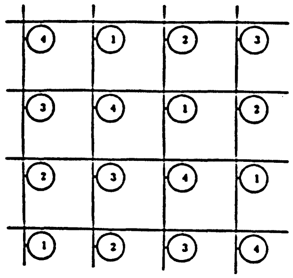
For a given application domain, $m$ is fixed, and for a given communication technology, $B$ is fixed. $c$ is constant for any interconnection scheme. So the equation says that the product $wd$ must remain constant. We denote this constant by $w_0$.

Let $nbrhood_r(w,d)$ be the number of PEs reachable from some PE in $d$ hops in an instance of the topology $r$ with the bus-width of $w$. Obviously, $nbrhood_r(w,d)$ increases with either of $w$ or $d$. Equation 6 tells us that we cannot hope to increase both simultaneously: their product must be kept constant ($=w_0$). This sets up an interesting trade-off between the two. The optimization problem thus reduces to maximization of $nbrhood_r(w,d)$ subject to the constraint that $wd = w_0$. Alternatively, it can be expressed as the maximization of $nbrhood_r(w,w_0/w)$, or of $nbrhood_r(w_0/d,d)$.

The approach for finding the optimal design parameters for a given topology is therefore to first find its *nbrhood* function, and then to maximize the special instance of it expressed above. If we cannot find the a closed-form expression for $nbrhood_r(w,d)$, we may calculate and plot $nbrhood(w_0/d,d)$ empirically, and look for the maxima.

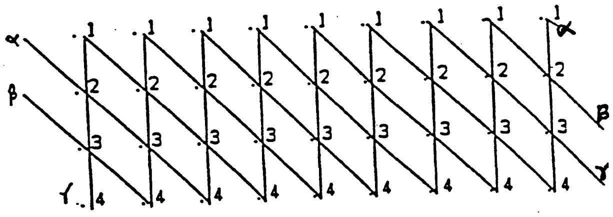
### 5.1 A simple topology

We first consider a simple topology to illustrate the method. An extension of the square grid of buses ( Figure 1) leads to the topology of Figure 2. If $w$ is the width of buses, then in 1 step we reach $2w-1$ PEs. For $d>1$ it can be seen that $nbrhood(w,d) = (d-1)w^2 + w^2/8$, assuming the source is



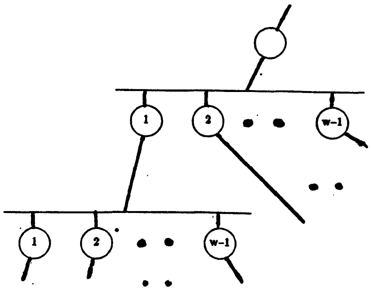
Square Grid of Buses

Figure 1



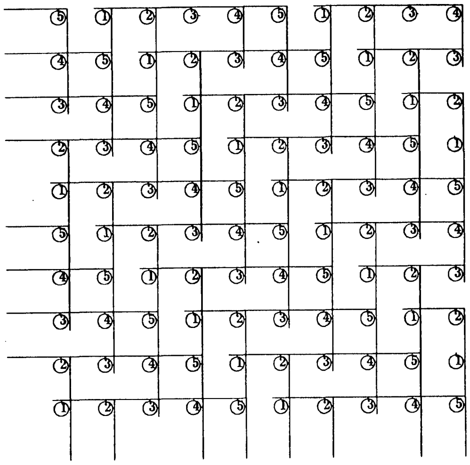
A linear extension of the Square Grid of Buses

Figure 2



Tree of Buses

Figure 3



A Lattice–mesh

Figure 4

at the center of a bus. The optimal w occurs at the maxima of $nbrhood(w,w_0/w) = (w_0/w-1)w^2+w^2/8$. By simple analysis, the optimal $w$ is $4w_0/7$. This corresponds to $d=w_0/w=7/4$. Approximating to the nearest integer, we conclude that the best way to arrange this topology is to let each bus span $w_0/2$ PEs and allow communication to a distance of 2.

### 5.2 Tree of buses

An instance of the tree–of–buses topology is shown in Figure 3. Notice that any node can be made to look like the root of two identical trees (ignoring the discontinuity introduced by the root and the leaves of the physical tree). So, the *nbrhood* function can be written as: $nbrhood(w,d) = 2(w_1^{(d+1)}-1)/(w_1-1)-1$ , where $w_1 = w-1$. For pedagogical value, we approximate this to: $2w_1^d - 1$. The optimization problem then reduces to maximizing: $w_1^{w_0/w}$ . The maxima occurs when $w_1+1 = w_1.ln(w_1)$. This leads to $w_1=3.59$, i.e. $w=4.59$ So we conclude that the width of buses should be 5. The communication distance can then be calculated as $w_0/5$.

### 5.3 The lattice–mesh

The *lattice-mesh* [4] can be thought of as a two–dimensional extension of the square grid of buses. The PEs are laid out on the lattice points in a rectangular $X_{max} \times Y_{max}$ matrix, where $X_{max}$ and $Y_{max}$ are both multiples of w. The layout of buses can be best explained by associating a label with PE. The label of a PE at (x,y) is (1 + (x+y) mod w). All the buses parallel to the X-axis start at a PE with label equal to one, and all the buses parallel to the Y-axis start at a PE with a label $Y_s$, where $Y_s$ is any label other than 1. Figure 4. shows a lattice–mesh of 100 PEs with a bus-width of 5. Buses extending beyond one end are connected consistently at the other end, forming a torroidal structure.

In $d$ hops, the maximum distance one can traverse along either axis is $wd/2$, because any path is a sequence of alternating X and Y axis movements. Moreover, it can be shown that the coordinates of the reachable PEs, assuming (0,0) to be the coordinates of the starting PE, are bounded by: $|X|+|Y| \leq wd/2+w-2$. (Intuitively, every pair of hops can traverse only a distance of $w$, except at the boundaries). Assuming $d \gg 1$, we ignore the smaller terms to get $|X|+|Y| \leq wd/2$. So the reachable PEs are confined within a diamond with distance from the center to a corner equal to $wd/2=w_0/2$. Therefore, nbrhood(w,d) is bounded from above by $2(w_0/2)^2 = w_0^2/2$, and so is independent of w and d! (Even if $w$ and $d$ vary, their product must remain constant by equation 6). I.e. beyond a certain point, increasing $d$ does not lead to any increase in $nbrhood(w,d)$.

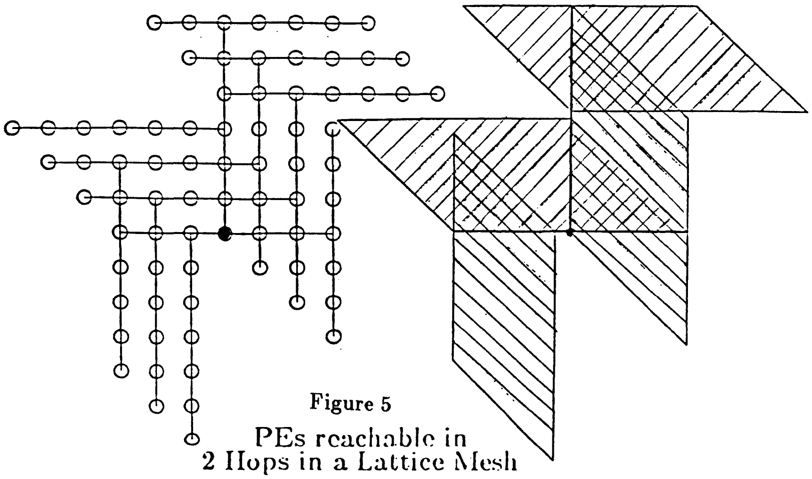


Figure 5

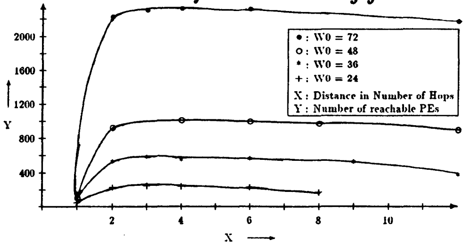
PEs reachable in 2 Hops in a Lattice Mesh

A general calculation of nbrhood(w,d) for lattice–mesh seems difficult. Instead, we derive the number of PEs reachable in a distance of 2. Figure 5–a shows the PEs reachable in 2 hops from the darkened PE, in a lattice–mesh with $w=7$. Figure 5–b depicts the reachable PEs schematically. The doubly shaded areas represent PEs that can be reached by two alternate paths. The reachable PEs are those within the shaded area. By elementary geometry,[1] $nbrhood(w,2) = 4(w^2)/2 - 3(1/2)(w/2)^2 = (13/8)w^2$. For two hops, $w=w_0/2$ (by Equation 6), and we get $nbrhood(w,2)=(13/32)w_0^2$. I.e. in two hops alone, we can reach about 80% of the upperbound on the number of reachable PEs!

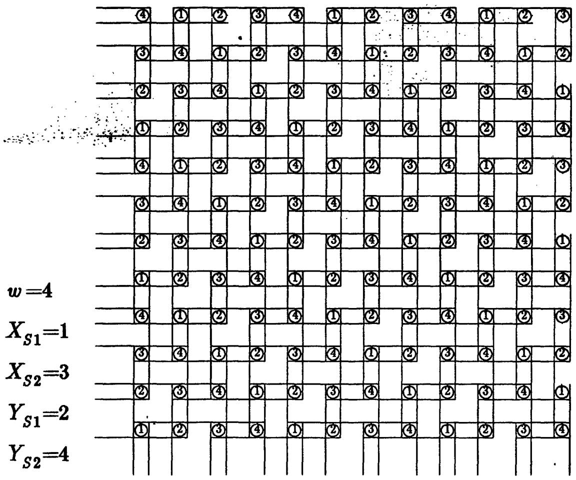
We therefore did some computations to find the maxima of $nbrhood(w_0/d,d)$ for specific values of $w_0$. The results are depicted in Figure 6. In all the instances examined, the maximum occurs at d = 3, and the difference between nbrhood($w_0$/2,2) and nbrhood($w_0$/3,3) was very small.

Notice that when the communication distance is increased from 1 to 2, for $w_0 = 24$, the number of reachable PEs increased from 47 to 223, even though the width of the bus dropped from 24 to 12. Thus at a very little (two-fold) increase in the delay we get a large increase in the neighborhood, without increasing the total communication requirements. Because of the low value of d, very few (1 if d=2) PEs incur the overhead of relaying the message. Therefore, the conclusion seems clear: ***limit communication to a distance of two or three and choose the width of buses accordingly.***

Figure 6



Maximum Reachable PEs in Lattice–mesh



A Double Lattice Mesh

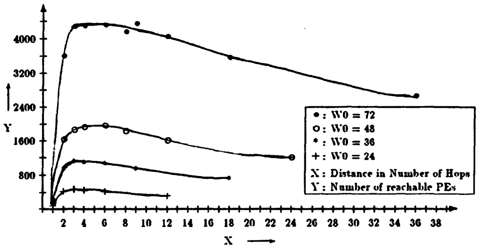
Figure 7

### 5.4 A Bus–topology better than the grid

Is there a bus–topology that is 'better' than the grid–of–processors, in the sense of having a larger neighborhood with similar hardware constraint (i.e. cost) and communication technology? To answer this question, we construct a bus topology that is a generalization of the grid, i.e. one of which the grid is an instance with $w$=2. Such a topology is shown in Figure 7. It has 4 connections per PE like the grid. It is called a double lattice–mesh (DLM) because it can be thought as two lattice–meshes overlapped on each other. A PE at ($x$,$y$) has the label 1+($x$+$y$) *mod* $w$. Analogous to the lattice–mesh, the DLM is paramterized by 4 numbers $X_{s1}$,$X_{s2}$,$Y_{s1}$,$Y_{s2}$ in addition to $w$. There are 2 sets of buses in each row (and column). Each set is arranged just like in the lattice–mesh, except that buses in one set start from PEs with label $X_{s1}$, while buses in the other set start from PEs with label $X_{s2}$. The buses parallel to the Y–axis are similarly defined. It can be easily seen that with w=2, this topology reduces to the grid of PEs.

Again, for the lack of a simple *nbrhood* function, we performed some computations to plot *nbrhood*($w_0$/$d$,$d$). Figure 8 shows the plots for different values of $w_0$. The rightmost point on each plot corresponds to the point–to–point grid. It can be verified from the plots that the bus topologies (w > 2) always do better than the grid. Moreover, $d$=3 is either the optimal distance or is very close to it.

[1] More accurate calculations for nbrhood(w,2) show that when w is odd, *nbrhood*($w$,2)=(13.$w^2$–4.$w$–1)/8, and when w is even, *nbrhood*($w$,$d$)=(13.$w^2$–6.$w$)/8.



Maximum Reachable PEs in Double Lattice–mesh

Figure 8

### 6 Conclusion

We demonstrated unscalability of global communication for a major class of inter–connection schemes, namely those with no additional switching elements. For many application domains, this limitation can be overcome by limiting the communication horizon of each processor. For the point–to–point topologies this strategy led to a simple limit on the communication radius. For the bus topologies, the problem of finding optimal communication neighborhoods is more interesting because of an additional degree of freedom for design: the width of the bus. We gave a general method of finding such neighborhoods, and applied it to several bus–topologies. Such calculations for a topology that generalizes the grid of processors were used to show that bus topologies can perform better in this respect than the point–to–point topologies.

We are investigating bus topologies in the context of a system for parallel processing of combinatorially explosive symbolic computations expressed as Logic Programs. In absense of global communication, the question of distribution of work becomes more important. Contribution of different topologies towards this needs to be investigated. Also, strategies such as (1) probabilistic distribution of communication distance instead of the absolute bound as suggested in this paper and (2) dynamic variation of this distance in response to variations in communication load need to be investigated. Many simulation studies are planned to that end.

**Abstract.** The KAP/205 is a Fortran source-to-source vectorizer which translates serial Fortran DO loops into explicit vector syntax for the Cyber 205, a supercomputer with memory-to-memory vector instructions. The translated program may be compiled using the Fortran-200 compiler and executed on the Cyber 205. This paper explains the optimizations of the KAP/205 which are peculiar to the Cyber 205 architecture and gives some speedups attained relative to the Fortran 200 compiler alone.

## 1. Introduction

The Control Data Cyber 205 supercomputer [1] has memory-to-memory vector instructions. Because of the penalty for starting a vector instruction and the requirement that vector operands be gathered when they are not contiguous, the Cyber 205 performs best when the program uses many long contiguous vector operands. The Cyber 205 is programmed predominantly in Fortran, using the Fortran-200 compiler [2]. Fortran-200, a Fortran-77 [3] based language, includes extensions such as explicit vector syntax and in-line machine code. These extensions allow users to get good performance from their programs, but require much recoding and make the programs entirely non-portable. Users of the Cyber 205 have long desired a better automatic vectorizer that would allow them to access the power of the Cyber 205 without recoding their programs. The KAP/205 fills this need.

The KAP/205 is a Fortran precompiler which accepts and regenerates Fortran-200 programs. The KAP/205 examines the DO loops in the source program and generates vector code where possible. The output of the KAP/205 is an equivalent Fortran-200 program with the vectorized DO loops replaced by explicit vector syntax and in-line machine code. The advantage of using the KAP/205 is that programs remain portable, and the users need not concern themselves with the peculiarities of the machine.

The second section of the paper describes important features of the Cyber 205 with respect to optimization. The third section describes the KAP/205 and how it maps programs onto the Cyber 205. The fourth section describes the vector optimizer of the KAP/205, which chooses the best method to execute a loop nest on the Cyber 205. The final section presents some speedup results of various programs executed on the Cyber 205.

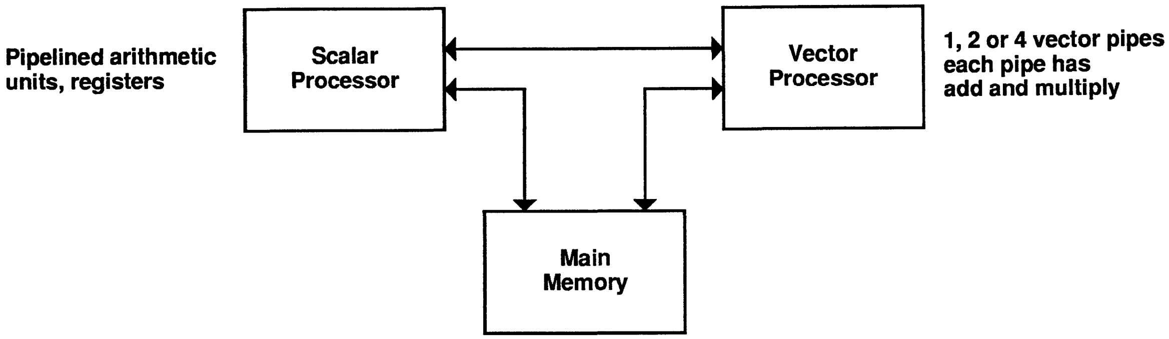
## 2. The Cyber 205 Supercomputer

The Cyber 205 is a high-speed, pipelined, memory-to-memory vector supercomputer. The basic clock is 20 nanoseconds, and the Cyber 205 can issue one instruction per clock in the best case. The machine is divided into a scalar unit and a vector unit sharing a common main memory, as shown in Figure 1. The floating point units are pipelined (even in the scalar unit), so floating point results can be generated at a high rate. In addition to simple vector arithmetic operations such as add and multiply, the Cyber 205 has vector reduction instructions, such as sum of a vector, product of a vector, and maximum and minimum of a vector. Vectors may have up to 65,535 elements. The vector unit can have one, two or four pipelines, which means that one, two or four 64-bit floating point results can be generated in each 20-nanosecond clock period during a vector instruction. Each vector pipeline has a multiplier and an adder, so linked-triad operations like A(I) = B(I)+C(I)×D, with an add, a multiply, and two vector inputs, can be executed with a single pass through the vector pipeline. In this case, each vector pipeline executes two floating point operations per clock (add and multiply); with four pipelines, the Cyber 205 can execute eight floating point operations every 20-nanosecond clock for a peak rate of 400 million floating point operations per second (400 megaflops). In addition, the Cyber 205 has HALF PRECISION operations; for 32-bit operands, each vector pipeline splits in half and can execute two adds and two multiplies in each clock period. Thus the maximum rate of the Cyber 205 is 800 megaflops using 32 bit operands.

Each vector instruction incurs a certain amount of startup time. Scalar instructions must be executed to set up the vector operand descriptors, but scalar instructions are very fast. Each vector instruction itself needs many clocks (as many as 50 clocks, or more than a microsecond, for some instructions) before the vector unit actually starts producing results. Some of this time is related to the pipeline depth of the vector arithmetic units, but much of it is required to start the vector operands streaming from the main memory.

### 2.1 Gathers and Scatters

All the vector arithmetic instructions require that the vector operands be stored in contiguous memory. Non-contiguous operands



Pipelined arithmetic units, registers

must be gathered into temporary vectors before use, and noncontiguous results must be scattered after generation. Periodic gathers and scatters are used when the stride is fixed, and indexed gathers and scatters are used for nonlinear indexing. For example, in Figure 2(a), the array C would be gathered before being added to the array B and stored in array A. Two vector instructions would be used to execute this loop: an indexed gather (using the index vector IP) and a vector add. In Figure 2(b), the first column of the matrix D would be gathered before being added. Again, two vector instructions would be used: a periodic gather (with a period of N, the size of a row of the matrix D), and a vector add.

Gathers and scatters on the Cyber 205 are slow compared to arithmetic operations. Since the speed of a gather or scatter does not increase with the number of vector pipelines, a gather or scatter operation is even slower relative to vector arithmetic on Cybers with multiple vector pipelines.

```
      REAL A(N),B(N),C(N)
      INTEGER IP(N)

      DO 100 I = 1,N
100   A(I) = B(I) + C(IP(I))
```

### 2.2 Vector IF hardware

A vector compare on the Cyber 205 generates a bit vector, with 1's where the test is true and 0's elsewhere. There are several different methods to use bit vectors to execute conditional vector operations [4]. The choice of the best method depends on various run-time parameters, such as the vector length, the density of the vector (percent of 1's in the bit vector), and the number of distinct vector operands in the code under control of the IF test.

The vector arithmetic operations of the Cyber 205 have an optional control vector field, so that the result is stored only where the bit vector is 1 (or only where it is 0, for the ELSE part of an IF). Where the bit vector is 0, the result vector is left unchanged. Use of control vectors is a natural method to execute simple vector IF statements.

When the density of the bit vector is small, other code sequences may be more efficient. An alternate method is to compress each operand vector into a temporary vector before performing any arithmetic, and decompress the result vectors afterwards. This shortens the vector length of the arithmetic operands. Obviously if the number of compresses and decompresses is larger than the number of arithmetic operations, then the control vector method will be faster, since compress and decompress operations run at the same speed as vector arithmetic. However, if the number of arithmetic operations is relatively large compared to the number of compress operations and the bit vector is sparse, then compressing the operands can pay off with short vectors throughout the IF block.

A third method to handle IF statements is applicable when the bit vector is very sparse, and the number of compress operations is relatively small. In this method an index vector containing the index values of the true elements of the bit vector is built. The compress (and decompress) operations above are replaced with indexed gather (and scatter) operations using this index vector. Even though the indexed gather instruction generates fewer results per clock period, this method can be faster since the vector length of the indexed gather operation is N×d, while the vector length of the compress operation is N (d is the density of the bit vector, i.e. the fraction of 1's in the bit vector; 0≤d≤1, so N×d≤N). So, while the compress instruction may produce 2 results per clock (on a 2-pipe Cyber 205), thus taking N/2 clocks (after startup), the gather instruction produces 0.8 results per clock (on average), thus taking 1.25×N×d clocks (after startup). If d is less than 0.4, this method has a chance of being faster. The additional cost of generating the index vector must be taken into account also.

An example of a DO loop containing an IF statement is given in Figure 3(a). Using control vectors for this loop using control vectors gives code similar to that in Figure 3(b); the vector code is shown here using Fortran 200 primitives. The first vector instruction generates the bit vector into a compiler temporary vector, CV. The vector comparison has a vector length of N. The next four vector instructions use the bit vector to control which elements of the result vector to store. Notice the linked-triad statement, performing a vector add and a vector multiply together. Each of these vector arithmetic instructions has a vector length of N. Assuming a 2-pipe Cyber 205, this vectorized loop would take 5×N/2 or 2.5×N clock periods, plus the time to start the four vector instructions, plus time for any scalar code.

Figure 3(c) uses compress/decompress code. The first vector instruction is the same as before, generating a bit vector into a compiler temporary vector. The next two vector instructions compress the vector operands into two more compiler temporary vectors. The vector compress instruction uses the bit vector to control the compress operation, and simultaneously computes the vector length of the result, shown as ND in the program. Each of the four vector arithmetic instructions has a vector length of N×d, where d is the density of the bit-vector. The last instruction decompresses the short result vector back into the original user array, again with a vector length of N. The three compress/decompress instructions would take 3×N/2 or 1.5×N clock periods (plus three startups). The four arithmetic operations would take 4×N×d/2 or 2×N×d clock periods (plus four startups).

```

```

(d) Indexed Gather/Scatter.

Figure 3. Vector IFs.

Adding in the time to generate the bit vector, this comes out to (2×d+2)×N clock periods + 8 startups. If d is less than 0.25, the compress/decompress method may be faster than the control vector method for this loop; of course, the extra startups must be factored in.

Figure 3(d) uses indexed gather/scatter code to execute the vector IF. Again, the first vector instruction generates the bit vector. The second vector instruction initializes an index vector with the index set (1,2,3,...,N). The third vector instruction compresses this index vector into itself; this creates a short index vector which contains the indices of the true elements of the bit vector. Each of these instructions has a vector length of N. The next two vector instructions gather the vector operands into compiler temporary vectors, analogous to the compress instructions in 3(c), with the difference that the vector length is N×d, not N as in the compress instruction. The four vector arithmetic instructions have vector lengths of N×d, and the last vector instruction scatters the short result vector back into the user array, also with a vector length of N×d. The first three instructions would take 3×N/2 or 1.5×N clock periods (plus three startups). The three gather/scatter instructions would take 3×N×d/0.8 clock periods, plus three startups (remember gathers operate at a rate independent of the number of pipes). The four arithmetic operations would take 2×N×d clock periods, plus four startups, just as in 3(c). This totals to (1.5+5.75×d)×N clock periods, plus ten startups. Thus, if d is less than 0.17, this has a chance of being faster than the control vector method (again, the startups must be taken into account). If d is less than 0.13, this has a chance of being faster than the compress method.

### 2.3 Fortran 200 Language

Programming the Cyber 205 is done predominantly in Fortran 200, a Fortran-77 based language with extensions to allow users to access the vector instruction set of the Cyber 205. Some of the vector extensions are shown in the example programs in Figure 3. The semicolon notation (A(1;N)) describes a starting point (A(1)) and a vector length (N), which is how the Cyber 205 hardware describes vector operands. Certain vector intrinsics (Q8VCMPRS, Q8VGATHR) use Cyber 205 vector instructions. In addition there are "special calls" to predefined subroutine names which map directly onto most Cyber 205 machine instructions.

Fortran 200 implements ROWWISE arrays, which are stored in row-major order (like Pascal) instead of column-major. In Figure 2(b), if the array D were declared ROWWISE, then no gather would be necessary in the vector code.

The Fortran 200 compiler includes a vectorizer which, compared to other automatic vectorizers, is relatively weak [5]. Because of this, users of the Cyber 205 learn and use the Fortran 200 vector extensions when they require better performance from their programs. The extensions are hard to use, and make programs non-portable and hard to maintain.

## 3. The KAP/205 Vectorizer

The KAP/205 was designed to alleviate the difficulty of getting good performance on the Cyber 205. The KAP/205 accepts Fortran 200 programs and vectorizes the DO loops, producing an equivalent program with some or all of the DO loops replaced by vector code. The KAP/205 uses Fortran 200 explicit vector notation, vector intrinsic functions and special Q8 calls (in-line assembler code) for vectorized DO loops. Messages and questions from the KAP/205 translator point out the parts of the program which might be further improved with additional help from the user.

The KAP/205 is one of a family of KAP products. The KAP is designed to be a rehostable and retargetable Fortran translation system for discovery of parallelism. Our first products are all source-to-source vectorizers.

The KAP uses the latest software technology for discovery of parallelism in programs. Much of our work is similar to that done at the Parafrase project at the University of Illinois [6,7,8]. Related techniques are also used in the PFC project at Rice University [9,10]. In Parafrase, as well as in the KAP, parallelism is discovered through the use of a precise data dependence graph which shows where data values are generated and where they are used within a DO loop or DO loop nest. The data dependence graph is processed (with simple graph traversal techniques) to find potential problem areas, which appear as cycles in the graph. Each data dependence cycle is carefully examined to see if it can be broken and the loop executed in parallel, or if part or all of the loop must be executed serially.

The KAP includes powerful algorithms for building a high quality data dependence graph. Exact data dependence tests for the most common types of array references are implemented, as well as sophisticated symbolic tests when variables appear as loop bounds or in subscripts. Several auxiliary transformations improve the data dependence graph, such as recognition of loop induction variables and promotion of scalars into arrays.

### 3.1 Retargeting KAP to the Cyber 205

A general purpose vectorizer does not solve the problem facing the users of the Cyber 205. Not all vector operations are equally efficient on this machine, as explained in Section 2. Some operations to be avoided are gathers and scatters of arrays. Short vector operations can sometimes be slower than performing the same code in scalar mode, due to the large startup time for vector instructions. (Interestingly, a vector divide with a vector length of 2 is faster than two scalar divides, because the vector divide unit is pipelined while the scalar divide unit is not; this is not true of other arithmetic operations.) Also, temporary arrays and vectors must be managed efficiently. Finally, many operations cannot be performed in vector mode on the Cyber, such as DOUBLE PRECISION arithmetic.

Retargeting the KAP to the Cyber 205 is made easier due to the modular design of the KAP. One of the first steps of the KAP is the *candidate finder*. This step examines DO loops to see that the operations within the DO loop are legal candidates for vectorization. For the KAP/205, statements with operations that cannot be executed in vector mode, such as DOUBLE PRECISION operations, are marked as non-vectorizable. READ and WRITE statements are similarly marked. DO loops consisting of all non-vectorizable statements are marked as completely serial, and are not studied further.

Much of the KAP, such as the *induction variable finder*, is machine independent, so retargeting these steps was no work at all. The two largest tasks we faced were customizing the vectorizer to produce and optimize vector code for the Cyber 205, and representing these vector constructs in efficient Fortran 200.

### 3.2 Retargeting the Vectorizer to the Cyber 205

The vectorizer of the KAP looks at different ways to execute each DO loop nest and chooses the best. For instance, the standard matrix multiply program shown in Figure 4(a) can be vectorized at least three different ways. In Figure 4(b), the inner DO loop was vectorized, as might be attempted by a simple-minded vectorizer; this results in a inner product of a column of A with a row of B. For the Cyber 205, however, a periodic gather of the column of A is necessary. In Figure 4(c), the second DO loop was interchanged to be the inner loop and was vectorized; this produces a vector operation in the inner loop. On the Cyber 205, this vector statement is actually a linked-triad (an add and a multiply, with one scalar and two vector operands), and would execute in one pass through the vector pipe. However, now two periodic gathers are required and a scatter of the result is also needed. In Figure 4(d), the outermost DO loop was interchanged and was vectorized; this produces a simple linked-triad vector operation in the inner loop with all stride-one vector operands.

The vectorizer step of the KAP actually attempts these different DO loop orderings. If DO loops are not perfectly nested, DO loop distribution may be used in order to allow more loop interchanging. A Cyber 205-specific *vector optimizer* decides which of the loop orderings should be chosen. Given the loop nest in Figure 4(a), the KAP/205 chooses the ordering in 4(d).

The KAP/205 also attempts to collapse loops. The maximum hardware vector length on the Cyber 205 is 65,535; nested loops often have a combined limit of less than this, and can sometimes be executed as a single long vector. *Loop collapsing* combines two or more loops. Other simple and well-known transformations are *statement reordering* to allow vectorization, and *cycle breaking* to eliminate simple data dependence cycles. Figure 5(a) shows a simple DO loop that can be vectorized only if the two statements are reordered; Figure 5(b) shows the equivalent vector Fortran 200 code. Figure 6(a) shows a DO loop with a cycle in its data dependence graph. Semantic analysis shows that this loop simply broadcasts an invariant value to the whole vector A, and thus can be easily vectorized.

```
          REAL C(L,M), A(M,N), B(L,N)

          DO 100 I = 1,L
          DO 100 J = 1,M
          DO 100 K = 1,N
      100  C(I,J) = C(I,J) + A(I,K)*B(K,J)
```

(a) Standard Matrix Multiply Program.

```
          DO 100 I = 1,L
          DO 100 J = 1,M
           TA(1;N) = Q8VGATHP(A(I,1;N), M, N ; TA(1;N))
      100  C(I,J) = C(I,J) + Q8SDOT( TA(1;N), B(1,J;N))
```

(b)Original inner loop (K loop) vectorized.

```
          DO 100 I = 1,L
          DO 100 K = 1,N
           TC(1;M) = Q8VGATHP(C(I,1;M), L, M;TC(1;M))
           TB(1;M) = Q8VGATHP(B(K,1;M), L, M;TB(1;M))
           TC(1;M) = TC(1;M) + A(I,K)*TB(1;M)
      100  C(I,1;M) = Q8VSCATP(TC(1;M), L, M;C(I,1;M))
```

(c) J loop vectorized.

```
          DO 100 J = 1,M
          DO 100 K = 1,N
      100  C(1,J;L) = C(1,J;L) + A(1,K;L)*B(K,J)
```

(d) I loop vectorized.

Figure 4. Loop Interchanging.

```
          REAL A(N),B(N),C(N)

          DO 100 I = 2,N-1
           A(I) = A(I) + B(I-1)
      100  B(I) = B(I) + 1.
```

(a) Unvectorizable statement order.

```
          B(2;N-2) = B(2;N-2) + 1.
          A(2;N-2) = A(2;N-2) + B(1;N-2)
```

(b) Equivalent vectorizable statement order.

Figure 5. Statement Reordering.

```
          REAL A(N)

          DO 100 I = 1,N
      100  A(I) = A(5)
```

(a)

```
          A(1;N) = A(5)
```

(b)

Figure 6.

### 3.3 Producing Efficient Fortran 200

The hardest task of retargeting the KAP to the Cyber 205 was the production of efficient Fortran 200 code. Since the vector constructs of Fortran 200 are so close to the hardware of the machine (even going so far as to define a vector DESCRIPTOR which maps onto the hardware vector operand descriptor), this code generation was very similar to code generation in a compiler. Our job was easier because we did not have to produce our own run-time system and did not have to compile the whole Fortran language.

However, translating the vector constructs into Fortran 200 restricted the operations we could perform. For instance, Fortran 200 does not allow LOGICAL vectors. In order to vectorize IF statements that test LOGICAL array elements, such as the one in Figure 7(a), an artificial method is needed in order to point a descriptor at the proper LOGICAL array. The KAP/205 generates a call to subroutine KQQASS (Figure 7(b)) which returns a descriptor that is used in the controlling expression. The code for KQQASS is a simple descriptor assignment, with the parameter types declared as INTEGER, since the type parameters are ignored by Fortran.

Another problem was that while most of the Fortran intrinsic functions had a vector form, many of them did not allow for conditional evaluation. To use AMOD under control of a conditional expression, for instance, the arguments need to be compressed and the result decompressed.

The only dynamic memory feature in Fortran 200 is dynamic allocation of descriptors. For this reason, the KAP/205 sometimes needs to generate index arithmetic to modify the pointer and length fields of the temporary descriptors. This makes the output of the KAP/205 for vectorized loops look very much like machine code.

```
          LOGICAL L(N)
          REAL A(N),B(I)

          DO 100 I = 1,N
           IF(L(N))A(I) = B(I)
      100 CONTINUE
```

(a) Original program.

```
          DESCRIPTOR LD
          INTEGER LD

          CALL KQQASS( LD, L(1), N )
          WHERE(LD .EQ. 1) A(1;N) = B(1;N)

          SUBROUTINE KQQASS( D, A, N )
          DESCRIPTOR D
          INTEGER D, A(*), N
          ASSIGN D,A(1;N)
          END
```

(b) Vectorized version.

Figure 7. Logical Vectors.

## 4. Vector Optimization in the KAP/205

As mentioned in section 3.2, the vectorizer of the KAP/205 actually discovers many different possible methods to execute loop nests. The "best" loop ordering is the one that will execute in the shortest time in all cases. Clearly this can be data dependent; take for example the matrix multiply case shown in Figure 4. To a casual observer, the vector code in Figure 4(d) is clearly better than the vector code in either of Figures 4(b) or 4(c); 4(d) has no gathers or scatters, and the vector operation is a linked-triad. It seems that this could hardly be improved upon. This assumes that the loop bounds are relatively close, which is certainly true for square matrices. However, cases do arise where the vector length of 4(d), L, is much smaller than either of the other two loop bounds. We can make a rough estimate of the amount of time to execute each vector code segment. For Figure 4(b), one gather operation (taking one startup time plus 1.25 clocks per item gathered) and one inner product (taking one startup plus N/2 clocks, assuming a two-pipe Cyber 205) are required, resulting in two startups plus 1.75×N clocks to execute the vector code. This must be multiplied by the outer loop bounds to get the real time. Note that this is a very rough estimate; in fact startup times are not equal for all instructions, and the serial loop overhead should be factored in.

A similar study of Figure 4(c) counts two gather and one scatter operation (taking three startups plus 3×1.25 clocks per item, total) and one linked-triad (which takes three startups, one for the LINK, one for the MPY and another for the ADD, plus M/2 clocks). Figure 4(d) requires just the linked-triad code (three startups plus L/2 clocks). These numbers are summarized in Figure 8.

If L, M and N are all the same order of magnitude, then the code in Figure 4(d) will be fastest. When L is relatively small, the time for

4(d) can be dominated by the startup time, and 4(b) can look more attractive. If both L and N are small, but M is large, then even 4(c) can turn out to produce the best performance. When all the loop bounds are small, scalar execution of the original loop may be the best method.

Arnold [11] showed that for the Cyber 205, performance of vector Fortran 200 code could be estimated with reasonable accuracy, but the performance of scalar code is much less predictable. The presence of IF statements in the loop makes the prediction process even less precise, but is adequate for a first approximation.

Obviously this analysis can only be applied when the loop bounds are known. In many cases, the loop bounds are parameters to a subroutine or are read in. Also, the probability that each conditional branch is taken must be known to determine the scalar speed and to choose the best method to vectorize that conditional from among the three methods shown above (qv Section 2.2). When these values are not known, some other process must be used to decide what loop ordering to generate. A simpler process is to count important characteristics, such as number of vector statements, number of gathers and scatters needed, and so on.

A third method to approach this problem is to symbolically estimate the execution time of each loop ordering, as we did in Figure 8. IF statements would be inserted to compare the symbolic time estimates using the actual run-time loop bounds in order to choose which loop ordering to execute. This requires generating code for all possible loop orderings.

The actual method used in the KAP/205 is a simple time estimator based on Arnold's results. The best one loop ordering is chosen based on the time estimates, and the code is generated from that loop ordering.

| Timing | | |
|---|---|---|
| code | startups | vector |
| 4(b) | 2×L×M | L×M×N×1.75 |
| 4(c) | 6×L×N | L×M×N×4.25 |
| 4(d) | 3×M×N | L×M×N×0.50 |

Figure 8.

### 4.1 User Interface

The problems with all these are the time required to do the transformations, to estimate the time, and so on, and the necessity to tell the user somehow what happened to his program. A simple vectorizer, that looks only at innermost loops, is much less powerful than the KAP, but at least is easy to understand. If a loop did not vectorize, it is easy to look at the loop and see why it did not vectorize. The KAP/205 has the additional problem of somehow telling the user that any of these three loops could be vectorized, but the DO I (or whatever) loop was vectorized because it was thought best; or, in some cases, a loop was vectorizable, but it was left scalar because it will be faster that way. This occasionally produces unexpected results (to the user). The user interface from the vector optimizer will have to be tuned as the KAP/205 receives more use.

## 5. Speedup Results Using the KAP/205

In this section, we will look at several speedup results using the KAP/205.

Figure 9(a) shows execution time for three different versions of a matrix multiply program for a range of matrix sizes. The line marked "FTN200" shows the execution time for the program shown in Figure 4(a) without the use of the KAP/205. The Fortran 200 compiler does not vectorize the inner loop, giving only scalar performance. The line marked "simple vectorizer" shows the execution time for the program in Figure 4(b); this is the code that a simple vectorizer which only looks at innermost loops might produce; this code is much better than scalar execution. The line marked "KAP/205" shows the execution time for the program in Figure 4(d), which is what the KAP/205 produces for this program; this shows how important loop interchanging and vector optimization are for vector machines. Figure 9(b) shows the megaflops obtained by each of these versions of the program. Figure 9(c) shows the speedup obtained by the KAP/205 over the Fortran 200 compiler and over the hypothetical simpler vectorizer.

Figure 10(a) shows execution times obtained by executing an EISPACK benchmark program with and without using the KAP/205, for a range of problem sizes. Figure 10(b) shows the speedup obtained by the KAP/205 over the Fortran 200 compiler alone. No hand code modification to the EISPACK subroutines was necessary to obtain these results.

Not all programs get the speedup exhibited by these two examples. However, over a wide range of programs, the KAP/205 obtains an average speedup of 1.7-2.0 over the Fortran 200 compiler alone. Some programs will not speed up at all, while others will get reasonable performance and still others will get fantastic speedup.

**Abstract.** The KAP/S-1 is a Fortran source-to-source vectorizer which translates serial Fortran DO loops into explicit vector syntax optimized for execution on the S-1 uniprocessor. This paper explains the optimizations of the KAP/S-1 which are peculiar to the S-1 architecture, including transformations to improve performance of the data cache.

## 1. Introduction

The S-1 Mark IIa supercomputer [1] is a shared memory multiprocessor. Each processor has a memory-to-memory vector instruction set. In order to relieve the load on the shared memory, each processor has a private cache memory. This computer is designed to execute existing and future programs used at the Lawrence Livermore National Laboratory. Most of these programs are now written in LRLTRAN, an extended Fortran language [2].

The KAP/S-1 is a Fortran precompiler which optimizes programs for the S-1 uniprocessor. The KAP/S-1 accepts Fortran-77 [3] with selected LRLTRAN extensions, and produces a modified program using vector syntax for those statements for which the S-1 compiler should generate vector instructions. Several optimizations are also done to improve the performance of the cache memory on the S-1, both for vectorizable and non-vectorizable loops.

The next section of this paper describes the S-1 supercomputer in more detail, concentrating on the features that affect vectorization and optimization in the KAP/S-1. Following that we describe the KAP/S-1 and how it optimizes programs. The fourth section focuses on the cache memory of the S-1 and how the KAP/S-1 attempts to improve the cache hit ratio.

## 2. The S-1 Mark IIa Supercomputer

The S-1 Mark IIa computer includes up to sixteen processors, which communicate through shared memory. Each processor has a private data cache memory and a vector instruction set. In this paper we deal only with optimization for a only with single processor.

The cache memory is 16K 36-bit words organized into 4-way set-associative, 16-word cache lines. Because cache loads are done 16 words at a time, random memory reference patterns will load down the cache-to-main memory link much more on the S-1 than on other machines. This is because each cache miss will result in 16 words being loaded from the main memory, even if only one of these words will be used. However, if memory references are stride-one (meaning contiguous memory addresses are referenced), then the cache memory will work well, since the first cache miss will load the missing word and 15 more words that will be referenced soon. This fits in well with the vector instruction set.

The vector instruction set of the S-1 is relatively limited. Vector adds, multiplies, and other simple operations, as well as MAX, MIN, sum and product reductions are all available. The operands of all of these operations must be stride-one, however. The S-1 has a matrix TRANSPOSE instruction which can be used to transpose arrays which are referenced in the wrong order, or to gather a column from an array into contiguous locations. None of the vector instructions include any method to handle conditionals.

## 3. The KAP/S-1 Vectorizer

The KAP/S-1 vectorizes and optimizes programs for execution on the S-1 uniprocessor. The KAP/S-1 accepts Fortran-77 programs augmented by selected LRLTRAN extensions and produces an equivalent program with some or all of the DO loops replaced by vector code. Vectorized DO loops are represented with vector syntax similar to the syntax proposed by the ANSI X3J3 committee, known as Fortran 8x [4]. The S-1 Fortran compiler accepts this syntax and generates vector code for the S-1. The KAP/S1 vectorizer is related to the KAP/205 and KAP/ST-100 [5,6], and uses many of the same vectorization enhancement techniques.

The vectorization was significantly tuned for the S-1. Because all vector operations on the S-1 require stride-one operands, stride-one array references are preferred. Non-stride-one vector operations are handled by the S-1 compiler, which inserts TRANSPOSE instructions to gather and scatter non-stride-one operands. DO loops can often be interchanged to obtain stride-one array references. For example, the DO J loop in Figure 1(a) could be vectorized, but the resulting vector operations would not have stride-one operands. However, by interchanging the loops before vectorization, the KAP/S-1 will generate the code in Figure 1(b), which has all stride-one array references.

```
      REAL A(100,100),B(100,100),C(100,100)

      DO 100 I = 1,N
       DO 100 J = 1,N
100     A(I,J) = A(I,J) + B(I,J)
```

(a) Non-stride-one.

```
      REAL A(100,100),B(100,100),C(100,100)

      DO 100 J = 1,N
100    A(1:N,J) = A(1:N,J) + B(1:N,J)
```

(b) Interchanged for stride-one.

Figure 1.

Vectorization of the stride-one loop is not always possible; the stride-one loop in Figure 2(a), the DO I loop, cannot be vectorized. In order to obtain vector code, the arrays must be left non-stride-one, as in Figure 2(b). The KAP/S-1 tries different loop orderings and chooses the "best" one, according to its criteria. These criteria include preferring vector code over serial code, and stride-one array operands over non-stride-one array operands. The KAP/S-1 also optimizes the performance of the cache memory, as discussed in the next section.

Interestingly, much of the initial work of customizing the KAP for the S-1 involved restricting the scope of vectorization to that which the S-1 hardware and the S-1 Fortran compiler would handle. For example, the KAP/S-1 precludes vector IFs, since the S-1 has no vector IF hardware. Also, the number of reduction and recurrence operations that the KAP/S-1 would recognize was limited to those for which the S-1 had instructions. Since the vector extensions used only the triplet (colon) notation for vector assignments, diagonal references (such as A(I,I)) could not be vectorized.

```
      REAL A(100,100),B(100,100),C(100,100)

      DO 100 J = 1,N
       DO 100 I = 1,N
100     A(I+1,J) = A(I,J) + B(I,J)
```

(a) Non-stride-one.

```
      REAL A(100,100),B(100,100),C(100,100)

      DO 100 I = 1,N
100     A(I+1,1:N) = A(I,1:N) + B(I,1:N)
```

(b) Vectorized non-stride-one.

Figure 2.

## 4. Optimizing the Cache Memory

Good performance of the cache memory is critical for good performance of the S-1 supercomputer. As was already mentioned, the KAP/S-1 interchanges loops to get stride-one array operands for vector code. For scalar code, the KAP/S1 interchanges loops to get stride-one array references to improve cache performance. Two other transformations were implemented to improve the cache memory performance. These were adapted from work by Abu-Sufah and others [7,8,9] which applies program transformations to improve virtual memory performance. The applications of these transformations to cache memories is clear.

### 4.1 Name Partitioning

The first transformation is *name partitioning*. Name partitioning splits a DO loop into several loops, each of which refers to a non-intersecting subset of the arrays in the loop. The increases locality of reference by reducing the number of arrays to which each DO loop refers. In Figure 3(a), the statements in the DO loop can be split into two distinct groups: the first and third assignments refer to the set of arrays {A,B}, and the second and fourth assignments refer to the set of arrays {C,D}. Figure 3(b) shows how name partitioning would distribute the DO loop into two loops, each of which refers to a subset of the arrays. The original loop refers to four different arrays during each iteration. Each of the distributed loops refers to only two different arrays, thus improving locality of data reference.

```
      DO 100 I = 1,N
       A(I) = A(I) + B(I) + T
       C(I) = C(I) + D(I) + T
       B(I) = B(I) / 2.
100    D(I) = D(I) / 2.
```

(a) Original loop.

```
      DO 100 I = 1,N
       A(I) = A(I) + B(I) + T
100    B(I) = B(I) / 2.
      DO 101 I = 1,N
       C(I) = C(I) + D(I) + T
101    D(I) = D(I) / 2.
```

(b) Name partitioned.

```
       A(1:N) = A(1:N) + B(1:N) + T
       C(1:N) = C(1:N) + D(1:N) + T
       B(1:N) = B(1:N) / 2.
       D(1:N) = D(1:N) / 2.
```

(c) Original loop vectorized.

```
       A(1:N) = A(1:N) + B(1:N) + T
       B(1:N) = B(1:N) / 2.
       C(1:N) = C(1:N) + D(1:N) + T
       D(1:N) = D(1:N) / 2.
```

(d) Name partitioned and vectorized.

Figure 3.

If the original DO loop were vectorized, as in Figure 3(c), the first vector statement will load arrays A and B into the cache memory, while the second vector statement will load arrays C and D. If the vector length, N, is very large, the cache will fill up when C and D are loaded, thus making A and B non-resident. This means that B will have to be reloaded into the cache when the third vector statement is executed. When the distributed loops are vectorized, as shown in Figure 3(d), the second vector statement refers to the array B, which will already be cache-resident.

### 4.2 Strip Mining

*Strip mining* [10] is a more important transformation for the S-1. Strip mining is usually thought to be important for vector machines with a small maximum vector length, such as vector register machines (like the Cray [11]). Proper strip mining, however, can also improve virtual memory (and cache memory) performance.

The DO loop in Figure 4(a) may be easily vectorized, producing the code in Figure 4(b). However, if N is very large, greater than 8,000, then the first vector statement will overflow the cache memory, and will have to start reusing cache memory positions for both the A and B arrays. When the first statement is done, the cache memory contains A(N-8000:N) and B(N-8000:N). When the second statement is started, the first elements accessed are A(1) and B(1); however, these locations were flushed back to the main memory by the first statement, and thus need to be reloaded. To make matters worse, during the execution of the second statement, each new element of A and B that is loaded will replace some later element of A and B in the cache, which will then need to be reloaded later in the vector statement, until all of the arrays A and B have been from main memory to cache and back twice. For loops which use more arrays, this effect is seen at shorter vector lengths.

The solution is to strip mine the DO loop before vectorizing it, as shown in Figure 4(c). The DO IBLOCK loop steps between strips of the inner loop, and is left serial by the vectorization process. The inner loop can be vectorized, as shown in Figure 4(d). The BLOCKSIZE is chosen so that the cache memory never overflows; a rough estimate is the size of the cache divided by the number of distinct arrays referenced in the loop (assuming stride-one array references); for this loop, BLOCKSIZE=8000 would probably be appropriate. The memory reference patterns of the inner loop are very different from the original loop. Since the vector length is never so large as to overflow

```
      DO 100 I = 1,N
       A(I) = A(I) + B(I) + T
100    B(I) = B(I) / A(I)
```

(a) Original loop.

```
       A(1:N) = A(1:N) + B(1:N) + T
       B(1:N) = B(1:N) / A(1:N)
```

(b) Original loop vectorized.

```
      DO 100 IBLOCK = 1,N,BLOCKSIZE
       ISTART = IBLOCK
       IEND = MAX(N,IBLOCK + BLOCKSIZE - 1)
       DO 100 I = ISTART, IEND
        A(I) = A(I) + B(I) + T
100     B(I) = B(I) / A(I)
```

(c) Strip mined.

```
      DO 100 IBLOCK = 1,N,BLOCKSIZE
       ISTART = IBLOCK
       IEND = MAX(N,IBLOCK + BLOCKSIZE - 1)
       A(ISTART:IEND) = A(ISTART:IEND) +
     X                  B(ISTART:IEND) + T
100    B(ISTART:IEND) = B(ISTART:IEND) /
     X                  A(ISTART:IEND)
```

(d) Strip mined and vectorized.

Figure 4.

the cache memory, the second statement will always find its operands in the cache memory. When the second strip starts, it overwrites the operands from the first strip in the cache memory; since they are not needed anymore (for this loop), they can be flushed with no cost later in the execution. The total amount of traffic between the cache memory and the main memory is reduced by a factor of two for long vectors, with a small overhead cost associated with executing the strip mining code. Notice that this type of strip mining only affects memory traffic when there is more than one reference to some array, since the memory traffic that is reduced is the second and subsequent cache loads. If there is only one reference to each array in the loop, then this type of strip mining will not affect the memory traffic at all.

More dramatic performance improvements can appear in DO loop nests. Consider the doubly-nested DO loop in Figure 5(a). The DO J loop can be vectorized, resulting in the code in Figure 5(b). This code can have problems similar to those which occurred in the loop in Figure 4. If the loop bound, N, is very large, then the first iteration of the serial DO I loop will overflow the cache memory with elements of A and B. On the second iteration of the DO I loop, the initial part of the A array will have to be reloaded from the main memory. In essence, the A array will have to be loaded from the main memory N times, once for each trip around the serial loop. Simple strip mining, shown in Figure 5(c), will not alleviate this problem, since the reference pattern for the A array will not change. However, once the DO J loop is strip mined, the outer DO JBLOCK loop can be independently interchanged with the DO I loop, giving the code in Figure 5(d). Vectorizing the inner loop, as shown in Figure 5(e), will produce a different memory reference pattern. In Figure 5(e), BLOCKSIZE is chosen so that each vector statement will not overflow the cache. That way, a strip of the A array can remain cache resident for the entire execution of the serial DO I loop. Each strip of A will be used N times, and then can be flushed back to the main memory since it is not used again in this loop. The memory traffic due to the A array is thus reduced by a factor of N. Loop interchanging of strip mined loops as shown here has clear applications for vector register machines also [12].

```
    DO 100 I = 1,N
     DO 100 J = 1,N
100   A(J) = A(J) + B(J,I)
```

(a) Original loop.

```
    DO 100 I = 1,N
100  A(1:N) = A(1:N) + B(1:N,I)
```

(b) Original loop vectorized.

```
    DO 100 I = 1,N
     DO 100 JBLOCK = 1,N,BLOCKSIZE
      JSTART = JBLOCK
      JEND = MAX(N,JBLOCK + BLOCKSIZE - 1)
      DO 100 J = JSTART,JEND
100    A(J) = A(J) + B(J,I)
```

(c) Strip mined.

```
    DO 100 JBLOCK = 1,N,BLOCKSIZE
     JSTART = JBLOCK
     JEND = MAX(N,JBLOCK + BLOCKSIZE - 1)
     DO 100 I = 1,N
      DO 100 J = JSTART,JEND
100    A(J) = A(J) + B(J,I)
```

(d) Strip mined and interchanged.

```
    DO 100 JBLOCK = 1,N,BLOCKSIZE
     JSTART = JBLOCK
     JEND = MAX(N,JBLOCK + BLOCKSIZE - 1)
     DO 100 I = 1,N
100    A(JSTART:JEND) = A(JSTART:JEND) +
   X                    B(JSTART:JEND,I)
```

(e) Strip mined, interchanged, and vectorized.

Figure 5.

### 4.3 Vectorization and Cache Performance

One unfortunate side effect of vectorization is a decrease in locality of reference. This happens because a loop which formerly executed several statements for a particular index value will, after vectorization, execute each statement for all the index values before going to the next. Thus, if more than one statement in a loop referenced the same array element, as in Figure 3, in the scalar version that array element would remain in the cache through all of the references. After vectorization, the cache will be filled with all of the operands of the first statement before executing the second statement. If the vector length is long enough that all the operands do not fit in the cache, then cache misses will result when the second statement is executed. This effect is countered by proper use of name partitioning and strip mining, as shown above. In nested loops such as those in Figure 4, vectorization and cache transformations will result in fewer cache misses than the scalar code, rather than more.

## 5. Conclusion

In this paper we have shown an example of vectorization for the S-1, a vector supercomputer with a cache. By using loop interchanging, name partitioning, and strip mining, the KAP/S1 improves the cache hit ratio by a significant factor both for loops that are vectorized and for those which remain scalar.

# Doacross: Beyond Vectorization for Multiprocessors (Extended Abstract)

**Ron Cytron**

IBM T. J. Watson Research Center
Yorktown Heights, New York
(work began while the author was at
the University of Illinois at Urbana-Champaign)

Although vector constructs could be executed with speedup on a multiprocessor, the resources of a multiprocessor are wasted unless there are constructs for which it outperforms a vector processor. This paper describes a method of executing iterative loops on a multiprocessor. Loops are classified by their parallelism and a class of loops is exposed that must execute sequentially on vector machines yet can execute with speedup on a multiprocessor.

## 1.0 Motivation and Background

Program performance can be improved through the execution of vector operations, where a single operation is applied concurrently to multiple operands. With the advent of vector processors came the need for vectorization: the compile-time identification of statements within loops that yield vector operations. However, programs do not consist solely of vector operations. Some form of multiprocessing is required to achieve concurrency for constructs of greater complexity than vector loops. However, current methods for programming multiprocessors either rely heavily on user assistance, or involve automatic techniques that are confined to identifying constructs that are even simpler than vector loops. This paper presents a compile-time technique for determining the parallelism of an arbitrary iterative loop, based on the dependences among statements within that loop. In particular, loops that must execute sequentially on a vector processor can execute concurrently on a multiprocessor.

## 1.1 Architectures

Vector processors and multiprocessors both achieve concurrency through multiple processing elements, but the capability and cost of each can be characterized by the following stylized architectures: An *SEA* machine (*S*ingle *E*xecution of *A*rray instructions) drives its processing elements in a parallel or pipelined manner from a control unit that processes a single stream of instructions. In a multiprocessor, each processing element is driven by a stream of instructions issued from its own control unit. One would expect that the multiprocessor, albeit more costly, would provide increased flexibility and performance over the SEA machine.

## 1.2 Dependence

A program can be regarded as a collection of operations that are constrained in their execution by *dependences*: certain operations must complete before other operations can commence. Let a *dependence graph* be constructed for a program, such that directed edges (arcs) connect dependent operations.[1] A dependence exists between two operations, either because they must share or not share some data (data dependence), or because one operation determines whether the other operation is performed (control dependence).

Consider two statements from a program: $S_i$ and $S_j$. If $S_i$ must store any of its output before $S_j$ can fetch all of its input, then a *flow dependence* exists between statements $S_i$ and $S_j$, denoted $S_i \; \delta \; S_j$. An *anti-dependence* exists from $S_i$ to $S_j$, denoted $S_i \; \bar{\delta} \; S_j$, if $S_i$ requires data from an area in which $S_j$ stores its output. Finally, an *output dependence* exists from $S_i$ to $S_j$, denoted $S_i \; \delta^o \; S_j$, if statements $S_i$ and $S_j$ store into common storage locations. Whichever statement executes last in the sequential program must store its output last in the concurrent program.

If statement $S_i$ determines whether statement $S_j$ is executed, then a *control dependence* exists between statement $S_i$ and statement $S_j$, written $S_i \; \delta^c \; S_j$.

## 1.3 Concurrent Execution of Loops

This paper describes the effects of concurrently executing *iterative loops*. An iterative loop contains a sequence of statements (the *loop body*) that is performed for a sequence of *iteration variable* values. The iteration space for an uninterrupted *normalized loop* with upper bound $N$ is the sequence $1,2,...,N$.[2]

A compiler for an SEA architecture must search a program for *vector loops*: loops containing operations that can be executed simultaneously for all iterations. Vectorizing compilers consider the dependence issues mentioned above to determine the vector loops of a program [1, 2, 9, 15]. Statements that participate in a *dependence cycle* cannot be executed as vector loops.

Consider the execution of a vector loop on a multiprocessor, where the iterations of the loop are executed on potentially

[1] In practice, the nodes of a dependence graph are often statements, which results in smaller graphs of coarser granularity.

[2] Any loop can be transformed into a normalized loop through *do-loop normalization* [14].

0190-3918/86/0000/0836 $01.00 © 1986 IEEE

different processors. The absence of a dependence cycle guarantees that the statements of the loop can be ordered, such that all dependences point lexically forward. All dependences then have the form $S_i \delta S_j$, where $i < j$. If processors are driven synchronously, then a compiler can schedule instructions such that dependences are honored without explicit synchronization. Synchronization is necessary if processors operate asynchronously; however, by the time statement $S_j$ executes, statement $S_i$ should have finished. The processor executing statement $S_j$ would probably not have to wait for statement $S_i$ to complete. For more details on synchronization, see [11].

Loops with cycles of dependence must be executed sequentially on an SEA architecture. However, as shown in this paper, such loops can exhibit parallelism when executed on a multiprocessor.

## 2.0 The Doacross Technique

This paper presents a technique that models the execution of sequential loops, vector loops, and loops of intermediate parallelism. The analysis is first presented for a single loop and is subsequently extended for arbitrarily-nested loops. This work is then compared with other methods for executing loops on multiprocessors.

### 2.1 The Doacross Schedule

Consider a single loop $L$ of $s$ statements ($S_1$, $S_2$ , ..., $S_s$ ) and $N$ iterations. Let virtual processors[3] be assigned to loop $L$ such that virtual processor $VP_i$ executes iteration $i$. If loop $L$ is a a vector loop, all $N$ iterations can execute concurrently. Consider the execution of statement $S_1$ of the vector loop. An instance of that statement exists in each virtual processor assigned to the loop. There is effectively no delay between the execution of consecutive instances of $S_1$ , because all virtual processors can start simultaneously. This style of execution corresponds to the total partition algorithm [8] that produces the *doall* schedule [5].

Consider the execution of loop $L$ as a sequential loop. With virtual processors assigned as above, the sequential schedule requires that processor $VP_i$ waits until processor $VP_{i-1}$ finishes its iteration.

Vector and sequential loops can therefore be modeled by a *doacross schedule* with *delay d*: each iteration is assigned to a virtual processor, but each virtual processor delays executing its loop body for the time period $d$, as shown in Figure 1.

```
DO i=1,N
  delay (d*(i-1))
  $S_1$
  $S_2$
   .
   .
   .
  $S_s$
  CONTINUE
```

Figure 1. A Doacross Loop

In general, the delay $d$ between consecutive iterations (virtual processors) can range from no delay (the vector loop case) to the time of the loop body (the sequential loop case). If $T(S_i, S_j)$ is the time for executing statements $S_i$ through $S_j$, inclusively, within an iteration of the loop ($i \leq j$), then a doacross loop has $d = 0$ for a vector loop and $d = T(S_1, S_s)$ for a sequential loop. These loops, and loops of intermediate parallelism, can be characterized by:

$$\textit{parallelism} = \frac{T(S_1, S_s) - d}{T(S_1, S_s)} \times 100 \text{ percent}$$

Sequential loops have 0% parallelism and vector loops have 100% parallelism. Loops of intermediate parallelism are of the greatest interest in this paper, because they achieve no speedup on an SEA architecture.

In a doacross loop of $N$ iterations, the last iteration will accumulate $(N - 1)d$ delay time before executing the loop body. When the loop body of the last iteration has been executed, the execution of the loop is complete:

$$T(loop) = (N - 1)d + T(S_1, S_s) \qquad [1]$$

### 2.2 Generalization of the Doacross Model

In this section, the doacross model is extended to accommodate multiple loops. Figure 2 shows the syntactic model of multidimensional doacross for $L$ nested loops; loop 1 is the outermost loop and loop $L$ is the innermost loop.

```
$B_0$
  $DO_1$ $i_1$=1,$N_1$
    delay (($i_1$-1) * $d_1$)
    $B_1$
    $DO_2$ $i_2$=1,$N_2$
      delay (($i_2$-1) * $d_2$)
      $B_2$
        .
          .
            .
              $B_{L-1}$
              $DO_L$ $i_L$=1,$N_L$
                delay (($i_L$-1) * $d_L$)
                $B_L$
              $ENDDO_L$
              $A_{L-1}$
            .
          .
        .
      $A_2$
    $ENDDO_2$
    $A_1$
  $ENDDO_1$
$A_0$
```

Figure 2. Multidimensional Doacross Model

[3] Virtual processors conveniently model an infinite processor system. Limited processor results appear in [4].

The execution of a doacross loop at nest level $l$ consists of an $N_l$-way fork, where the branch corresponding to the iteration variable $i_l$ delays $(i_l - 1)d_l$ clocks before beginning the execution of block $B_l$. At the end of a doacross loop, the branches join together. For example, a doubly-nested loop structure with no delay at either nest causes all iterations of both nests to execute in parallel.

Consider the timing of a doacross loop at nest level $l$. Iteration $N_l$ delays $(N_l - 1)d_l$ clocks, and then executes block $B_l$, $DO_{l+1}$, and block $A_l$. The time to execute the statements of Figure 2 is therefore:

$$B_0 + \sum_{l=1}^{L} ((N_l - 1)d_l + T(B_l) + T(A_l)) + A_0 \qquad [2]$$

where $T(B_l)$ and $T(A_l)$ represent the time to execute a particular block of code from Figure 2.

## 2.3 Dependence Considerations

This section considers the effects of dependences on delay. Although all dependences in a loop can contribute to a loop's delay, each dependence can be considered separately,[4] with the delay for a loop chosen as the minimum delay that satisfies all dependences.

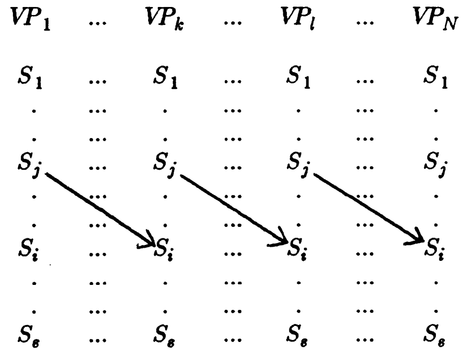
### 2.3.1 Data Dependence

Consider a loop of $s$ statements as shown in Figure 3. Consider two statements, $S_j$ and $S_i$, where $S_j$ lexically precedes $S_i$ ($j < i$). An arc in the dependence graph of Figure 3 from $S_j$ to $S_i$ means that during the sequential execution of the loop, statement $S_j$ computes data used by $S_i$. Let $I_k$ represent the iteration in which $S_j$ computes the data, and let $I_l$ represent the iteration in which $S_i$ uses the data. The semantics of sequential programs execution guarantee that $I_k \leq I_l$; the iteration in which the data is used cannot occur earlier than the iteration in which the data is computed.

```
DO I=1,N
  delay ((I-1) * ??)
  $S_1$
  .
  .
  $S_j$
  .
  .
  $S_i$
  .
  .
  $S_s$
```

Figure 3. A Loop with Unknown Delay

Consider a virtual processor assignment of the iterations of Figure 3 with no delay, as shown in Figure 4. Each column represents the statements that are executed sequentially within a virtual processor. If processors execute at approximately the same rate, virtual processor $VP_l$ will not reach statement $S_i$ of iteration $I_l$ (a column of Figure 4) before statement $S_j$ in virtual processor $VP_k$ has finished. The dependence, as shown in the schedule of Figure 4, is satisfied by the time it is needed, even in the absence of any delay. Because this dependence points forward in the program source, it is called a *lexically-forward dependence*; such dependences do not contribute to a loop's delay. As mentioned in Section 1.3, some architectures may require synchronization to honor such dependences.

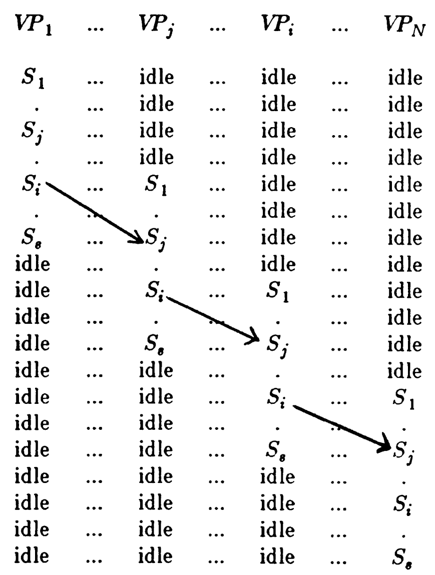


$VP_1$ ... $VP_k$ ... $VP_l$ ... $VP_N$
$S_1$ ... $S_1$ ... $S_1$ ... $S_1$
$S_j$ ... $S_j$ ... $S_j$ ... $S_j$
$S_i$ ... $S_i$ ... $S_i$ ... $S_i$
$S_s$ ... $S_s$ ... $S_s$ ... $S_s$

Figure 4. Loop with Lexically-Forward Dependences

Suppose the dependence were reversed, such that $S_i \; \delta \; S_j$. This type of dependence points backward in the program source, so it is called a *lexically-backward dependence* (abbreviated *LBD*). A lexically-backward dependence can be transformed into a lexically-forward dependence, if $S_i$ and $S_j$ do not participate in a dependence cycle, by reordering the two statements. Those lexically-backward dependences that cannot be eliminated by reordering are the only LBDs of interest in this paper: statements $S_i$ and $S_j$ participate in a dependence cycle, $S_i \; \delta \; S_j$, and $j \leq i$. The semantics of sequential programs guarantee that $I_k < I_l$, since $S_j$ executes no later than $S_i$ within the same iteration. A zero-delay loop schedule will not satisfy the dependence, since virtual processor $VP_l$ will arrive at statement $S_j$ before virtual processor $VP_k$ can satisfy the dependence by executing $S_i$. Delay must be introduced, such that $S_i$ of virtual processor $VP_k$ executes before $S_j$ of virtual processor $VP_l$, as shown in Figure 5.

[4] Multiple dependence relationships can exist between nodes of a dependence graph. The dependence graph is therefore a multigraph, but each dependence can be treated separately.



| $VP_1$ | ... | $VP_j$ | ... | $VP_i$ | ... | $VP_N$ |

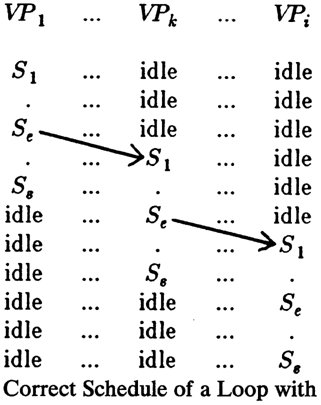
Figure 5. Correct Schedule of a Loop with LBDs

### 2.3.2 Control Dependence

Control dependences are caused by conditional and unconditional branching in programs. There are two cases of branching that must be considered: intra-loop branching and loop exits. The result of an intra-loop branch causes either the omission or repetition of a portion of the loop body, which affects the execution time of a loop. Delay is a probabilistic measure, and represents the time interval observed at the start of an iteration that is *expected* to satisfy dependences. The issue of intra-loop branching and the calculation of delay will be resolved by associating probabilities with statement execution times.

In the absence of loop exits, all iterations of a loop are executed. Consider the program with a loop exit at statement $S_e$. During its sequential execution, some iterations of the loop might be skipped. Like a loop with an LBD, delay must be introduced to accommodate the loop exit, as shown in Figure 6.



| $VP_1$ | ... | $VP_k$ | ... | $VP_i$ |

Figure 6. Correct Schedule of a Loop with a Loop Exit

## 2.4 Calculation of Delay

There are only two constructs that contribute to a loop's delay: loop exits and lexically-backward dependences. The following sections show how to estimate delay for these two cases. After some definitions, a recursive timing formula is presented. Invoking the recursive timing formula once yields the (closed) formula for calculating delay in a single loop. The recursive formula can be invoked again to yield an equation for calculating delay in a double loop structure. The optimal solution to this equation lies in the linear programming domain, but several special cases are discussed. The general formulation for a loop nest of $L$ loops is found by invoking the recursive timing formula $L$ times.

### 2.4.1 Dynamic Statement Instances

Let a program consist of a static sequence of $s$ statements: $S_1$, $S_2$ , ..., $S_s$. Consider statement $S_i$ that is surrounded by $L$ normalized iterative loops. Let $I_1, I_2, ..., I_L$ represent the iteration variables of the $L$ loops, where $I_1$ is the iteration variable of the outermost loop, and $I_L$ is the iteration variable of the innermost loop that surrounds $S_i$. Each iteration variable can assume only integer values in its *iteration sequence*. If the upper bound of iteration variable $I_l$ is $N_l$, then the iteration sequence of that iteration variable is $<1, 2, ..., N_l>$ in the absence of loop exits.

The $L$ loops form an $L$-dimensional integer Cartesian space. The space is composed of discrete points, where each point represents a particular assignment of values to iteration variables from their corresponding iteration ranges [15]. In the absence of loop exits, statement $S_i$ will be executed for all possible values that the iteration variables can assume. The number of times statement $S_i$ executes is therefore $\prod_{l=1}^{L} N_l$.

A *dynamic statement instance*, or simply an *instance*, is the execution of a statement for a specific point in the iteration space of its surrounding loops [8]. The pair $(S_i, \hat{I})$ represents an instance of statement $S_i$ for the *iteration vector* $\hat{I}$. The components of the iteration vector correspond to values of iteration variables for the loops surrounding $S_i$ : $(i_1, i_2, ..., i_L)$. Let $\hat{I}_{|q|}$ represent the iteration vector $\hat{I}$, truncated to its first $q$ elements $(1 \le q \le L)$.

### 2.4.2 The Delta Vector

Consider two statements, $S_i$ and $S_j$, that participate in a lexically-backward data dependence: $S_i \ \delta \ S_j$; some dynamic statement instance of $S_i$ generates data or control information that is used by a dynamic statement instance of $S_j$. Let the instance of $S_i$ be $(S_i, \hat{I})$ and let the instance of $S_j$ be $(S_j, \hat{J})$. Let $CN(S_i, S_j)$ be the number of loops that surround *both* $S_i$ and $S_j$; these are called the *common loops* of $S_i$ and $S_j$. The $\Delta$-*vector* is defined as the difference in iteration index values of the two instances:[5]

$$\Delta = \hat{I}_{|CN(S_i,\, S_j)|} - \hat{J}_{|CN(S_i,\, S_j)|}$$

As developed by Wolfe [15], dependence information is available only for the common loops of $S_i$ and $S_j$. This discussion

[5] A given dependence can give rise to multiple $\Delta$-vectors, but these can be accommodated as distinct edges of the dependence multigraph, each treated separately.

considers only those Δ -vectors that are valid over the common loops of $S_i$ and $S_j$, although the results can be generalized.

As above, let $T(S_j, S_i)$ be the time for executing statements $S_j$ through $S_i$, inclusively, and let $T(S_i)$ be (an abbreviation for) the time for executing only statement $S_i$. Finally, let $\tau(S_i, \hat{I})$ be the time at which $(S_i, \hat{I})$ begins to execute.

### 2.4.3 A Recursive Timing Formula

Consider a statement instance $(S_i, \hat{I})$, where $L = |\hat{I}|$. Statement $S_i$ is surrounded by $L$ loops, with $I_L$ as the innermost loop. The time at which $S_i$ begins to execute with the iteration vector $\hat{I}$ can be defined in terms of the time at which the innermost loop starts and the time at which $S_i$ executes within the innermost loop. In terms of $\tau()$,

$$\begin{aligned}\tau(S_i, \hat{I}) = \tau(DO_L, \hat{I}_{|L-1|}) + (i_L - 1)d_L \\ + T(DO_L, S_i) - T(S_i)\end{aligned} \qquad [3]$$

$\tau(DO_L, \hat{I}_{|L-1|})$ refers to the time at which the innermost do loop $(DO_L)$ begins to execute with the iteration vector $\hat{I}_{|L-1|}$ . This term regards $DO_L$ as a statement within the scope of its outer loop $(DO_{L-1})$. The rest of the expression represents the time at which statement $S_i$ executes, for iteration $i_L$ and delay $d_L$ : $T(DO_L, S_i)$ accounts for the execution of statements from the $DO_L$ through $S_i$, inclusively; $T(S_i)$ is subtracted to make the formula reflect the time at which $S_i$ starts.

The dependence $S_i\delta S_j$ implies that for some iteration vectors, $\hat{I}$ and $\hat{J}$, statement $S_j$ must execute after statement $S_i$ has completed execution. In terms of $\tau()$,

$$\tau(S_j, \hat{J}) \geq \tau(S_i, \hat{I}) + T(S_i)$$

Since $\hat{J} = \hat{I}$ - Δ, the above formula can be rewritten:

$$\tau(S_j, \hat{I} - \Delta) \geq \tau(S_i, \hat{I}) + T(S_i) \qquad [4]$$

After adding $T(S_j, S_i) - T(S_i)$ to both sides of Formula 4:

$$\begin{aligned}\tau(S_j, \hat{I} - \Delta) + T(S_j, S_i) - T(S_i) \geq \\ \tau(S_i, \hat{I}) + T(S_j, S_i)\end{aligned} \qquad [5]$$

By observing that for some *DETLA*-vector $\hat{K}$:

$$\tau(S_i, \hat{K}) = \tau(S_j, \hat{K}) + T(S_j, S_i) - T(S_i)$$

Formula 5 becomes:

$$\tau(S_i, \hat{I} - \Delta) \geq \tau(S_i, \hat{I}) + T(S_j, S_i) \qquad [6]$$

Statement $S_i$ with iteration vector $\hat{I} - \Delta$ cannot start execution until $T(S_j, S_i)$ time has elapsed since the start of statement $S_i$ with iteration vector $\hat{I}$. Since $\hat{J} = \hat{I} - \Delta$, the instance of statement $S_i$ in the iteration in which $S_j$ sinks the dependence for $S_i\delta S_j$ cannot execute until $T(S_j, S_i)$ time after the instance of statement $S_i$ begins to execute in the iteration in which statement $S_i$ sources the dependence.

Using Formula 3, the references to $\tau()$ on the left and right of 6 become:

$$\begin{aligned}\tau(S_i, \hat{I} - \Delta) = \tau(DO_L, (\hat{I} - \Delta)_{|L-1|}) + (i_L - \Delta_L - 1)d_L \\ + T(DO_L, S_i) - T(S_i)\end{aligned}$$

and

$$\tau(S_i, \hat{I}) = \tau(DO_L, (\hat{I})_{|L-1|}) + (i_L - 1)d_L + T(DO_L, S_i) - T(S_i)$$

where $\Delta_L$ is the last (innermost) entry in the Δ-vector. Formula 6 can then be rewritten:

$$\begin{aligned}\tau(DO_L, (\hat{I} - \Delta)_{|L-1|}) - \Delta_L d_L \geq \\ \tau(DO_L, \hat{I}_{|L-1|}) + T(S_j, S_i)\end{aligned} \qquad [7]$$

### 2.4.4 The Single Loop Case

Formula 7 references the delay in the innermost loop, the innermost Δ- vector entry, and the static execution time between statements $S_j$ and $S_i$. Formula 7 also requires the time at which the next outer loop begins to execute with iteration vectors $\hat{I}$ and $\hat{I} - \Delta$ , each truncated before the innermost loop (length $L - 1$). Consider the case of a single iterative loop; because a single loop cannot have an outer loop, the recursive references to $\tau()$ vanish in Formula 7, leaving:

$$-\Delta_L d_L \geq T(S_j, S_i)$$

In terms of linear programming [6, 7], the above formula represents a *constraint* for the delay parameter $d_L$. This constraint should be set to minimize the *objective* function:

$$T(DO_L) = (N - 1)d_L + T(S_1, S_s),$$

which is the time to execute $N$ iterations of a doacross loop containing $s$ statements and delaying $d_L$ time between successive iterations. A single loop can contain a lexically backward dependence only when the iteration in which data is used occurs after the iteration in which data is computed. $\Delta_L$ was constructed from a particular $\hat{I}_L - \hat{J}_L$ for $S_i\delta S_j$ . $\hat{J}_L$ must therefore occur after $\hat{I}_L$ , assuring $\Delta_L < 0$ . The delay $d_L$ is easily solved:

$$d_L \geq \frac{T(S_j, S_i)}{-\Delta_L}.$$

The delay due to the pair of statement instances $(S_i, \hat{I})$ and $(S_j, \hat{J})$ is calculated from the time interval between $S_j$ and $S_i$ and the distance (in iterations) across which the data is passed. Since the above formula provides a lower bound for $d_L$, all delays arising from pairs of statements in a loop can be satisfied by choosing the delay of maximum value for all pairs. An algorithm for determining the delay for a loop in this manner is given in [4].

Consider the example shown in Figure 7. Each assignment statement is linked to the next assignment statement via a forward and backward arc in the data dependence graph. Figure 7 includes a table of estimated execution times for the statements. To estimate $d$ (the delay for the loop), all pairs of statements involved in lexically-backward dependences $(S_i\delta S_j)$ must be considered. For each pair $(S_j, S_i)$, the function *T()* must be evaluated. Note that in this example, the Δ-vector for each backward dependence is (-1). The delay for the loop should be 4 time units per iteration, since the pairs $(S_3, S_2)$ and $(S_4, S_3)$ both yield $T() = 4$. Figure 7 contains the timing schedule for this example.

By delaying each iteration, Figure 7 shows how the $S_3 \delta S_2$ dependence is satisfied. The second processor commences execution of $S_2$ at time step 5; $S_3$ finishes execution in the first processor during time step 4. C(1) will not be requested in $VP_2$ until $VP_1$ has calculated C(1). Note also that the third processor in Figure 7 is really unnecessary; $VP_1$ finished its loop body during time step 7, so $VP_1$ could have executed the third iteration. This is an example of limited processor scheduling, which is discussed in [4].

```
DO i=1,N
  delay((i-1)*d)
  S1:  A(i) = B(i-1) + 37
  S2:  B(i) = A(i) + C(i-1)
  S3:  C(i) = B(i) + D(i-1)
  S4:  D(i) = C(i) + E(i-1)
  S5:  E(i) = D(i) + 77
  ENDDO
```

| Statement | Execution Time |
|---|---|
| $S_1$ | 1 |
| $S_2$ | 2 |
| $S_3$ | 2 |
| $S_4$ | 2 |
| $S_5$ | 1 |

Figure 7. A Single Loop Example

### 2.4.5 The Double Loop Case

Because a single loop has no outer loop, the references to $\tau()$ vanished from Formula 7. A double loop contains an inner loop and an outer loop; if the references to $\tau()$ in Formula 7 are expanded using Formula 3, a new formula results that reflects the situation of two loops: one at nest $L$ and one at nest $L-1$, surrounded by a third loop at nest $L-2$:

$$\tau(DO_{L-1},(\hat{I} - \Delta)_{|L-2|}) + - \Delta_{L-1}d_{L-1} - \Delta_L d_L \geq \qquad [8]$$

$$\tau(DO_{L-1}, \hat{I}_{|L-2|}) + T(S_j, S_i)$$

Since there are only two loops, then the references to $\tau()$ vanish from Formula 8, yielding:

$$-\Delta_{L-1}d_{L-1} - \Delta_L d_L \geq T(S_j, S_i) \qquad [9]$$

Formula 9 imposes conditions on $d_L$ and $d_{L-1}$ such that dependences within two nest levels are satisfied; the optimal setting of the two delays for a single dependence in a two-loop environment cannot be determined from Formula 9. The global objective is to minimize the execution time of the two-loop construct; the execution time for the multidimensional doacross model, restricted to two loops surrounding $s$ statements, is given by:

$$T(DO_{L-1}) = (N_{L-1} - 1)d_{L-1} + (N_L - 1)d_L + T(S_1, S_s) \qquad [10]$$

The minimization of Formula 10 with respect to the constraint of Formula 9 is a linear programming problem, with Formula 10 as the objective function. The objective can be simplified by symbolically replacing constant terms:

$$T(DO_{L-1}) = \eta_1 d_{L-1} + \eta_2 d_L + \eta_3 \qquad [11]$$

where

$$\eta_1 = N_{L-1} - 1$$
$$\eta_2 = N_L - 1$$
$$\eta_3 = T(S_1, S_s)$$

Consider the case in which both $\Delta_{L-1}$ and $\Delta_L$ are negative. The boundary expression for Formula 9 can then be written:

$$d_{L-1} \geq \frac{T(S_j, S_i) + \Delta_L d_L}{-\Delta_{L-1}} \qquad [12]$$

or

$$d_{L-1} \geq \alpha_1 - \alpha_2 d_L$$

where

$$\alpha_1 = -\frac{T(S_j, S_i)}{\Delta_{L-1}}$$

$$\alpha_2 = \frac{\Delta_L}{\Delta_{L-1}}$$

Consider the case where all delay is charged to the outermost loop $d_{L-1}$; no delay is charged to the inner loop, so $d_L = 0$. The objective function becomes:

$$T(DO_{L-1}) = \alpha_1 \eta_1 + \eta_3 \qquad [13]$$

Similarly, all delay can be charged to the inner loop $d_L$; no delay is charged to the outer loop, so $d_{L-1} = 0$. The objective function becomes:

$$T(DO_{L-1}) = \frac{\alpha_1}{\alpha_2}\eta_2 + \eta_3 \qquad [14]$$

A comparison of Formula 13 with Formula 14 decides whether it is best to charge all delay to the outer loop or to the inner loop. If $\eta_1 < \frac{\eta_2}{\alpha_2}$, then all delay should be charged to the outer loop. Consider the assignment of delay when the loop bounds are the same ($\eta_1 = \eta_2$); if $\alpha_2 < 1$, then all delay should be charged to the outer loop. Recall that $\alpha_2$ was calculated from the ratio of $\Delta_L$ to

$\Delta_{L-1}$. The decision as to which loop should be assigned all delay is reduced to a comparison of the $\Delta$-vector elements for the loops involved.

When viewed as a linear programming problem, the two cases given above form the *extreme points* of the convex set delineated by Formula 9. The general solution must be one of the extreme points [7], so the two cases provide the general solution for a double loop where $\Delta_{L-1}$ and $\Delta_L$ are negative:

| Choose | | When |
|---|---|---|
| $d_L = 0$ | charge outer loop | $\frac{(N_{L-1}-1)}{(N_L-1)} < \frac{\Delta_{L-1}}{\Delta_L}$, |
| $d_{L-1} = 0$ | charge inner loop | otherwise |

Similar inequalities can be derived for $\Delta$-vectors of other signs. An interesting case occurs where $\Delta_L$ is positive[6] and $d_{L-1} = 0$. For Formula 9 to be satisfied, $d_L$ must become negative: iteration $i$ is started $d$ time units *after* iteration $i + 1$. A doacross schedule for a negative delay $d$ corresponds to running the loop in reverse with a delay of $- d$. The accommodation of negative delays requires straightforward modifications of the timing formulae (such as Formula 10) to account for the magnitude, and not the sign, of delays. Of greater concern is the conflict that could arise when two dependences place unsatisfiable constraints on delay: one dependence could require a positive delay while another dependence requires a negative delay. In the following section, an efficient algorithm is presented that sacrifices optimality but avoids such a conflict.

### 2.4.6 A General Solution

The single loop case was derived by eliminating the references to $\tau()$ from Formula 8 in the absence of any outer loops. Expanding $\tau()$ once by substituting Formula 3 into Formula 8 exposed the solution to the double loop case. Further expansion of $\tau()$ leads to the general delay formula for a dependence nested in $L$ loops between statements $S_j$ and $S_i$:

$$- \sum_{l=1}^{L} \Delta_l d_l \geq T(S_j, S_i) \qquad [15]$$

When posed as a linear programming problem, Formula 15 is the constraint under which the following objective function should be minimized:

$$T(DO_1) = \sum_{l=1}^{L} (N_l - 1) d_l + T(S_1, S_s)$$

The objective function is exactly the formula used to time the multidimensional doacross model in Formula 2. The *simplex algorithm* can find optimal values for the delay in all loops, and although this algorithm's possible running time is exponential, its expected running time is reasonable [6]. However, the presence of multiple dependences and $\Delta$-vectors in a loop greatly increases the complexity of choosing optimal delays. This section presents an algorithm that performs a single pass over the loops surrounding a block of statements to establish the minimum delay that should be observed in the surrounding loops due to dependences in that block of statements. Consider a nest of loops as shown in Figure 2 and the calculation of delay $d_k$ at nest $k$ to satisfy the dependence $S_i \delta S_j$, when each statement is from block $B_k$ or block $A_k$. Let $\Delta$ be the distance vector associated with $S_i \delta S_j$. Assume $d_{k+1}, d_{k+2}, \ldots, d_L$ are already known, but $d_1, d_2, \ldots, d_{k-1}$ are as yet undetermined. Since only one pass is desired over the loops, $d_k$ must be set such that Formula 15 is satisfied even if $d_1, d_2, \ldots, d_{k-1}$ are all 0. Therefore, $d_k$ is set such that for $S_i \delta S_j$ and the dependence's associated distance vector $\Delta$,

$$- \sum_{l=k}^{L} \Delta_l d_l \geq T(S_j, S_i)$$

The algorithm consists of two nested traversals of the loop nest shown in Figure 2. The outer traversal calls for the assignment of delays that satisfy the dependences of blocks $B_j$ and $A_j$. The inner traversal considers the dependences and assigns delays appropriately in the loops that surround blocks $B_j$ and $A_j$.

```
Input:
    A nested structure of $L$ loops as in Figure 2
Output:
    Delays $d_1, d_2, \ldots, d_L$ that satisfy all dependences in the $L$ loops.
for j:=L downto 1 do
    Let $\gamma$ be the dependence graph for statements in blocks $B_j$ and $A_j$.
    for k:=j downto 1 do
        Let Q = all pairs $\{((S_i, S_j), DELTA)\}$ such that $i \geq j$ and $(S_i \delta S_j) \in \gamma$ with distance vector $\Delta$.
        Let $Q = Q \cup \{((S_e, S_1), -1)\}$ if $S_e$ exits from loop $k$.
        $d_k = \max_{q \in Q} \frac{\sum_{l=k+1}^{L} \Delta_l d_l + T(S_j, S_i)}{-\Delta_k}$.
    end for
end for
```

Note that the algorithm establishes the delay at each loop as the maximum delay required by dependences associated with that loop. At loop $k$, if some dependence required a negative delay while others required a positive delay, then loop $k$ would be assigned a positive delay. Any dependence that requires a negative delay will be eventually accommodated as the algorithm proceeds to the outermost nest, since an LBD must have some $\Delta_l < 0$, $l < k$ (the dependence is from a sequential program).

## 2.5 Comparison with Other Methods

This section compares doacross with two other techniques for multiprocessor compilation of loops. The first method, *loop distribution*, is the direct application of a transformation developed for SEA compilation that separates the vector and sequential statements of a loop into multiple loops [10, 14]. The second method, *partitioning*, is targeted for multiprocessors [8]; vector and sequential statements are not separated, but statements that participate in a dependence cycle are placed in a partition and the iterations of a loop are pipelined through the partitions [5]. Neither of these two methods provides the performance of doacross.

[6] $\Delta_{L-1}$ is always negative for a flow dependence from a sequential program.

### 2.5.1 Loop Distribution

Consider a loop $L$ of $N$ iterations with $q$ statements participating in dependence cycles and $s - q$ statements that appear in vector loops after loop distribution. Let the statements be numbered such that statements $S_1$, $S_2$, ..., $S_q$ are the statements that participate in dependence cycles and statements $S_{q+1}$, $S_{q+2}$ , ..., $S_s$ are the statements that appear in vector loops after distribution. Only one processor is used for the sequential execution of the $q$ statements; the time for executing the sequential statements is therefore $N \times T(S_1, S_q)$ . $N$ processors are used for the vector execution of the $s - q$ statements; the time for executing the vector statements is therefore $T(S_1, S_s) - T(S_1, S_q)$ . The total time for executing the statements of loop $L$ is $(N - 1) \times T(S_1, S_q) + T(S_1, S_s)$ . The time for executing the distributed loops is identical to the time for executing a doacross schedule of loop $L$ when $S_q \delta S_1$ and the delay is therefore $T(S_1, S_q)$ . In this example of loop distribution, $S_q$ and $S_1$ are members of a strongly-connected component of the dependence graph of loop $L$. Since this condition does not imply $S_q \delta S_1$, the delay for the doacross schedule of loop $L$ is bounded by $T(S_1, S_q)$.

Distributing the loops causes another problem for multiprocessors even if $S_q \delta S_1$. The sequential portion of the loop uses one processor, but the vector portion utilizes $N$ processors. If $N$ processors are dedicated to the distributed loops of loop $L$, then $N - 1$ processors are idle during the execution of the distributed sequential loops. These sequential loops dominate the computation for large $N$. If processors are allocated dynamically, the processor allocation for loop $L$ grows from 1 to $N$ processors when a distributed vector loop is encountered and diminishes from $N$ to 1 when a distributed sequential loop is encountered. This fluctuation in processor usage is expensive when the overhead for processor allocation and deallocation is significant. In [4], a formula is developed for determining the maximum number of processors that a doacross loop with a given delay can use. If $S_q \delta S_1$, the delay assigned by doacross is $T(S_1, S_q)$ . The number of useful processors (as determined by [4]) is $T(S_1, S_s)/T(S_1, S_q)$ . These processors are allocated for the duration of the execution of loop $L$. In terms of program performance, doacross can use fewer processors yet provide at least the performance of loop distribution for multiprocessors. In terms of processor usage, the schedules produced by doacross utilize processors more uniformly than the schedules produced by loop distribution.

### 2.5.2 Partitioning

In [8], there are two types of partitioning: *total partitioning* and *partial partitioning*. Total partitioning is possible only when a loop contains no dependence cycles; such loops correspond exactly to zero-delay loops under doacross. These loops are also called *forall* loops in [5]. Doacross assigns delays to loops that contain lexically-backward dependences that (by definition) participate in a dependence cycle.

Consider a loop $L$ of $s$ statements: $S_1$ , $S_2$, ..., $S_s$. Partial partitioning uses the distance vectors of dependences to divide the index set of a loop $L$ into independent partitions; each partition can then be assigned to a processor. The number of partitions created by the partial partitioning algorithm is given by the greatest common divisor of all negated distances in the dependence graph of loop $L$. Consider the loop of Figure 7. There is a dependence arc between each pair of adjacent statements, and data is either passed within an iteration ($\Delta = 0$) or across one iteration ($\Delta = -1$). The greatest common divisor of the negated distances is 1; only one partition is created by the partial partitioning algorithm of [8]. Consider the pipelining algorithm of [5] that is based on partial partitioning. The statements of a loop are partitioned by the strongly-connected components of the data dependence graph associated with the loop. Let $\Pi_t$ be the most time-consuming partition of a loop. The delay associated with a pipeline schedule is the time for executing the statements of $\Pi_t$.

Doacross introduces a delay that accounts for the most time-consuming lexically-backward dependence. Consider the partition $\Pi_t$; unless there is a dependence from the last statement of $\Pi_t$ to the first statement of $\Pi_t$, the delay introduced by doacross is strictly less than the delay introduced by [8] and [5] pipelining. The example of Figure 7 shows that doacross provides improved performance over partitioning. Pipelining places $S_1$ through $S_5$ in a single processor; since the dependence $S_5 \delta S_1$ does not exist in Figure 7, doacross can schedule multiple processors for the execution of the loop.

## 3.0 Summary and Extensions

This paper characterizes loops that obtain no performance gain on an SEA machine, yet benefit from execution on a multiprocessor. Such loops are parameterized by a measure of their parallelism. This measure defines the optimization problem of rearranging statements to minimize delay (thus maximizing parallelism). In [4], this problem is formally defined and a heuristic is given for its solution. For special dependence graphs, Munshi has shown optimal solutions [12]. Doacross also assumes that statements appear in the same order within each processor. Cuny has shown that by allowing the order to differ between processors, delay can be reduced [3]. In [4], the techniques presented in this paper are applied to routines from the EISPACK package [13], with very favorable results.

For this work to be useful, a mapping of iterations to processors must be defined. [4] presents a processor allocation algorithm for doacross loops, modelled after the *predictor-corrector* algorithms for numerical analysis.

## 4.0 Acknowledgements

The author is grateful to his colleagues at the University of Illinois at Urbana-Champaign who contributed to the development of this material as a dissertation, especially David Kuck, who as thesis advisor directed and motivated this work. Thanks also to Constantine Polychronopoulos and Jih-Kwon Peir, for their helpful suggestions and reading of this work. The author also thanks members of the Advanced Fortran group at IBM Research, especially Fran Allen and Michael Burke. Michael Burke contributed a shorter and more intuitive development of the material in Sections 2.4.3 and 2.4.5 . The author also thanks a referee for his thorough reading of this paper and suggestions. Thanks also to Ken Zadeck and Marc Donner for their text processing expertise.

**Abstract**—*Large-Grain Data Flow* (LGDF) combines dataflow techniques with traditional sequential programming to provide a high level model for parallel processing. The user designs parallel applications using networks of program modules connected by datapaths. The resulting specification is automatically transformed for efficient parallel scheduling on a particular underlying architecture. Program execution is controlled via producer/consumer data synchronization. This paper describes the LGDF parallel processing approach, and proposes methods for implementing efficient LGDF schedulers for a specific computer that employs a ring communication architecture, the CDC CYBERPLUS.

## 1. INTRODUCTION

The difficulty in achieving reliable, efficient, maintainable, and portable parallel programs argues strongly for the use of higher level, possibly more restricted, models of parallelism than those provided by basic machine facilities. Programmers can use the higher level model to design applications, and then can rely on automatic means (such as a preprocessor) to generate a concrete implementation tailored for a particular parallel machine. Our experience has shown that programming within the restrictions of a suitable higher level parallel model can make parallel program design significantly more reliable and *even easier* than design using a sequential computation model[1].

Several other approaches to solving the problems of parallel programming have been proposed. Automatic transformation, advocated by Kuck and others[2], envisions development of software tools to automatically transform "dusty deck" FORTRAN for parallel processing. Complex control and data dependencies make this approach very difficult, and results can be poor. Another problem with the automatic transformation approach is that it does not lead to development of novel, highly efficient parallel algorithms, which user-visible parallelism tends to encourage.

At least for the near future, layered languages show promise for making up for the deficiencies of FORTRAN as a parallel processing language. Users code parallel operations using macros. The macros are expanded to produce low level synchronizing operations suitable for a particular parallel machine. This tends to lead to fewer bookkeeping errors in the coding of process synchronization, as well as providing a degree of portability of code between different parallel processors. Ideally, one can simply modify the definitions of the macros to get layered language programs running on a different parallel machine.

A particular layered language approach, Large-Grain Data Flow (LGDF) is described in Section 2. Section 3 presents a brief discussion of the architecture of the CDC CYBERPLUS emphasizing characteristics that are relevant to parallel program interaction. Possible LGDF scheduler implementation strategies for CYBERPLUS are discussed in Section 4. Conclusions and extensions are given in Section 5.

## 2. OVERVIEW OF LGDF

Large-Grain Data Flow (LGDF) combines some features of dataflow computation with subroutine-like code resembling traditional sequential programming. A comparison between LGDF and sequential coding is illustrated in Fig. 1. The main difference between the data flow and sequential versions for this small program lies in the way that the specified computation (C=A+B) is *scheduled*. Scheduling occurs in traditional sequential programming via the flow of control, represented by the successive values of the program counter. The subroutine P10 will be *called* when the process reaches appropriate control points in the program. In contrast, the LGDF program P10 is scheduled for execution asynchronously, whenever appropriate, based on the arrival of the input values A and B, and on the availability of buffer space to write out a new computed value for C.

```
SEQUENTIAL                  LARGE-GRAIN DATA FLOW
PROGRAMMING                 PROGRAMMING

SUBROUTINE ADD(A, B, C)     begin_(p10)

C = A+B                         C = A+B
                                clear_(A)
RETURN                          clear_(B)
END                             set_(C)
                                suspend_

                            end_(p10)
```

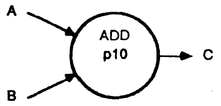

Fig. 1. Traditional and LGDF programs for C = A+B.

The program shown in Fig. 1 is more fine-grained than the typical LGDF program, which corresponds to 5 to 50 or more FORTRAN statements.

### 2.1. LGDF NETWORKS

*Datapaths* link LGDF programs to form *networks* (Fig. 2) that allow communication of data values from one program to another. Datapaths can be in one of two states: *empty* or *full.*

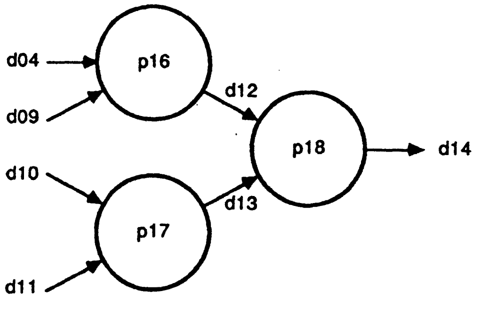

Fig. 2. LGDF network.

0190-3918/86/0000/0845 $01.00 © 1986 IEEE

An LGDF program is activated (asynchronously) depending only upon the state of its associated input and output datapaths:

> **Execution Rule**—A program may start an execution cycle if and only if all of its input datapaths are in the *full* state and all of its outputs are in the *empty* state.

Programs can change the state of an output datapath from empty to full by means of the LGDF function *set_*. A *set_* has the effect of making the data associated with a datapath available to activate downstream programs. In a similar fashion, programs can *clear_* their inputs in order to make the space available for writing into by upstream programs.

LGDF networks coordinate parallel process activation via data flow interactions. Each datapath arc in a network represents both a ***shared memory*** and an associated data flow interlock mechanism. The control mechanism provided by the program execution rule can be used to synchronize access to shared data areas with a simple producer/consumer protocol. This protocol precludes race conditions for shared data (write/read conflicts).

An LGDF program that has finished computation and data flow interactions for the current execution cycle can ***suspend_***. At that point, it is subject to the:

> **Data Flow Progress Rule**—Upon suspension of an execution cycle, a program must have cleared at least one input or set at least one output datapath. Otherwise, it is terminated.

Programs that are in the ***terminated*** state cannot be scheduled for further execution. However, unaffected parts of the same network may still execute. By designing programs that satisfy the Data Flow Progress Rule, many types of parallel program design problems can be avoided.

LGDF networks can be combined into hierarchies, since any node in a network may be defined either by an LGDF program or by another LGDF network. The meaning of this is the same as if the lower level network were substituted graphically for the higher level network abstraction.

Applications designed using LGDF are implemented with the aid of a prototype set of software tools that rely on macro-expansion techniques to generate appropriate scheduling code for various target computers. Several steps are involved in LGDF programming. First, a hierarchical set of LGDF network data flow graphs is designed, based on logical data dependencies inherent in the application. The structure of the resulting network is encoded in a ***wirelist*** file. Data declarations for each datapath in the network are packaged separately. The programmer then writes the LGDF programs, combining FORTRAN with a small set of LGDF macros. Finally, the LGDF programs are macro-expanded to produce compilable FORTRAN code for the particular machine, and this code is compiled and executed. For more details on the software tools and use of LGDF for parallel processing see [3].

The basic idea in LGDF programming is to balance the average grain size of LGDF programs in a network with scheduling overhead in order to reduce the significance of the overhead. This will in general depend on the capabilities of the given architecture, the efficiency with which the LGDF implementation mechanisms exploit those capabilities, the particular application algorithm, and the strategy for data flow parallelization of the algorithm.

## 3. CYBERPLUS ARCHITECTURE

A Control Data CYBERPLUS Parallel Processing System[4] [5] consists of an ensemble of up to 16 very fast processors (20 nanosecond cycle time) organized in a ring structure and interfaced to a host CYBER computer. There is a great deal of internal parallelism possible within one CYBERPLUS CPU. Each processor can contain up to nineteen independent functional units. A crossbar interconnection provides for the routing of results from the output of each functional unit to the input of any or all functional units on the next cycle. A CYBERPLUS processor contains two types of memory, a bulk memory (up to 512K 64-bit words) for data and a smaller (4K 240-bit words) program memory for executable code. Code overlays can be stored in the bulk memory for rapid transfer to the program memory as needed.

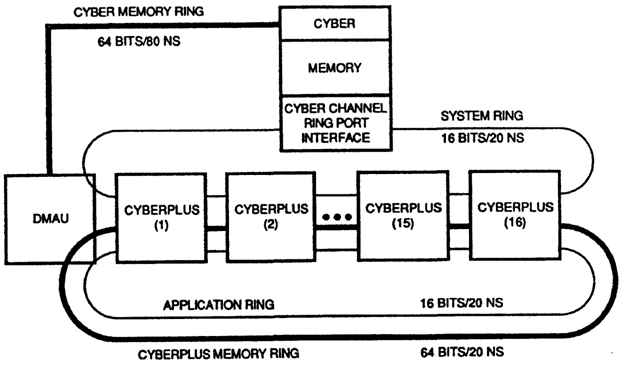

Fig. 3. Typical CYBERPLUS ring group.

At a higher level of parallelism, up to 16 CYBERPLUS processors can be interconnected in a ring group and interfaced to the host mainframe, as shown in Fig. 3. Up to four ring groups can be interfaced to the one host computer.

Two rings allow for the transfer of 16-bit data, the System Ring and the Application Ring. These rings interconnect the CYBERPLUS processors. The System Ring also provides an interface to the host CYBER computer through its standard I/O channel. The CYBER Memory Ring provides a 64-bit wide data path between the CYBERPLUS bulk memories and the memory of the host computer through a direct memory access port. The CYBERPLUS Memory Ring allows 64-bit transfer of data between the CYBERPLUS bulk memories.

### 3.1. SYSTEM AND APPLICATION RINGS

This dual ring system provides a high speed parallel channel for interconnecting the processors and the host computer of a CYBERPLUS Parallel Processing System. The rings are formed by connecting the individual ring ports of the processors in a circular structure. Each ring port has an input and output register. These channels are 29 bits wide, with 16 bits of data and 13 bits of control information making up a ring packet. Ring packets move sequentially and synchronously around the ring from one register to the next, at the rate of 20 nanoseconds per transfer. This results in a peak data transfer capability between processors of 800 megabits per second per ring. A ring port can remove a ring packet from the ring and place the same or a new ring packet on the ring on every cycle. Ring packets currently on the ring have priority over ring packets trying to enter the ring from a processor.

Each processor has two ring ports, one for the System Ring and one for the Application Ring. The System Ring ports respond to an extended instruction set that provides additional control over the CYBERPLUS processors. The host uses the System Ring to transfer programs and data to and from each processor in a ring group and to initiate the execution of programs in the processors.

The System Ring and the Application Ring can be connected to circulate data in opposite directions, allowing processors equal access to both left and right neighboring processors. Both rings can also be used by application programs for the transfer of data among the processors and for synchronization of the application processes running in the processors.

## 3.2. CYBER AND CYBERPLUS MEMORY RINGS

The CYBER Memory Ring and the CYBERPLUS Memory Ring are supported by the Direct Memory Access Unit (DMAU). Via the System Ring, a program initiates, monitors, and terminates all of the data transfers conducted by the DMAU. The DMAU also provides a queueing system to allow the stacking of data transfer requests, reducing the transition time from one data transfer request to the next. A data transfer request may specify multiple destinations, allowing the broadcast of a block of data to any or all processors in the ring group on one trip around the ring.

The CYBERPLUS Memory Ring allows block transfers between the local bulk memories of the processors to proceed at a rate of one 64-bit word each 20 nanosecond cycle. This results in a maximum transfer rate of 3200 megabits per second. Block transfers between CYBERPLUS local memories and CYBER host memory use the CYBER Memory Ring and proceed at a rate limited by the maximum access rate of the host memory system (800 megabits per second).

The DMAU provides a much higher bandwidth data path between the host computer and the CYBERPLUS local memories than the System Ring (800 vs 24 megabits per second). It also supports higher interprocessor data rates than the System and Application Rings alone (3200 vs 1600 megabits per second).

## 4. IMPLEMENTATION OF LGDF ON CYBERPLUS

Our primary goal in designing an LGDF scheduler for the CYBERPLUS is to minimize scheduling overhead. To achieve this, we need to minimize the time when one processor must lock out other processors from accessing shared scheduler tables. Efficient mechanisms must also be designed for the transfer of data among LGDF processes. Secondary considerations include providing the ability to schedule arbitrarily large LGDF networks, and scheduling processes efficiently with any number of processors. Also important is the ability to simulate LGDF parallelism on a single CYBERPLUS processor. This aids in implementing large networks, provides the ability to debug applications in a more controlled (less parallel) setting, and provides greater flexibility in assigning processes to processors.

The smaller the average grain size in a given application, the more opportunity there is for parallel computation. However, for the CYBERPLUS, it would be inefficient to schedule computations on a very low level, such as the basic arithmetic operations. The amount of sequential computation in an average grain should be large enough relative to the scheduling process to reduce overhead to an acceptable percentage, say ten percent or less.

Since the amount of code required for an LGDF scheduler is typically quite small, we have chosen to implement a resident scheduler in each processor. This avoids the overhead of passing messages between a processor and a single central scheduling process. In addition, parts of the scheduling process can accomplished in parallel. However, to maintain scheduler integrity, the distributed LGDF schedulers must obtain exclusive access to certain system information contained in shared tables for a portion of the scheduling process.

### 4.1. LGDF SCHEDULER TABLE INTERLOCKING

Even though the CYBERPLUS has no shared global memory, the effect of a shared table can be implemented by keeping a copy of it in each processor's local memory. A processor wishing to update a system table does so under the protection of an interlock scheme. The processor then updates its local copy, broadcasts the new table to all other processors via the CYBERPLUS Memory Ring, and releases the interlock[1].

To implement the required interlocking, a token passing scheme is used. Two different types of tokens are required: D tokens to protect access to (subsets of) datapath state tables, and P tokens to protect access to (subsets of) LGDF process state tables. In the following discussion, we will assume that only two tokens exist, one of each type. The processor which currently owns each token is known by the schedulers on all other processors. If a processor needs a token which it does not own (e.g., because an LGDF process which it is executing requests a *clear_* or *set_*), it sends an interrupt message over the ring to the current owner. If the current owner of the token no longer needs it, the token is sent to the requesting processor by broadcasting the processor number of the new owner to all processors via the ring. Thus, when ownership changes, each requesting processor is notified of the new owner and can determine if it now has the token. If a requesting processor did not get the token on a change of ownership, a new request can be made to the new owner for the token.

The requirement that the scheduler be able to handle arbitrarily large LGDF networks, combined with the limited program memory of CYBERPLUS, indicates that LGDF programs should be stored as overlays in the CYBERPLUS bulk memory. When the scheduler wishes to execute an LGDF process, it loads the overlay from bulk memory into program memory and then branches to it. This also allows each processor to execute any of the LGDF processes of the application.

P (process) token interlocking behaves as follows. First, the scheduler obtains the P token which allows it to examine the process queue. The process queue contains the name of all processes which have previously been identified as eligible to execute. A process is removed from the queue and the revised queue is broadcast to all other processors via the CYBERPLUS Memory Ring. The P token is then released and the appropriate LGDF process overlay is loaded into program memory and executed. When the process suspends, it returns to the scheduler, which checks for violation of the LGDF Data Flow Progress Rule, then attempts to select a new process for execution.

If the process queue was empty when the P token was obtained, the scheduler must also obtain the D (datapath) token. All eligible processes (i.e., that satisfy the LGDF Execution Rule) that are not currently executing are placed into the eligible process queue, and scheduling resumes as described above[2]. If the eligible process queue is still empty, the scheduler enters an idle loop. When any processor changes the state of a datapath (full to empty or empty to full), it sends a special "change message" to all processors via the ring. Any schedulers in the idle loop will be interrupted by this message. They then compete for the P token in order to obtain a process to execute.

To achieve independence of the scheduling code from the number of processors, all processors are treated as equals (there are no masters or slaves). All CYBERPLUS processors contain the same application programs and scheduling code, as shown in Fig. 4. The processors compete for the chance to advance the state of the computation by running any eligible process, as described above.

### 4.2. IMPLEMENTING LGDF DATAPATHS

Since each processor can execute any of the LGDF processes, all datapaths of the network must be available to each processor. This can be accomplished by keeping a copy of each datapath in the bulk memory of each processor. A process which wants to write on a datapath first updates its local copy of that datapath,

[1] It might seem more efficient to broadcast updates to system tables, rather than the entire table, but the tables required to store the data flow state for LGDF networks tend to be very small (a few bits per datapath and per process).

[2] Note that the P and D tokens are not explicitly released. The scheduler is merely willing to pass the tokens to whichever scheduler requests it next.

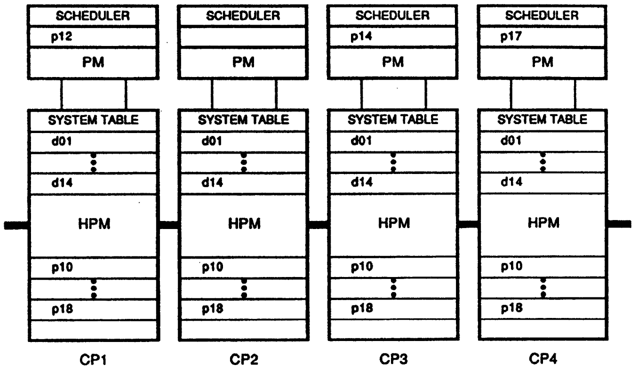

Fig. 4. LGDF scheduler on CYBERPLUS.

then broadcasts the update via the CYBERPLUS Memory Ring. The process then can then change the state of the datapath to full by executing a *set_*. (In the simplified producer/consumer model of LGDF parallel processing under consideration here, each datapath can only be written by a single LGDF process, so no write/write conflicts are possible). A drawback to this scheme is that when datapaths represent large arrays, the duplication can consume large amounts of bulk memory.

Several alternatives exist when this duplication causes a problem with resources. As shown in Fig. 5, the memory of the host processor can be used as a global memory for the processors in the ring group. In this scheme, the producer process writes the array to host memory and places a pointer to it in the datapath, which is then broadcast to all processors in the ring group. When the consuming process executes, it can load the array directly into its local memory, thus avoiding duplication in other processors.

Fig. 6 shows another alternative that avoids the transfer time to and from host memory. However, this method requires a memory manager on each processor as part of the scheduler. In this scheme, the producer process obtains a block of local memory from its scheduler to contain the large array to be passed to the consumer process. The address of this block and processor number are placed in the datapath, which is broadcast to all other processors in the ring group. The producer process can suspend and allow other processes to execute in that processor, but the block containing the array is protected by being reserved through the memory manager. When the consumer process for this array executes, the datapath will contain the processor number and the address of the required array. The array is transferred directly to the consumer processor via the Memory Ring. The scheduler then sends a message via the ring to the producer processor's memory manager, releasing the block of memory in that processor.

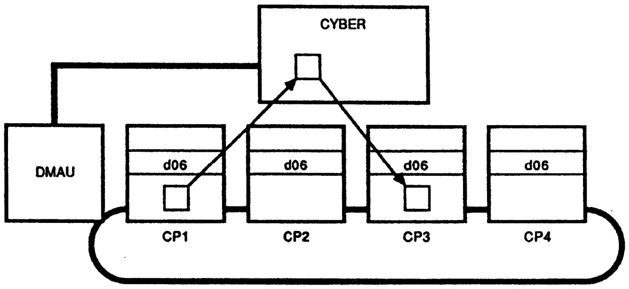

Fig. 5. Datapath via CYBER memory.

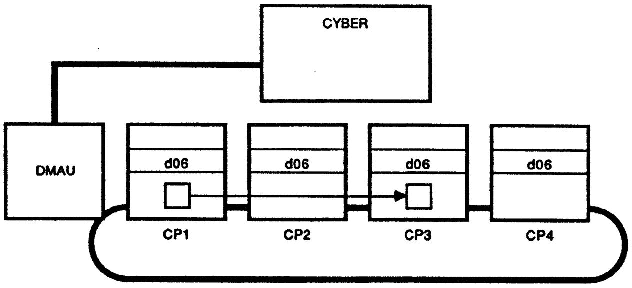

Fig. 6. Datapath via managed memory.

Another method for handling extremely large arrays is through use of disk storage on the host (or directly on the ring group). The array is written to disk, perhaps in piecemeal, by the producer processor. A descriptor pointing to it is placed in the datapath, and the datapath is broadcast via the CYBERPLUS Memory Ring to all other processors. The consuming process then references the datapath to obtain the disk descriptor and reads the data, again perhaps piecemeal, directly into its local memory.

## 5. CONCLUSIONS AND EXTENSIONS TO WORK

An alternative approach to placing schedulers and all code and data in each CYBERPLUS processor is to download code and data from the CYBER host onto a CYBERPLUS only as needed, with all scheduling done by the host. This implementation would reduce duplication of program and data storage, but the scheduling overhead would be much larger. Thus, a larger average grain size would be required to keep the significance of overhead small. Another possible strategy is to allow LGDF programs running on the host to interact transparently with LGDF programs on the CYBERPLUS processors, and migrate back and forth automatically.

The design described in this paper envisions no distinction among CYBERPLUS processors -- any processor can run any LGDF process. For very large systems, there could be specialized schedulers on different CYBERPLUS nodes. One or more CYBERPLUS processors would be dedicated to each portion of the total LGDF network. This would require the ability to subset the shared system tables. For example, in a CYBERPLUS configuration with multiple ring groups, subsets of the network could be assigned to each ring group, with a master scheduler located on the CYBER host coordinating data flow between sub-nets.

# *Macro vs Micro Dataflow: A Programming Example*

*Maya B. Gokhale*

*University of Delaware*
*Newark, Delaware 19716*

Although there are yet to be developed formal methodologies for parallel algorithm design, several important principles (domain decomposition, substructuring, dataflow) have been established as useful in writing parallel algorithms. This paper is an exploration into the principle of data flow, examined at two levels- macro (or task level) and micro (or instruction level). Several versions of concurrent algorithms are presented for a simple linear algebra problem. The macro dataflow programs use an extended Fortran for the Denelcor HEP. The micro dataflow programs use a dataflow programming language Manchester Dataflow (MaD). Programming effort and efficiency considerations in each environment are contrasted.

## 1. Introduction

The design of efficient parallel algorithms is still in the realm of "black art." However, because of the great progress in developing parallel algorithms, there are certain principles of parallel programming which have been established. This paper investigates a specific methodology- dataflow- by means of a case study. Two parallel environments are studied. The first extends the traditional sequential program by supporting concurrent cooperating tasks which share data structures (task level parallelism). The Denelcor HEP is our example of this programming environment. The second is a tagged token dynamic dataflow system, the Manchester Dataflow Machine [1] programmed in Manchester Dataflow Language (MaD). This machine supports parallelism at all levels, from task to individual instruction.

The next section expands on the notions of task level and instruction level parallelism. Each machine is described briefly. Then, we discuss a simple problem: solving an upper triangular system of simultaneous equations using back substitution. An algorithm is outlined to solve the problem under each of the two computation models. Efficiency issues under each model are discussed. Finally we compare and contrast the programming effort required for each model.

## 2. Two levels of Parallelism

In both task level (also called macro) and instruction level (micro) parallelism, the programming model involves concurrent execution of instructions. At the macro level, the unit of concurrency is the process or task. Within a task, instructions are executed sequentially. A machine to support such a form of parallelism usually follows the sequential computer model. The concurrency is supported in hardware by duplication of processing units (PU). Each PU has its own PC, ALU, and register set. The programmer specifies the concurrency by using such primitives as "create task" (or "fork") to start a new concurrent process, and "synchronize" (or "join") to coordinate execution of concurrent processes.

Instructional level parallelism might at first glance be thought to be at the extreme end of task level parallelism. However, in a task level parallel environment, there is some measureable overhead associated with task set up to context switch among tasks. Efficiency demands that the task be sufficiently large that context switch overhead does not overwhelm the computation time. If parallelism at the instruction level is to be supported, an entirely different computation model (and therefore machine realization) is required.

In practice, data flow has been the most popular model developed for instructional level parallelism. Rather than instruction execution controlled by one (or more) program counter(s), an instruction is executed on a data flow machine when all the operands required by the instruction are available. Completion of an instruction causes a new result to be propagated to other instructions which use it as an operand.

### 2.1 The Denelcor HEP

The HEP is a shared memory multiprocessor with a tagged data memory. Each location may be either full or empty. A location may be read only if the tag indicates that it is full. A location may be written only if the tag indicates that it is empty. The HEP is programmed in an extended Fortran IV. The extensions provide for asynchronous variables used for process synchronization; process creation (a fork command); a coroutine facility; and the ability to specify local variables.

The challenge in creating efficient programs for the HEP is to set up independent concurrent instruction streams. The instruction steams related to one problem constitute a Task System. The processes can be synchronized through the scoreboarded memory [2].

### 2.2 The Manchester University Data Flow Machine

Machine language for a data flow machine takes the form of a directed graph rather than the traditional linear sequence of instructions. A node in the graph represents a unit of computation; an arc represents the flow of data into and out from the units of computation. A node may "fire" or be executed whenever data (also called a "token") is available on the input arcs, and as a result, produce data on the output arcs. Variable names in a data flow language denote values rather than locations [4]. For this reason, reassignment to variables (e. g. , `I := I + 1`) is not generally permitted.

The simple scenario outlined above becomes more complicated in the presence of multiple sets of data for an instruction. To keep data sets distinct, some implementations provide for data tagging. Each token carries with it an identification as to the block level at which it belongs. The tag can also be used to differentiate elements of an array.

Definition of array elements poses a special problem for data flow machines. The semantics of the data flow programming language must ensure that reassignment to individual elements is not permitted. However, when a generalized subscript expression is used to index an array, there is no way to guarantee at compile time that reassignment will not occur. For this reason, data flow languages often have restrictions on the definition of arrays. In the Manchester Dataflow language (MaD) [3], assignment to individual array elements is not allowed. Instead, the programmer must formulate one expression which computes the values of all elements of the array.

## 3. Algorithm Design for Parallelism: An Example

At this point, using dataflow as the guiding principle, we would like to investigate algorithm design for each form of parallelism discussed above, macro and micro. Our goal is to discover: 1) styles of programming and 2) machine characteristics which influence both algorithm performance and ease of programming.

The vehicle we use for the investigation is a very simple problem in linear algebra. The problem is to solve a set of simultaneous equations. The coefficient matrix is assumed to have been reduced to upper triangular form by some standard technique. Thus, back substitution can be performed on the coefficient matrix to solve for the unknowns.

0190-3918/86/0000/0849 $01.00 © 1986 IEEE

The problem may be formulated as follows:

Given a set of n equations in n unknowns,

$$\begin{array}{cccccc} a(1,1)x(1) & a(1,2)x(2) & \cdots & a(1,n)x(n) & = & b(1) \\ 0 & a(2,2)x(2) & \cdots & a(2,n)x(n) & = & b(2) \\ 0 & 0 & \ddots & & & \\ 0 & 0 & \cdots & a(n,n)x(n) & = & b(n) \end{array} \qquad (1)$$

find $x(i), i = 1 \cdots$ n , where x(i) is given by

$$\frac{x(i) = b(i) - \sum_{k=i+1}^{n} \quad a(i,k) * x(k)}{a(i,i)} \qquad (2)$$

### 3.1 Back Substitution on the HEP

We first look at a concurrent task-based solution to (2). Let each process P(i) be responsible for the computation of x(i).

```
P(i):
    (1) Form the sum a(i,k)*(k),   k = i+1 ... n.
    (2) Take b(i) - (1).
    (3) Let x(i) = (2) / a(i,i).
```

In addition to the code for each process, we must plan for task initiation and synchronization among the tasks. For synchronization, semaphored variables are used. We will make the x vector a semaphored variable, a "$" variable in HEP Fortran. The "$" variables are placed in the special scoreboarded memory. $x(n) may only be read by P(n-1) when the location is FULL. The algorithm is written so that only P(n) writes $x(n). Therefore, even if P(n-1) tries to read $x(n) before the value has been computed, the process will merely wait on the FULL condition. The programmer is responsible for correct use of the scoreboarded variables to synchronize tasks. The graph of Figure 1 shows the flow of shared data (e. g., the $x variables) among tasks.

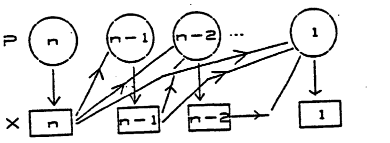

Figure 1. Flow of shared variables among tasks

Unfortunately, we cannot merely prepend an x with "$". When process P(i) reads a semaphored variable, it sets the semaphor EMPTY. Thus all the other processes are stalled: each is waiting for FULL on the variable, and this event will not occur again. Our solution to this problem involves having multiple copies of the variable, one for each process using it. Figure 2 shows the HEP version of the back substitution algorithm. x(i) is the local copy of P(i)'s result. The scoreboarded copies are written to $x(Processor-num, i), where the processor-num can vary from 1 to i-1.

```
For i=n to 1 by -1
    Create process P(i)

P(i):
    sum=0
    for k=n to i+1 by -1
        sum = sum +
            a(i,k) * $x(i,k)
    $x(i) = \frac{(b(i)-sum)}{a(i,i)}$
    for k=i-1 to 1 by -1
        $x(k,i) = x(i)
```

Figure 2. Synchronized Task-based Back Substitution

With this approach, counting only floating point operations and synchronization stores, a 4-equation problem takes 20 timesteps. Each additional equation adds a cost of 4 timesteps.

A slight modification to the order of evaluation of intermediate terms of the program in Figure 2 results in an improved execution time. We revise the body of P(i) as in Figure 3. The subtraction of the sum products on the left from b(i) on the right is done at the beginning rather than at the end. With this approach, the cost of each additional equation is 3 timesteps rather than 4 because of the overlapped subtraction.

In summary, there are two classes of program design we have employed. The optimizations represented by Figure 3 could be made by a fairly standard mechanical optimizer. They involve expression rearrangement and partial loop unfolding. However, the decision at the outset to create a process for each equation; to run the loops from n downto 1; the synchronization method: these design decision are not as readily mechanizable. This class of decision is made by the knowledgeable programmer.

```
P(n):
    for k = n-1 to 1 by -1
        $x(k,n) = $\frac{b(n)}{a(n,n)}$

P(i) (i<n):
    sum = b(i) -
        a(i,n)*$x(i,n)
    for k=n-1 to i+1 by -1
      sum = sum -
        a(i,k)*$x(i,k)
    x(i) = $\frac{sum}{a(i,i)}$
    for k=n-1 to i+1 by -1
    $x(k,i) = x(i)
```

Figure 3. Task-based Back Substitution Optimized

### 3.2 Back Substitution on the Data Flow Machine

We next implement an algorithm to solve the same problem on the data flow machine. On the HEP we manually decompose a problem into concurrent tasks. We must observe from the problem description which groups of operations can be done in parallel and then explicitly code those groups into discrete tasks. In contrast, on the data flow machine, the concurrency is managed automatically by the hardware. We can look at the algorithm as a whole rather than as a collection of cooperative tasks. The difficulty on the data flow machine is to formulate and code the algorithm correctly in the data flow language.

On the HEP a vector $x in the scoreboard memory holds the values of x(i). Elements of the vector are defined incrementally by different tasks. In MaD this incremental definition is not allowed. Instead the vector must be defined completely by one expression. This constraint results in a programming style unfamiliar to most conventional language programmers.

In MaD an array is represented by a (possibly multi-dimensional) STREAM. A stream is a sequence of objects of some type terminated by a special token called "end-of-stream". The vector of unknowns must be declared in MaD as a "stream of real". Instead of the familiar definition

$$x(i) = (b(i) - sum)/a(i,i)$$

we must use list processing operators such a CONS to put together the vector x. By using CONS, we create a new list which is the old list plus a new x(i).

The vector x is produced as follows:

The value of one element of x depends on values of other, previously computed elements. For example, the value of x(n-1) depends on the value of x(n). In MaD we handle this problem by iteratively producing new versions of x. Initially x is null. Then a new version of x is created which has one element, written [x(n)]. The next version of x has two elements, [x(n-1), x(n)], etc. Essentially, we are manipulating the vector as a list, and using the cons operator to put a new element to the front of the list.

This seems to violate the single assignment rule. However, this limited form of reassignment is permissible in MaD as long as the reassignment is done within a repetitive block, and we differentiate between "old" and "new" values of x at each iteration. The MaD code for computing x is as follows:

```
new x = cons( (b(i) - sum) / a(i,i), x(i))
```

The next problem is the computation of sum, which is the name used for the

```
sum(a (i,k)*x(k) ), k = i+1 ... n.
```

This computation illustrates another way to specify concurrency in MaD, the FOR EACH clause. Given a stream, in this case, the current list x, the clause "for each x" causes some action to be performed involving each element of the list x. For the sum block, the product a(i,k)*x(k) is formed. sum is computed in a nested block within a while loop in Figure 4, which gives the complete (but incorrect) block in which x and sum are computed. Although this code seems correct at face value, it contains a subtle timing problem. Consider the sequence of computation for x and sum:

Initially `x = [b(n)/a(n,n)]` and `sum = 0`.

The new value of sum is a(n-1,n)*x(n). The new value of x is [(b(n-1) - 0) / a(n-1,n-1), x(n)]. This is incorrect for x(n-1) because the sum used in the computation of x is the OLD sum. Because an incorrect value has been generated for x(n-1), an incorrect value is computed for sum at the next iteration, and the error is propagated to each subsequent x(i). This problem occurs even if sum is initialized to a(n-1,n)*x(n). The new x will be

```
[ (b(n-1) - a(n-1,n)*x(n)) / a(n-1,n-1) , x(n)]
```

but the new sum will be

```
a(n-2,n-1)*x(n) instead of
a(n-2,n-1)*x(n-1) + a(n-2,n)*x(n)
```

The problem is that the new sum computation needs the NEW x, not the old one. The correct code should require the keyword "new" in the for each clause:

```
for each xi in new x do ...
```

Unfortunately, the implementation of the MaD compiler used for this example does not support the use of a "new" version of a variable on the right hand side of a definition. The final (correct) code from which results on parallelism are taken is shown in Figure 5. We are forced to cycle through the loop 2n times. On the "odd" cycle, we update sum, and on the "even" cycle, we update x.

```
declare x:  stream real; i:  integer; sum:  real;
initi := n-1; sum := 0;
    x := [b(n)/a(n,n)]; [* x initially contains x(n) *]
while i > 0 do          [* iterative loop *]
    new i := i-1;
[* add the next x(i) to the front of x *]
    new x := cons((b(i)-sum)/a(i,i), x);
    new sum := declare  [* a nested block *]
        prod:  real; k:  integer; xi:  real;
        init k := i+1; prod := 0;
        for each xi in x do
            [* concurrent loop *]
            new prod := prod + a(i,k)*xi;
            new k := k+1;
        return prod;    [* as the new sum *]
return x;
```

Figure 4. (Incorrect) Data Flow Back Substitution

```
declare x:  stream real; i:  integer; sum:  real;
        oddd:  boolean;
initi := n-1; sum := 0; oddd := true;
    x := [b(n)/a(n,n)]; [* x initially contains x(n) *]
while i > 0 do          [* iterative loop *]
    new i := if oddd then i else i-1;
[* add the new x(i) to the front of x *]
    new x := if not oddd then cons((b(i)-sum)/a(i,i), x)
        else x;
    new sum := if oddd then
    declare                     [* a nested block *]
        prod:  real; k:  integer; xi:  real;
        init k := i+1; prod := 0;
        for each xi in x do
            [* concurrent loop *]
            new prod := prod + a(i,k)*xi;
            new k := k+1;
        return prod     [* as the new sum *]
        else sum;
    new oddd := not oddd;
return x;
```

Figure 5. (Correct) Data Flow Back Substitution

The results for a 4-equation problem are summarized in Figure 6. S1 is the total number of machine instructions executed. Sinf is the total number of time steps needed for the computation given as many processors as could be used. The Average Parallelism figure determines the maximum number of processors which can be utilized, in this case 9 (8.8). The number of result tokens generated can be greater than the number of instructions because some instructions generate two result tokens. The Max Matching Store Occupancy indicates how many tokens were waiting in the associative memory for another token with a matching tag to arrive.

```
s1 = 2526       Sinf = 288
Average Parallelism of 8.8
3114 Result Tokens Generated
Max Matching Store Occupancy = 115 Tokens
```

Figure 6. Data Flow Back Substitution: Unoptimized

In this example, as in the HEP case, there are optimizations which the programmer can use to increase performance. In the computation of sum, prod is created iteratively in spite of the for each construct. The old value of prod is used at each step to compute a new value. MaD (and most data flow languages) have a more parallel construct to accomplish the same function. We can create a stream of a(i,k)*x(k), k = i+1 .. n. All these multiplications can occur in parallel. Another list processing operator ALL is used to create a stream from the products. When individual data items are defined separately, the all operator can be used to gather them into a stream. This operator cannot be used to define x because a new element of x is defined in terms of previously computed elements would not be available incrementally. However, previous values of prod are not needed in this case. When the entire stream is produced, we can apply the reduction "+!" to the steam. This identical to the APL "/" operator: a "+" is inserted between adjacent stream elements, and the new expression is evaluated. If logarithmic reduction is implemented, the n-element steam can be added in log n time steps. The results in emulation from this optimization are summarized in Figure 7. Although the total number of time steps and the maximum matching store occupancy have decreased, there is an added cost in this optimisation: the total number of instructions executed has increased, and more result tokens have been generated. A maximum of 10 PE's could be utilized in this case.

In this case, as in the task-based dataflow, we have observed two categories of optimizations. The iteration replaced by the reduction operator is an optimization well within the range of current optimization techniques. The timing problem and the generation of the stream are in the realm of expert programmer.

```
S1 = 2604 Sinf = 265
Average Parallelism of 9.8
3210 Result Tokens Generated
```

```
Max Matching Store Occupancy = 101 Tokens
```

Figure 7. Data Flow Back Substitution: Optimized

## 4. Conclusions from the Experiment

We find even in this simple problem that the programmer bears the burden of management of parallelism for both task level and instruction level parallel machines. On the HEP, we can observe that

- The programmer bears complete responsibility for organizing the task system, including the decisions as to which groups of operations should go into which tasks.
- The programmer must synchronize among tasks correctly. Shared variables must be allocated in the scoreboarded memory, and a proper discipline of definition and access maintained so that race conditions and deadlock are avoided.
- The programmer must arrange the order of evaluation within a task to maximize concurrency. Shared variables should be computed as early as possible so that waiting tasks can continue.
- Actual allocation of functional units to tasks is handled automatically. Thus at the Fortran level, the programmer need not statically assign processors to tasks.

The first two tasks are not readily automated. However program analysis tools such as graphical display of data dependencies could help the programmer detect errors and/or possible optimizations. The third can be accomplished to a certain extent by mechanical optimization, and the fourth is already handled by the operating system and hardware.

With instruction level dataflow, we have seen that the programmer is not really freed from these concerns in the data flow environment. Data flow languages (of which MaD is a fair representative) do limit the expressive power of the programmer. We note that

- Rather than having access to the more problem-oriented data structures of vectors and matrices, we are forced to use lists and list processing constructs to build the vectors.
- As illustrated in the first version of back substitution in MaD, subtle timing problems can still crop up. We are required to have a detailed understanding of timing considerations as in hardware design ("old" as opposed to "new" values in an iteration) to come up with a correct program. Although we do not have to explicitly code synchronization, we still have to be aware of what is produced when.
- The programmer also bears responsibility for using perhaps less familiar forms of optimize the program. In this example, we had to know about the combination of FOR EACH, ALL, and reduction to parallelize computation of sum. If we code the algorithm in a sequential way, it is not going to be magically parallelized by virture of running on a data flow machine.

Of these points, the first could be remedied by using a language which allows partial assignment assignment to an array in conjunction with runtime hardware to detect duplicate definition (perhaps with I-structures [5]). The second is once again in the realm of expert programmer. The third could be done by a mechanical optimizer.

We see that the principle we have chosen to investigate - dataflow - although manifested differently at the macro and micro levels, is nontheless invaluable as a means of structuring an algorithm. In order to design the task system for the HEP version of the program we first observed the inherent data dependencies of the problem (Figure 1), and then used those data dependencies to generate a structured synchronization mechanism among the tasks. We voluntarily observed the discipline that each variable x(i) had one producer and many consumers, and used the scoreboarded memory resource to implement this discipline. This dataflow usage of the shared variables made the program more easily understandable and better organized. At the instruction level, we were also guided by the flow of data to operators to arrive at a correct and efficient algorithm. Thus, the notion of data flow, that data dependencies and only data dependencies should govern a computation sequencing is a valuable tool by which to structure a concurrent algorithm.

## 5. Acknowledgements

I would like to thank Dr. Swarn P. Kumar for her assistance in the HEP portion of this work; the Data Flow Group at Manchester University for providing the emulation systems; and ICASE for the use of their facilities for this project.

Stanford University
Stanford, California 94305

## 1 Introduction

This paper presents several parallel algorithms for graph problems, in particular for perfect graphs. Our main result is a deterministic $\mathcal{NC}$ algorithm for solving the two processor scheduling problem, answering an important open problem posed in [VV85]. We also present an $\mathcal{NC}$ algorithm for transitively orienting comparability graphs. By combining these two results, we obtain an $\mathcal{NC}$ algorithm for the matching problem on co-comparability graphs (the complements of comparability graphs) and nearly co-comparability graphs. In addition our transitive orientation algorithm gives us $\mathcal{NC}$ algorithms for several additional problems, such as identifying permutation graphs and finding the maximum weighted clique and optimal colorings in comparability graphs. Comparability, co-comparability, and permutation graphs are all subclasses of perfect graphs.

Scheduling problems have a long history and extensive literature. The most fundamental scheduling problems involve unit time execution tasks with precedence constraints restricting the order of execution. When the number of processors varies, the problem is $\mathcal{NP}$-complete [Ull75]. There are no published polynomial time algorithms for a fixed number of processors greater than two. The first polynomial time algorithm for the two processor case was published in 1969 [FKN69]. Faster algorithms were given by Coffman and Graham [CG72] in 1972, and a decade later, Gabow [Gab82,GT83] found an asymptotically optimal algorithm. Recently, Vazirani and Vazirani have published a randomized parallel solution [VV85]. Like Fujii et. al. they use the connection between matching and two processor scheduling, so their algorithm relies on an $\mathcal{RNC}$ matching subroutine such as [KUW85b] or [MVV].

In contrast, our scheduling algorithm [HM86b] is deterministic and does not require the aid of a matching subroutine. Therefore we are able to exploit the relationship between matching and two processor scheduling in the other direction, obtaining a deterministic parallel matching algorithm for co-comparability graphs.

The only ingredient required to convert our scheduling algorithm into a matching result is an $\mathcal{NC}$ transitive orientation subroutine. This routine takes an undirected graph and directs the edges so that the resulting digraph is transitively closed. Those graphs which can be transitively oriented are called comparability graphs. The complements of comparability graphs are co-comparability graphs. Kozen, Vazirani and Vazirani, in independent work, coupled a transitive orientation routine with our two processor scheduling algorithm to achieve an $\mathcal{NC}$ matching algorithm on co-comparability graphs [KVV85]. Our transitive orientation subroutine is also the key element in our algorithms for testing for permutation graphs and finding maximum weighted cliques and optimal colorings on comparability graphs.

## 2 Main Theorems and Applications

In this section we give some definitions, state our main results, and prove several important consequences. We use $[a, b]$ to denoted a directed arc and $(a, b)$ to denote an undirected edge between vertices $a$ and $b$.

A *perfect graph* is an undirected graph where the chromatic number and maximum clique size of every induced subgraph coincide. A *precedence graph* is an acyclic, transitively closed digraph. Thus if arcs $[a, b]$ and $[b, c]$ are in a precedence graph, then so is the arc $[a, c]$. A *comparability graph* is an undirected graph with the property that every edge can be assigned a direction such that the resulting graph is a precedence graph. The complement of a comparability graph is a *co-comparability* graph. Precedence graphs are equivalent to partial orders. Some graphs, such as a simple three-cycle, are both comparability and co-comparability graphs.

The undirected graph $G = (V, E)$ is a *permutation graph* if there exists a pair of permutations on the vertices such the edge $(v, v') \in E$ if and only if $v$ preceeds $v'$ (or $v'$ preceeds $v$) in both permutations. Permutation graphs are equivalent to the comparability graphs of partial orders with dimension two. A graph is both a comparability graph and a co-comparability graph if and only if it is a permutation graph [PLE71]. Permutation graphs, comparability graphs and co-comparability graphs are all subclasses of perfect graphs [Gol80].

This work was supported by in part by a grant from the AT&T Foundation, ONR contract N00014-85-C-0731, and NSF grant DCR-8351757.

An instance of the two processor scheduling problem is given by a precedence graph $\vec{G} = (V, \vec{E})$. Each vertex represents a task whose execution requires unit time on either of two identical processors. If there is a directed edge from task $t$ to task $t'$, then task $t$ must be completed before task $t'$ can be started. A schedule is a mapping from tasks to timesteps such that at most two tasks are mapped to each timestep and for all tasks $t$ and $t'$ if $t$ must preceed $t'$ ($t \prec t'$) then $t$ is mapped to an earlier timestep than $t'$. The length of a schedule is the number of timesteps used. An optimal schedule is one of shortest length.

The maximum matching problem on co-comparability graphs and the two processor scheduling problem are closely related. If $G$ is a co-comparability graph and $\vec{\bar{G}}$ is a transitive orientation of $G$'s complement, then the pairs of tasks mapped to the same timestep in an optimal two processor schedule of $\vec{\bar{G}}$ correspond to a maximum matching in $G$. Furthermore, there is a sequential algorithm for converting any maximum matching for $G$ into an optimal two processor schedule for $\vec{\bar{G}}$ [FKN69]. In [VV85] it was conjectured that this process is inherently sequential, but with our two processor scheduling algorithm it can be solved quickly in parallel.

**Theorem 1:** *Two processor scheduling is in $\mathcal{NC}$.*

**Proof:** We outline an $O(\log^2 n)$ time algorithm in section 3. Further details can be found in [HM86b]. □

**Theorem 2:** *There is an $\mathcal{NC}$ algorithm which detects if an undirected graph is transitively orientable, and if so finds a transitive orientation.*

**Proof:** We present such an algorithm in section 4. See also [KVV85]. □

**Corollary 2.1:** *There is an $\mathcal{NC}$ algorithm which detects whether or not a graph is a permutation graph.*

**Proof:** Graph $G$ is a permutation graph if and only if both $G$ and $\bar{G}$ are comparability graphs [PLE71]. Therefore, by running our transitive orientation algorithm on both $G$ and $\bar{G}$, we can determine if $G$ is a permutation graph. □

**Corollary 2.2:** *There is an $\mathcal{NC}$ algorithm which finds a maximum node-weighted clique in comparability graphs.*

**Proof:** Given a comparability graph $G$, we find a transitive orientation, $\vec{G}$. Examine any $k$-path in $\vec{G}$. Because $\vec{G}$ is transitively closed, the nodes on the $k$-path form a $k$-clique in $G$. Similarly, every $k$ clique in $G$ is a $k$-path in $\vec{G}$. Thus the problem of finding a maximum node-weighted clique in $G$ reduces to finding a maximum weight path in $\vec{G}$. Since $\vec{G}$ is a DAG, standard parallel techniques (i.e. transitive closure) can be used to find a heaviest path in $G$. □

**Corollary 2.3:** *There is an $\mathcal{NC}$ algorithm which finds a minimal node-coloring of comparability graphs.*

**Proof:** Given a comparability graph $G$, we find a transitive orientation, $\vec{G}$. We say that a vertex $v$ is on level $i$ in $\vec{G}$ if the longest (directed) path from $v$ to a sink contains exactly $i$ vertices. Clearly any pair of nodes on the same level are not adjacent in $G$, so they can be assigned the same color. Every node on level $i > 1$ is a predecessor of at least one node on level $i - 1$. Therefore, if $\vec{G}$ has $k$ levels then $\vec{G}$ has a path of length $k$ and $G$ has a $k$-clique. Since no coloring can use less colors than the size of the largest clique, this yields an optimal coloring. □

**Theorem 3:** *There is an $\mathcal{NC}$ algorithm for finding maximum matchings on co-comparability graphs.*

**Proof:** One such algorithm is given in section 5. □

This theorem is extended to nearly co-comparability graphs in section 5.

**Corollary 3.1:** *Maximum matchings for permutation graphs and partial orders of dimension 2 can be found in $\mathcal{NC}$.*

**Proof:** As stated above, these graphs are co-comparability graphs. □

**Corollary 3.2:** *There is an $\mathcal{NC}$ algorithm which finds maximum matchings on interval graphs.*

**Proof:** Interval graphs are a subclass of co-comparability graphs [GH64]. □

## 3 Two Processor Scheduling

The scheduling algorithm is built around a routine that, for any precedence graph, computes the length of the graph's optimal schedule(s). This length routine is applied repeatedly in order to find an actual optimal schedule for the input graph.

Let $G = (V, \prec)$ be the precedence graph we are interested in. If $t \prec t'$ then $t$ is a predecessor of $t'$ and $t'$ is a successor of $t$. For any pair of tasks, $t, t' \in V$, define $V^t_{t'}$ to be the set of tasks which are both successors of $t$ and predecessors of $t'$ and $G^t_{t'}$ to be the subgraph of $G$ induced by $V^t_{t'}$. The *schedule distance* between tasks $t$ and $t'$, $SD(t, t')$, is the length of an optimal schedule for $G^t_{t'}$. If $t \not\prec t'$ then $SD(t, t') = 0$.

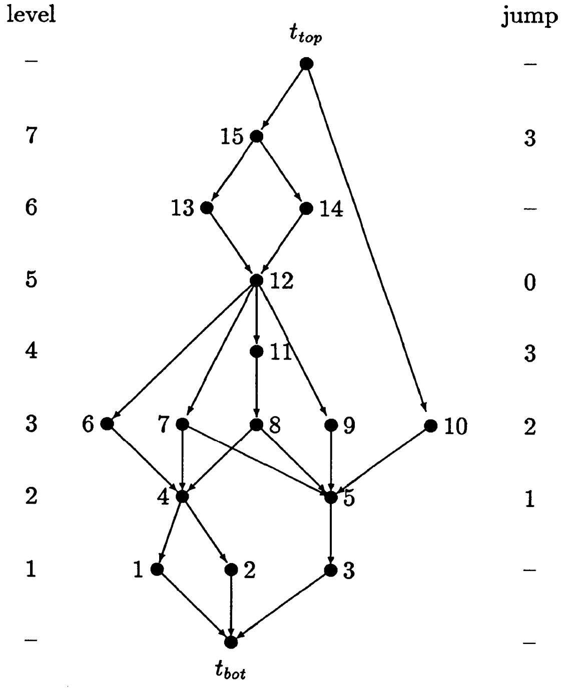

Figure 1: This is a precedence graph containing fifteen tasks (transitive arcs have been omitted). The special tasks $t_{top}$ and $t_{bot}$ are added when computing the length of optimal schedules for $G$. The levels of the original graph are on the left and the jump sequence is on the right.

**Lemma 3.1:** *Let $S$ be a set of tasks such that for all $\hat{t} \in S$:*

**i.** $t \prec \hat{t} \prec t'$;

**ii.** $\mathrm{SD}(t, \hat{t}) \geq k$; *and*

**iii.** $\mathrm{SD}(\hat{t}, t') \geq l$.

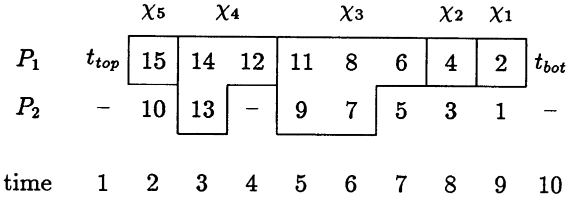
*Then* $\mathrm{SD}(t, t') \geq k + l + |S|/2$.

**Proof:** Count the number of timesteps required to schedule those tasks between $t$ and $t'$. There must be at least $k$ timesteps before the first task in $S$ is scheduled. It takes at least $|S|/2$ timesteps to complete the tasks in $S$. After the last task in $S$ has been completed, at least $l$ additional timesteps are required. Therefore $SD(t, t') \geq k + l + |S|/2$. □

The distance algorithm (see figure 2) uses a method like transitive closure to compute the schedule distance between all pairs of tasks in a precedence graph $G = (V, A)$. It initially guesses that the scheduling distance between each pair of tasks is zero. By repeatedly applying lemma 3.1 to each pair of tasks in parallel the algorithm refines its guesses. Below we prove that after $\log |V|$ iterations, the algorithm's guess for each pair of tasks has converged to schedule distance. The distance algorithm has a straightforward implementation on an $n^5$ processor P-RAM taking $O(\log^2 n)$ time.

```
$d_0(\star, \star) := 0$;
for $i := 1$ to $\lceil \log n \rceil$ do
    for all $t, t'$ with $t \prec t'$ do in parallel
        for all $0 \leq k, l < n - 1$ do in parallel
            $S_{t,t',k,l} := \{s : t \prec s \prec t',$
                        $d_{i-1}(t, s) \geq k,$
                        $d_{i-1}(s, t') \geq l\}$;
            $d_i(t, t') := \max_{S_{t,t',k,l} \neq \emptyset} \{d_{i-1}(t, t'),$
                        $k + l + \lceil |S_{t,t',k,l}|/2 \rceil\}$;
$SD(\star, \star) := d_{\lceil \log n \rceil}(\star, \star)$
```

Figure 2: The distance algorithm.



|  |  | $\chi_5$ | $\chi_4$ |  | $\chi_3$ |  |  | $\chi_2$ | $\chi_1$ |  |
|---|---|---|---|---|---|---|---|---|---|---|
| $P_1$ | $t_{top}$ | 15 | 14 | 12 | 11 | 8 | 6 | 4 | 2 | $t_{bot}$ |
| $P_2$ | – | 10 | 13 | – | 9 | 7 | 5 | 3 | 1 | – |
| time | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |

Figure 3: This is a lexicographically maximal jump schedule for the graph in figure 1. Each of the sets $\chi_i$ is boxed.

**Lemma 3.2:** *The distance algorithm always computes the schedule distance between every pair of tasks.*

**Proof:** Lemma 3.1 guarantees that the distances computed by the algorithm are never greater than the the schedule distances.

In [CG72] it is shown how to construct sets of tasks $\chi_0, \chi_1, \ldots, \chi_k$ for any precedence graph such that:

- Those tasks in any $\chi_i$ are predecessors of all tasks in $\chi_{i-1}$, and
- The length of optimal schedules for $G$ is $\sum_i \lceil |\chi_i|/2 \rceil$ (See figure 3).

Our algorithm doesn't compute these $\chi$s, we simply use their existence to prove that the distances the algorithm does compute converge to the scheduling distance.

Examine how the distance algorithm computes the schedule distance between an arbitrary pair of tasks, $t$ and $t'$. Let $\chi_1, \chi_2, \ldots, \chi_k$ be a set of $\chi$s for $G^t_{t'}$, $\chi_0 = \{t\}$, and $\chi_{k+1} = \{t'\}$. After the first iteration of the outer loop, the distance computed between any task in $\chi_i$ and one in $\chi_{i+2}$ is at least $\lceil |\chi_{i+1}|/2 \rceil$. After the second iteration, the distance computed between any task in $\chi_i$ and any task in $\chi_{i+4}$ is at least $\lceil \chi_{i+1}/2 \rceil + \lceil \chi_{i+2}/2 \rceil + \lceil \chi_{i+3}/2 \rceil$ ($S = \chi_2$, $k = \lceil \chi_{i+1}/2 \rceil$, $l = \lceil \chi_{i+1}/2 \rceil$). Each iteration we double the number of $\chi$s accounted for.

After $\log k$ iterations, the computed distance between $t$ and $t'$ is at least the optimal schedule length for $G^t_{t'}$, and thus at least $SD(t, t')$.

Since $G$ contains $n$ tasks, each $G^t_{t'}$ has at most $n - 2$ $\chi$s. Therefore, after $\lceil \log n \rceil$ iterations the algorithm computes the schedule distance for each pair of tasks. □

The distance algorithm can be used to compute the length of optimal schedules for a graph. Augment the graph with two dummy tasks, $t_{\text{top}}$ and $t_{\text{bot}}$, which are a predecessor and successor (respectively) of all other tasks in $G$. Now $SD(t_{\text{top}}, t_{\text{bot}})$ is the length of $G$'s optimal schedules, and can be found using the distance algorithm.

The method for converting the distance algorithm into one which finds an optimal schedule involves several constructions. For the sake of brevity this paper contains only an outline of our method. Interested readers should consult [HM86b] for a more detailed presentation.

The search for an optimal schedule can be restricted to the class of *Lexicographically Maximal Jump* (LMJ) schedules. Each task $t$ in the precedence graph is assigned a *level* equal to the number of tasks in the longest path from $t$ to a sink. *A level schedule* gives preference to tasks on higher levels. More precisely, suppose levels $L, \ldots, l + 1$ have already been scheduled and there are $k$ unscheduled tasks remaining on level $l$. If $k$ is even level schedules pair the $k$ tasks with each other and there is no *jump* from level $l$. If $k$ is odd, a level schedule pairs $k-1$ of the tasks with each other and the remaining task $t$ is paired with a task from a lower level $l' < l$. In this case, level $l$ *jumps* to level $l'$. We assume that there are an unlimited number of dummy tasks on level 0 which can be paired with any other tasks. The *jump sequence* of a level schedule is the levels jumped *to*, listed in decreasing order by level jumped *from* (see figure 1). The *Lexicographically Maximum Jump (LMJ)* sequence is the jump sequence (resulting from some level schedule) that is lexicographically greater than any other jump sequence resulting from a level schedule. An *LMJ schedule* is a level schedule whose jump sequence is the LMJ sequence. Note that our definition of LMJ is similar to the definitions of highest level first in [Gab82] and [VV85]. The following theorem establishes the importance of LMJ schedules.

**Theorem 4:** [Gab82] *Every LMJ schedule is optimal.* □

Our two processor algorithm uses the distance algorithm to find the LMJ sequence and which jump (if any) a pair of tasks can be used for. In general, there will be many possible pairs for each jump. A path doubling computation finds a consistent set of task pairs for the jumps. The remaining tasks are paired up within levels. Since there are never precedence constraints between two tasks on the same level, this pairing can be done arbitrarily. An LMJ schedule is obtained by sorting the resulting set of task pairs (both for jumps and within levels).

## 4 Transitive Orientation

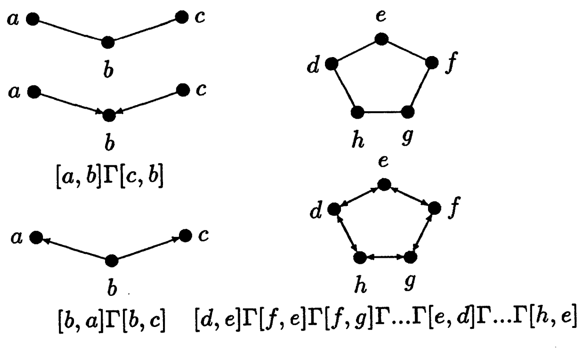
The transitive orientation problem is nontrivial because some edges cannot be oriented independently. If the edges $(a, b)$ and $(b, c)$ are in the graph to be oriented, but the edge $(a, c)$ is not, then the edges $(a, b), (b, c)$ cannot be oriented independently. If we choose the arc $[a, b]$ then we are forced to include the arc $[b, c]$ in the transitive orientation (see figure 4). The binary relation $\Gamma$ reflects this simple kind of forcing. [PLE71]. Given $G = (V, E)$, we say that $[a, b]\Gamma[a', b']$ if $(a, b) \in E$; $(a', b') \in E$ and either $a = a'$ and $(b, b') \notin E$ or $b = b'$ and $(a, a') \notin E$. Thus $[a, b]\Gamma[a, b]$ and if $[a, b]\Gamma[c, b]$ then $[b, a]\Gamma[b, c]$, however $[a, b] \not\Gamma [b, a]$.

The reflexive, transitive closure of $\Gamma$, $\Gamma^*$, is an equivalence relation on the possible orientations of edges in $E$. For obvious reasons, we call these equivalence classes *implication classes.* If $A$ is a set of arcs (e.g. an implication class) then $A^*$ denotes the set of undirected edges $\{(a, b) : [a, b] \in A \vee [b, a] \in A\}$, and $A^{-1}$ is the set of arcs $\{[b, a] : [a, b] \in A\}$. A set of arcs $A$ is *consistent* if $A \cap A^{-1} = \emptyset$, and is *inconsistent* when $A \cap A^{-1} \neq \emptyset$.

Implication classes and $\Gamma$-decompositions have been studied by M.C. Golumbic. Many of the lemmas in this section also appear in [Gol77] or [Gol80].

**Lemma 4.1:** *If $A \neq B$ are implication classes of $G$ then either $A = B^{-1}$ or $A^* \cap B^* = \emptyset$.*

**Proof:** Assume that $(a, b) \in A^* \cap B^*$. Without loss of generality, let $[a, b] \in A$. If $[a, b] \in B$ then $B = A$ since implication classes are equivalence classes. Therefore $[b, a] \in B$, and $[b, a] \notin A$. By definition, if $[a, b]\Gamma[a', b']$ then $[b, a]\Gamma[b', a']$. Thus some $[c, d]\Gamma^*[a, b]$ if and only if $[d, c]\Gamma^*[b, a]$, so $A = B^{-1}$. □



$[a, b]\Gamma[c, b]$

$[b, a]\Gamma[b, c]$ $[d, e]\Gamma[f, e]\Gamma[f, g]\Gamma \ldots \Gamma[e, d]\Gamma \ldots \Gamma[h, e]$

Figure 4: Graphs and Implication Classes

Given an undirected graph $G_1 = (V, E)$ pick any implication class $B_1$ and delete it, forming $G_2 = (V, E - B_1^*)$. Next form $G_3$ by removing some implication class $B_2$ from $G_2$. Continue the process until removing $B_k$ from $G_k$ results in a graph with no edges. The sequence of implication classes removed, $B_1, B_2, ..., B_k$, is called a $\Gamma$-*decomposition* of $G$. The following theorem points out the usefulness of $\Gamma$-decompositions.

**Theorem 5:** *(TRO Theorem [Gol80]) Let $B_1, B_2, ..., B_k$ be a $\Gamma$-decomposition of an undirected graph $G$. The following statements are equivalent:*

**i.** *$G$ is a comparability graph.*

**ii.** *Every implication class of $G$ is consistent.*

**iii.** *Each $B_i$ in the $\Gamma$-decomposition is consistent.*

*Furthermore, when these conditions hold the union of the $B_i$s is a transitive orientation of $G$.*

**Proof:** The proof of this theorem requires several technical lemmas, and thus is beyond the scope of this paper. The interested reader is referred to [Gol77,Gol80]. □

The TRO theorem suggests a sequential algorithm for transitively orienting comparability graphs. One can take any edge, orient it arbitrarily, find the associated implication class, add the implication class to the transitive orientation and remove it from the comparability graph. Repeating this procedure yields a $\Gamma$-decomposition of the comparability graph and therefore a transitive orientation. This is essentially the algorithm in [PLE71].

In order to parallelize this algorithm it is neccessary to understand how implication classes change during a $\Gamma$-decomposition. We will see below that the changes are very simple: implication classes are either merged with other implication classes or remain unchanged.

**Lemma 4.2:** *Let $A$ and $B$ ($A^* \neq B^*$) be implication classes of $G = (V, E)$. Then all of the arcs in $A$ are in the same implication class of $G' = (V, E - B^*)$.*

**Corollary 4.2.1:** *Let $B$ be an implication class of $G = (V, E)$. Every implication class of $G' = (V, E - B^*)$ is the union of implication classes of $G$.*

**Proof:** A $\Gamma$ relationship between two arcs is lost only if one of the arcs is deleted or a triangular edge added. Removing $B^*$ certainly doesn't add any triangular edges, and by Lemma 4.1 $A^* \cap B^* = \emptyset$, so all edges of $A^*$ remain in $G'$. □

Three edges, $(a, b), (a, c), (b, c)$ in an undirected graph $G$ form a *tricolored* triangle if $G$ has three implication classes, $A$, $B$, and $C$ such that $A^* \neq B^* \neq C^* \neq A^*$ and $(a, b) \in A^*, (b, c) \in B^*$, and $(a, c) \in C^*$. We say that $A$ and $B$ are *triangle related*, written $A \triangle B$, if either $A = B^{-1}$ or there is a tricolored triangle in $G$ with one edge in $A^*$ and another edge in $B^*$.

**Lemma 4.3:** *Let $G = (V, E)$ be an undirected graph with implication classes $A$ and $B$, $A^* \neq B^*$. $A$ is not an implication class of $G' = (V, E - B^*) \Longleftrightarrow A \triangle B$.*

**Proof:** ($\Leftarrow$) Since $A \triangle B$, $G$ contains a tricolored triangle $(b, c) \in A^*, (a, c) \in B^*, (a, b) \in C^*$. Without loss of generality, let $[b, c] \in A$ and $C \neq A$ be the equivalence class containing $[b, a]$. The edge $(a, c)$ is not in $E - B^*$, so $[b, c] \Gamma [b, a]$ in $G'$. Since $A$ is not closed under the $\Gamma$ relation, it can not be an implication class of $G'$.

($\Rightarrow$) By Lemma 4.2 $A$ is a proper subset of some implication class for $G'$. Therefore in $G'$ and arc $[b, c] \in A$ is $\Gamma$ related to an arc $[b, a] \notin A$ (the case where $[b, c] \Gamma [a, c]$ is analogous). Let $C$ be the implication class of $G$ containing $[b, a]$ ($A \neq C \neq B$). Since $[b, c] \Gamma [b, a]$ in $G'$ but not in $G$, the triangular edge $(b, c)$ must be in $B^*$. Thus $(b, c) \in A^*, (a, b) \in C^*, (a, c) \in B^*$ form a tricolored triangle in $G$ and $A \triangle B$. □

**Lemma 4.4:** *Let the implication classes $B_1, ..., B_k$ of $G = (V, E)$ be an independent set under the $\triangle$ relation. Then in $G' = (V, E - B_1^*)$, $\{B_2, ..., B_k\}$ is an independent set (under $\triangle$) of implication classes.*

**Corollary 4.4.1:** *If implication classes $B_1, ..., B_k$ of $G$ form an independent set under the $\triangle$ relation, then $B_1, ..., B_k$ are the first $k$ implication classes in a $\Gamma$ decomposition of $G$.*

**Proof:** By Lemma 4.3, $B_2, ..., B_k$ are all implication classes of $G'$. Assume to the contrary that $G'$ contains a tricolored triangle $(a, b) \in B_i^*, (a, c) \in B_j^*, (b, c) \in A^*$. The arc $[b, c]$ belongs to some implication class $C$ of $G$. By Lemma 4.2, $B_i^* \neq C^* \neq B_j^*$. Therefore, $(a, b), (a, c), (b, c)$ is a tricolored triangle in $G$ and $B_i \triangle B_j$ – contradiction. □

**Lemma 4.5:** *Let $B_1, B_2, ..., B_k$ be a maximal independent set under the $\triangle$ relation for some graph $G_1 = (V, E)$. Every implication class of $G_{k+1} = (V, E - B_1^* - B_2^* - ... - B_k^*)$ is the union of at least two implication classes of $G$.*

**Corollary 4.5.1:** *The number of implication classes for $G$ is at least twice the number of implication classes for $G_{k+1}$.*

**Proof:** Every other implication class of $G$ is $\triangle$ related to some $B_i$. Therefore, by Lemma 4.3 every implication class of $G$ is merged with at least one other implication class of $G$ during the formation of $G_{k+1}$.

Since implication classes are never split (Lemma 4.2), every implication class of $G_{k+1}$ must be the union of at least two implication classes of $G$. □

The input to our algorithm is an undirected graph $G_1 = (V, E)$. Our algorithm's output is either $\vec{G}$, a transitive orientation of $G_1$, or an indication that $G_1$ has no transitive orientation. The algorithm proceeds in several iterations. Graph $\vec{G_1}$ is initialized to $(V, \emptyset)$. During iteration $i$ the algorithm determines a maximal independent set of implication classes for $G_i$. These implication classes are deleted from $G_i$ forming $G_{i+1}$, and added to $\vec{G_i}$ forming $\vec{G}_{i+1}$ From Lemma 4.5 the number of implication classes in $G$ is halved each iteration. Therefore, after $\log n$ iterations $G$ will contain no edges and $\vec{G}$ will be a transitive orientation of the original graph.

Each iteration consists of the following four steps:

1. Determine the implication classes of $G_i$. This can be done using standard parallel techniques such as solving two-SAT formulae or finding connected components [SV82].
2. Determine the $\triangle$ relation on implication classes.
3. Use a maximal independent set subroutine, such as [KW84,Lub85], to obtain a maximal independent set, $M$ of implication classes.
4. In parallel, for each of the $A_j$s in $M$, delete $A_j^*$ from $G_i$, and add $A_j$ to $\vec{G_i}$.

Step 3 is the most expensive of these steps, requiring $O(\log^2 n)$ time and $n^4$ processors. The $\log n$ iterations can therefore be done in $O(\log^3 n)$ time on $n^4$ processors.

## 5 Maximum Matching

The two processor scheduling and transitive orientation algorithms can be used to find maximum matchings on co-comparability graphs. To find a maximum matching on the co-comparability graph $G = (V, E)$, first create the comparability graph $\bar{G} = (V, \{(a, b) : (a, b) \notin E\})$. Applying the transitive orientation routine converts $\bar{G}$ into a precedence graph. An optimal two processor scheduled can be found for the precedence graph using our scheduling algorithm. We will see below that the pairs of tasks scheduled together form a maximum matching of $G$.

Let $S$ be any optimal two processor schedule for $\overset{\rightrightarrows}{G}$. A *task-pair* of $S$ is a pair of tasks mapped to the same timestep by $S$. Since there are no precedence relationships between tasks in a task-pair and each task is mapped to a single timestep, the set of task-pairs of $S$ form a matching in $G$. Because $S$ is an optimal schedule, no schedule has more task-pairs.

A task is *available* at some point in a schedule if it can be executed without violating the precedence constraints.

**Lemma 5.1:** *If co-comparability graph $G$ has a perfect matching then $\overset{\rightrightarrows}{G}$ has a schedule where every task is in a task-pair.*

**Proof:** We say a pair of tasks is *mated* if the pair is in the perfect matching. Construct the schedule (and modify the "mated" relationship) iteratively as follows:

> If two mated tasks are both available, schedule one such mated pair. Otherwise find two mated pairs, $(t, t')$ and $(s, s')$, such that $t$ and $s$ are available and there is no precedence relationship between $t'$ and $s'$. Schedule $t$ with $s$ and mate $t'$ with $s'$.

Note that there are never precedence constraints between a pair of mated tasks. This method clearly takes two tasks each timestep and does not violate the precedence constraints. What we must show is that it always constructs a schedule for $\overset{\rightrightarrows}{G}$.

Assume to the contrary that at some point it does not find a pair of tasks to schedule. Let $U$ be the set of available tasks and $U'$ be the set of tasks which are mated to tasks in $U$. Since the method fails, $U \cap U' = \emptyset$ and there is a precedence relationship between every pair of tasks in $U'$ (i.e. $U'$ is totally ordered). Let $t'$ be the task in $U'$ which preceeds all other tasks in $U'$. Since $t' \notin U$, there must be some $t \in U$ such that $t \prec t'$. However, by the transitivity of precedence, $t$ also preceeds its mate – contradiction. □

**Lemma 5.2:** *Let $\overset{\rightrightarrows}{G} = (V, \prec)$ be a precedence graph and $S$ a two processor schedule for $\overset{\rightrightarrows}{G}' = (V - \{t\}, \prec)$. A single timestep containing $t$ can be inserted into $S$ yielding a schedule for $\overset{\rightrightarrows}{G}$.*

**Proof:** Let $t'$ be the last predecessor of $t$ in $S$. Insert task $t$ immediately after the timestep containing $t'$. Obviously there are no precedence conflicts between $t$ and its predecessors. Since $S$ is valid schedule, there are no precedence conflicts between tasks in $V - \{t\}$. Therefore any precedence conflict which is violated is of the form $t \prec \hat{t}$. By transitivity $t'$ also preceeds $\hat{t}$, so $\hat{t}$ comes strictly after $t'$ in $S$. Since $t$ is inserted immediately after $t'$, task $t$ appears before $\hat{t}$ in the modified schedule. □

Let $M$ be the tasks in a maximum matching on $G$. The above Lemmas suggest a way to obtain a schedule, $S$, for $\overset{\rightrightarrows}{G} = (V, \prec)$ where the paired tasks of $S$ are precisely the tasks in $M$. Start by finding an optimal schedule, $S'$ for the subgraph of $\overset{\rightrightarrows}{G}$ induced by $M$ and add the tasks in $V - M$ one at a time. One $\mathcal{NC}$ implementation of this algorithm involves bucket sorting the tasks in $V - M$ based on which task-pair of $S'$ they follow. By topologically sorting the tasks within each bucket we can quickly determine where each task should be inserted.

**Theorem 6:** *The task-pairs of any optimal schedule for $\vec{\vec{G}}$ form a maximum matching on $G$.*

**Proof:** Let $M$ be the tasks in some maximum matching of $G$. Let $S$ be an optimal schedule for the subgraph of $\vec{\vec{G}}$ induced by $M$. By Lemma 5.1, the task-pairs of $S$ form a maximum matching on $G$. By Lemma 5.2 we can insert the other tasks of $\vec{G}$ one at a time without disturbing the task-pairs. Therefore, the task-pairs of the resulting schedule for $\vec{\vec{G}}$ form a maximum matching on $G$. Since every optimal schedule has the same number of task-pairs and the task-pairs of every schedule form a matching, the task-pairs of any optimal schedule for $\vec{\vec{G}}$ forms a maximum matching on $G$. □

If $\bar{G}$ is not transitively orientable it may still be possible to find a maximum matching in $G = (V, E)$. Assume we are given a set $U$, consisting of $O(\log n)$ edges, such that $\bar{G} \cup U$ is transitively orientable. The following method finds a maximum matching in $G$.

For each $S' \in 2^S$ such that $S'$ is a matching find (in parallel) a maximum matching in $G' = (V - \{v : (v, v') \in S'\}, E - S$. A maximum matching for $G$ occurs whenever the cardinality of the maximum matching for $G'$ plus $|S'|$ is maximal.

A graph $G$ is a $k$-nearly comparability graph when:

— $G$ has at most $k \log n$ inconsistent implication classes and

— each inconsistent implication class of $G$ is split into consistent implication classes by the addition of at most $k$ edges.

A $k$-nearly co-comparability graph is the compliment of a $k$-nearly comparability graph.

Let $G$ be a $k$-nearly co-comparability graph (for some constant $k$). The following is an outline of an $\mathcal{NC}$ algorithm for finding a maximum matching in $G$. In parallel examine each set, $T$, of $k$ edges not in $\bar{G}$. Determine which inconsistent implication classes are split when $T$ is added to $\bar{G}$. For each inconsistent implication class $A$, pick any set of $k$ edges which splits $A$ into consistent implication classes. At most $k^2 logn$ edges are picked, so the above method can be used to find a maximum matching for $G$.

## 6 Conclusions

Although the algebraic approach was used to obtain the first parallel matching algorithms [KUW85b,MVV], these are randomized algorithms. It is interesting that we can obtain deterministic matching algorithms for wide classes of graphs using a purely combinatorial approach. Perhaps the combinatorial approach will yield deterministic algorithms for matching on other classes of graphs as well.

It was surprising how much more difficult computing the actual schedule was than simply computing its length. In higher complexity classes such as $\mathcal{P}$ and $\mathcal{NP}$ it is often easy to go from the decision problem to computing an actual solution, because of self reducibility. However this does not necessarily seem to be the case for parallel complexity classes. To support this observation we note that the random $\mathcal{NC}$ algorithm for finding the cardinality of a maximum matching is much simpler than the random $\mathcal{NC}$ algorithm for determining an actual maximum matching [KUW85a].

There are several open problems related to scheduling. We are attempting to extend our two processor result to the case when the tasks have nonuniform start times and/or deadlines. When the precedence constraints are restricted to in-trees or out-trees there are parallel algorithms for generating schedules on an arbitrary number of processor [DUW84,HM86a]. It is an open problem whether interval-ordered tasks [PY79] can be scheduled in parallel.

One variant of the two processor problem that we know to be $\mathcal{NP}$-complete (by reduction from the clique problem) allows incompatibility edges as well well as precedence constraints. When there is an incompatibility constraint between two tasks they can be executed in either order, but not concurrently. Incompatibility constraints arise naturally when two or more tasks need the same resource, such as special purpose hardware or a database file.

# Communication-Efficient Parallel Graph Algorithms

Charles E. Leiserson
Bruce M. Maggs

Laboratory for Computer Science
Massachusetts Institute of Technology
Cambridge, Massachusetts 02139

*Abstract*—Communication bandwidth is a resource ignored by most parallel random-access machine (PRAM) models. This paper shows that many graph problems can be solved in parallel, not only with polylogarithmic performance, but with efficient communication at each step of the computation. We measure the communication requirements of an algorithm in a model called the *distributed random-access machine* (DRAM), in which communication cost is measured in terms of the congestion of memory accesses across cuts of an underlying network. The algorithms are based on a communication-efficient variant of the tree contraction technique due to Miller and Reif.

## 1. Introduction

Underlying any realization of a parallel random-access machine (PRAM) is a communication network that conveys information between processors and memory banks. Yet in most PRAM models, communication issues are largely ignored. The basic assumption in these models is that in unit time each processor can simultaneously access one memory location. For truly large parallel computers, however, computer engineers will be hard pressed to implement networks with the communication bandwidth demanded by this assumption. The difficulty of building such networks threatens the validity of the PRAM as a predictor of algorithmic performance. This paper introduces a more restricted PRAM model, which we call a *distributed random-access machine* (DRAM), to reflect an assumption of limited communication bandwidth in the underlying network.

We measure the cost of communication in a network in terms of the number of messages that must cross a cut of the network, as in [9] and [12]. Specifically, a *cut* $S = (A, \overline{A})$ of a network[1] is a partition of the network into two sets of processors $A$ and $\overline{A}$. The *capacity* $\text{cap}(S)$ is the number of wires connecting processors in $A$ with processors in $\overline{A}$, i.e., the bandwidth of communication between $A$ and $\overline{A}$. For a set $M$ of messages we define the *load* of $M$ on a cut $S = (A, \overline{A})$ to be the number of messages in $M$ between a processor in $A$ and a processor in $\overline{A}$. The *load factor* of $M$ on $S$ is

$$\lambda(M, S) = \frac{\text{load}(M, S)}{\text{cap}(S)},$$

and the *load factor* of $M$ on the entire network is

$$\lambda(M) = \max_S \lambda(M, S).$$

The load factor provides a simple lower bound on the time required to deliver a set of messages. For instance, if there are 10 messages to be sent across a cut of capacity 3, the time required to deliver all 10 messages is at least the load factor 10/3.

Networks in which the load-factor lower bound can be met to within a polylogarithmic factor as an upper bound include volume and area-universal networks, such as fat-trees [9,12] and meshes of trees [13]. The load factor can be also met to within a polylogarithmic factor as an upper bound by the standard universal routing networks, such as the Boolean hypercube, the butterfly (a.k.a. FFT, Omega), and the cube-connected cycles, but the lower bound is weak because every cut of these networks is large relative to the number of processors in the smaller side of the cut. Networks for which the load factor lower bound cannot in general be approached to within a polylogarithmic factor as an upper bound include linear arrays, meshes, and high-diameter networks in general.

Whereas communication is essentially free in PRAM models, the cost of communication in a DRAM depends on the locality of memory accesses as measured by the load factor of an underlying network. The DRAM is an attempt to abstract the essential communication characteristics of volume and area-universal networks without relying in detail on any particular network. Much as the PRAM can be viewed as an abstraction of a hypercube, in that algorithms for a PRAM can be implemented on a hypercube with only polylogarithmic performance degradation, the DRAM can be viewed as an abstraction of a volume or area-universal network. Fast, communication-efficient algorithms on a DRAM translate directly to fast, communication-efficient algorithms on, for example, a fat-tree.

This paper shows that many graph problems for a graph $G = (V, E)$ can be efficiently solved with $O(|E|)$ processors in the DRAM model. The algorithms we give apply to all of the popular PRAM models because a PRAM can be viewed as a DRAM in which communication costs are ignored. In fact, the algorithms we give can all be performed on an exclusive-read, exclusive-write DRAM, and when run on a PRAM, they are nearly as efficient in the PRAM model as corresponding concurrent-read, exclusive-write PRAM algorithms in the literature.

The remainder of this paper is organized as follows. Section 2 contains a specification of the DRAM model and the implementation of data structures in the model. The section demonstrates why the "recursive doubling" technique frequently used in parallel algorithms is inefficient in the DRAM model. It also defines the notion of a *conservative algorithm* as a concrete realization of a communication-efficient algorithm, and gives a "Shortcut Lemma" that forms the basis of the conservative algorithms in this paper. Section 3 presents a conservative "recursive pairing" technique that can be used to perform many of the same functions as recursive doubling. Section 4 presents a linear-space, conservative "tree contraction" algorithm based on the ideas of Miller and Reif [17]. Section 5 presents *treefix computations,* which are generalizations of the parallel prefix computation [3,7,18] to trees. We show that treefix computations can be performed using the tree contraction algorithm of Section 4. Section 6 gives short,

[1] We assume that the communication network is an *interconnection network,* meaning that the processors are interconnected as a graph, and routing of messages is performed by the processors. The generalization to a *routing network,* where routing can be done by switches that are not processors, is straightforward, but complicates the definitions.

efficient parallel algorithms for tree and graph problems, most of which are based on treefix computations. Section 7 contains some concluding remarks.

## 2. The DRAM model

This section presents the DRAM model. We show how a data structure can be embedded in a DRAM and define the load factor of a data structure. We demonstrate that many existing PRAM algorithms are not communication efficient in the DRAM model by examining the "recursive doubling" technique [21] used extensively by algorithms in the literature. We introduce the notion of a *conservative* algorithm as one in which the load factor of each set of memory accesses can be bounded above by the load factor of the input data structure. Our conservative algorithms are based on a simple lemma that shows how pointers in a data structure can be "shortcut" without increasing the load factor.

A DRAM consists of a set of $n$ processors. All memory in the DRAM is local to the processors, with each processor holding a small number of $O(\lg n)$-bit registers. A processor can read, write, and perform arithmetic and logical functions on values stored in its local memory. It can also read and write memory in other processors. (A processor can transfer information between two remote memory locations through the use of local temporaries.) Each set of memory accesses is performed in a memory access *step*, and any of the standard PRAM assumptions about simultaneous reads or writes can be made. Our algorithms use only mutually exclusive memory references, however, so these special cases never arise.

The essential difference between a DRAM and a PRAM is that the DRAM models communication costs. We presume remote memory accesses are implemented by routing messages through an underlying network. Each cut $S = (A, \overline{A})$ of the processors has an assigned capacity $\text{cap}(S)$. For a set $M$ of memory accesses, we define $\text{load}(M, S)$ to be the number of accesses in $M$ between a processor in $A$ and a processor in $\overline{A}$. The load factor of $M$ on $S$ is $\lambda(M,S) = \text{load}(M,S)/\text{cap}(S)$, and the load factor of $M$ on the entire network is $\lambda(M) = \max_S \lambda(M, S)$. The basic assumption in the DRAM model is that *the time required to perform a set $M$ of memory accesses is $\lambda(M)$.*

Because the load factor of a set of memory accesses is the time required to perform them, the embedding of a data structure within a DRAM affects the time required to perform operations on the data structure. A natural way to embed a data structure in a DRAM is to put one record of the data structure into each processor. The record can contain pointers to records in other processors, as well as auxilliary local storage. As an example of how the embedding of a data structure influences communication costs, consider an embedding of a list in which alternate list elements are placed on opposite sides of a narrow cut. If each element fetches a value from the next element in the list, the load factor across the cut is large. Thus, a set of memory accesses that theoretically takes unit time in the PRAM model can require considerably more time due to network congestion. On the other hand, there may be a better embedding for the list in which the number of list pointers crossing any cut is small compared to the capacity of the cut.

We can measure the quality of an embedding by generalizing the concept of load factor to a set of pointers. The *load* of a set $P$ of pointers across a cut $S = (A, \overline{A})$, denoted $\text{load}(P, S)$, is the number of pointers in $P$ from a processor in $A$ to a processor in $\overline{A}$ or vice versa, and the load factor is $\lambda(P) = \max_S \text{load}(P,S)/\text{cap}(S)$. The load factor of a data structure is the load factor of the set of its pointers.

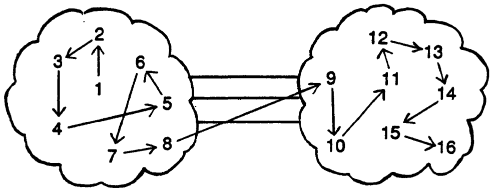

**Figure 1: A cut of capacity 3 separating two halves of a linked list. The load of the list on the cut is 1. At the final step of recursive doubling, each element on the left side of the cut accesses an element on the right, which induces a load of 8 on the cut.**

For many problems, good embeddings of data structures can be found (see Section 7). Even if a good embedding of a data structure is found, however, there is no guarantee that standard PRAM algorithms will behave efficiently on the data structure. To illustrate this point, consider the "recursive doubling" or "pointer jumping" technique which is used extensively by algorithms in the literature. The idea is that each element $i$ of a list initially has a pointer $p(i)$ to the next element in the list. At each step, element $i$ computes $p(i) \leftarrow p(p(i))$, doubling the distance $d(i)$ between $i$ and the element it points to (until it points to the end of the list). This technique can be used, among other things, to compute the distance of each element to the end of the list. For each element $i$, $d(i)$ is initially one. At each pointer jumping step, element $i$ computes $d(i) \leftarrow d(i) + d(p(i))$. In a PRAM model, the running time on a linked list of length $n$ is $O(\lg n)$. Variants of this technique are used for path compression [17,19,21], vertex numbering [20,21], and parallel prefix computation [21].

In the DRAM model, however, recursive doubling can be expensive even if a data structure has a good embedding. Figure 1 shows a cut of capacity 3 separating the two halves of a linked list of 16 elements. In the first step of recursive doubling, the load on the cut is only 1 because the only access across the cut occurs when element 8 copies the pointer of element 9. In the second step the load is 2 because element 7 accesses element 9 and element 8 accesses element 10. In the third step, the load is 4, and in the fourth step, the load is 8, as each of the first eight elements makes an access across the cut. Since the load factor of the cut in the fourth step is 8/3, this set of accesses will require a least 3 time units. Whereas the capacity of the cut was large enough to support the memory accesses across it in the first step, by the fourth step it was insufficient. The only way to guarantee that recursive doubling runs fast is to ensure that every cut of the network is sufficiently large to accommodate worst-case communication patterns. In the next section, we shall show how a *recursive pairing* strategy can perform many of the same functions as recursive doubling in a communication-efficient fashion.

All of our algorithms have the property that the load factor of memory accesses in any step is bounded by the load factor of the input data structure. We define a set $M$ of memory accesses to be *conservative* with respect to another set $M'$ of memory accesses if $\lambda(M) \leq \lambda(M')$, and we make the natural generalization of this definition to pointers and data structures. A *conservative algorithm* is one all of whose memory accesses are conservative with respect to the input data structure.

An algorithm that communicates only across pointers in the input data structure is conservative, but may require time linear in the diameter of the data structure to pass information between two elements. The following simple, but important, lemma shows how to shortcut pointers in the input data structure without in-

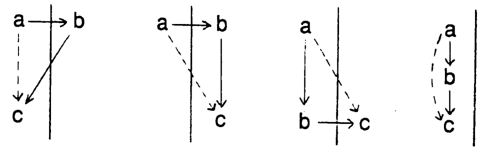

Figure 2: The Shortcut Lemma. In each of the four cases illustrated, the load factor across the cut is either unchanged or diminished by replacing $a \rightarrow b$ and $b \rightarrow c$ with $a \rightarrow c$.

creasing communication requirements.

**Lemma 1 (Shortcut Lemma)** *Let $P$ be the set of pointers in a data structure containing pointers $a \rightarrow b$ and $b \rightarrow c$. Then the set $P'$ of pointers defined by*

$$P' = P \cup \{a \rightarrow c\} - \{a \rightarrow b, b \rightarrow c\}$$

*is conservative with respect to $P$.*

**Proof:** We shall show that $\lambda(P', S) \leq \lambda(P, S)$ for any cut $S$ of the underlying network, which implies that $\lambda(P') \leq \lambda(P)$. Consider the eight ways in which $a$, $b$, and $c$ can be assigned to sides of the partition induced by a cut $S$. Half the cases can be eliminated by symmetry if we assume that $a$ is on the left side. In each of the four remaining cases, the load factor across the cut is either unchanged or diminished when $a \rightarrow b$ and $b \rightarrow c$ are replaced with $a \rightarrow c$, as is shown in Figure 2. ∎

We shall typically use a straightforward generalization of the Shortcut Lemma. Specifically, we can shortcut any set of pointer-disjoint paths in a data structure without increasing the load factor.

Because the algorithms presented in this paper are based on the Shortcut Lemma, they are not only conservative, but they are also independent of the cut capacities of the DRAM and of the embedding of an input data structure in the DRAM. Thus, independent of the underlying network, the algorithms are correct, and if the embedding of the input data structure is good, the algorithms run fast. Moreover, for a specific embedding on a specific DRAM, the running time can be analyzed precisely.

## 3. List contraction

In this section we show that a conservative "recursive pairing" algorithm, Algorithm LC can perform many of the same functions on lists as recursive doubling. The idea is to construct a $O(\lg n)$-height binary *contraction tree* whose leaves are the elements in the list. After building the contraction tree, operations such as broadcasting from the root or parallel prefix can be performed in a conservative fashion.

Algorithm LC is a randomized algorithm, and with high probability, the height of the contraction tree and the number of steps on a DRAM are both $O(\lg n)$. A deterministic variant based on deterministic coin tossing [5] runs in $O(\lg n \lg^* m)$ steps, where $m$ is the number of processors in the DRAM, and produces trees of height $O(\lg n)$.

Algorithm LC requires a constant amount of extra space for each element in the input list. Each processor contains two elements, an element in the list, and a *spare* element that will act as an internal node in the contraction tree. We call the two elements in the same processor *mates*. Each element holds a pointer to an unused internal node, which for each list element initially points to its mate. The use of spare nodes allows the algorithm to distribute the space for the internal nodes of the contraction tree uniformly over the elements in the list. Spare internal nodes are used in [1] and [14] for similar reasons, but in a different context.

Algorithm LC now proceeds as follows.[2] (For a more complete description, see [16]). In each iteration, each element in the list randomly picks either its left or right neighbor. If two elements pick each other, they merge, and the left element takes control. A new internal node of the contraction tree is made using the spare of the left element. The spare for the new node is the spare of the right element. The new node's left child is the left element, and its right child is the right element. The new nodes and the unpaired nodes then form themselves into a "contracted" list in the terminology of Miller and Reif [17].

To describe the efficiency of randomized algorithms such as Algorithm LC, we shall use the term "with high probability," by which we shall mean "with probability $1 - O(1/n^k)$ for any constant $k > 0$," where $n$ is the size of the input.

**Theorem 2** *With high probability, Algorithm LC takes $O(\lg n)$ steps to construct a contraction tree for a circular list of $n$ elements.* ∎

**Theorem 3** *With high probability, the height of the contraction tree is $O(\lg n)$.*

**Proof:** The height of the contraction tree is not greater than the number of iterations of Algorithm LC. ∎

We can now prove that Algorithm LC is conservative.

**Theorem 4** *Algorithm LC is conservative.*

**Proof:** The key idea is that the order of the list elements and their spares is preserved by the operation of contraction. By convention, let the mate of an element in the input list lie in the order between that element and its right neighbor. Then in each iteration, an active element's spare lies between the element and its right neighbor in the contracted list. Thus, both the pointers of the contracted list and the pointers between active elements and their spares correspond to disjoint paths in the input list. The memory accesses in a step of the algorithm correspond to a set of pointers between active elements and their left or right neighbors in the contracted list, or to a set of pointers between active elements and their spares. ∎

Once a contraction tree has been constructed, it can be used to broadcast a value to all of the elements of the list, to accumulate values stored in each element of the list, and more generally, for performing *prefix computations*. Let $\mathcal{D}$ be a domain with a binary associative operation $\oplus$ and an identity element $\varepsilon$. A prefix computation [3,7,18] on a list with elements $x_1, x_2, \ldots, x_n$ in $\mathcal{D}$ puts the value $y_i$ in element $i$ for $i = 1, 2, \ldots, n$, where $y_i = x_1 \oplus x_2 \oplus \cdots \oplus x_i$.

A prefix computation on a list can be performed by a conservative, two-phase algorithm on the contraction tree. The leaves of the contraction tree from left to right are the elements in the list from $x_1$ to $x_n$. The first phase proceeds bottom up on the tree. Each leaf passes its $x$ value to its parent. As the algorithm proceeds, each internal node receives values from its left and right children, call them $z_l$ and $z_r$. The node saves value $z_l$, and passes $z_l \oplus z_r$ to its parent. The second phase proceeds top down after the root receives values from its children. The root then passes

[2] A similar algorithm works for circular lists.

$\varepsilon$ to its left child and its $z_l$ value to its right child. Each child receives a value from its parent, call it $z_p$, and passes that value to its left child and $z_l \oplus z_p$ to its right child. Each leaf receives the correct $y$ value.

The algorithm performs the prefix computation in $O(\lg n)$ steps. At each step, the algorithm communicates across a set of pointers in the contraction tree, all of which are the same distance from the leaves in the first phase and from the root in the second. That this computation is performed in a conservative fashion is a consequence of the following lemma.

**Theorem 5** *Let $CT$ be a contraction tree computed by Algorithm LC on an input list $L$, and suppose $P$ is a set of pointers of $CT$ in disjoint subtrees of $CT$. Then $P$ is conservative with respect to $L$.*

**Proof:** An inorder traversal of $CT$ alternately visits list elements (leaves) and their mates (internal nodes) in the same order that the list elements and mates appear in $L$. Thus, the pointers in $P$ correspond to disjoint paths in $L$. By the Shortcut Lemma, any set of pointers that correspond to disjoint paths in the list $L$ are conservative with respect to $L$. ▮

Algorithm LC, which constructs a contraction tree in $O(\lg n)$ steps, is a randomized algorithm. By using the "deterministic coin tossing" technique of Cole and Vishkin [5] the algorithm can be performed nearly as well deterministically. Specifically, the randomized pairing step can be performed deterministically in $O(\lg^* m)$ steps on a DRAM with $m$ processors, where $\lg^* m$ is the number of times the logarithm function must be successively applied to reduce $m$ to a value no greater than 1. The overall running time for list contraction is thus $O(\lg n \lg^* m)$.

## 4. Tree contraction

This section presents a conservative tree contraction algorithm, Algorithm TC, based on the tree contraction ideas of Miller and Reif [17]. The algorithm uses a recursive pairing strategy to build a contraction tree for an input rooted binary tree in much the same manner as Algorithm LC does for a list. Algorithm TC is a randomized algorithm, and with high probability, the height of the contraction tree and the number of steps on a DRAM are both $O(\lg n)$. A deterministic variant based on deterministic coin tossing [5] runs in $O(\lg n \lg^* m)$ steps, where $m$ is the number of processors in the DRAM, and produces trees of height $O(\lg n)$.

We now outline Algorithm TC which performs tree contraction. (For a more complete description, see [16].) At each step, nodes in the input tree are paired. The pairing strategy has each node pick from among its neighbors according to how many children it has. A leaf picks its parent with probability 1. A node with exactly one child picks its child or its parent, each with probability 1/2. A node with two children picks each child with probability 1/2. The root, which has no parent, picks its children with equal probability. If two nodes pick each other, they merge and the parent takes over. A new internal node of the contraction tree is made from the spare of the parent in the pair. The spare of the new node is the spare of the child in the pair. One child in the contraction tree is the parent of the pair, and the other child in the contraction tree is the child of the pair. The new nodes and the unpaired nodes form themselves into a new tree, which is guaranteed to be binary by the the pairing strategy. The algorithm is applied recursively to the new tree.

After the input tree has been contracted to a single node, it may be "expanded" by undoing the contractions in the reverse of the order in which they occurred. When an internal node of the contraction tree expands to a parent–child pair, the tree pointers of these nodes are used to restore the tree to the state it had when the contraction took place. These pointers have been undisturbed by the algorithm since the nodes merged. The expansion requires only constant space at each node. In the next section we will see that tree expansion allows us to describe treefix computations recursively.

The proof that, with high probability, Algorithm TC takes $O(\lg n)$ steps to contract an input rooted binary tree to a single node requires three technical lemmas. The first lemma shows that in a binary tree, the number of nodes with two children and the number of leaves are nearly equal. The second lemma provides an elementary bound on the expectation of a discrete random variable with a finite upper bound. The last lemma presents a "Chernoff" [4] type bound on the tail end of a binomial distribution.

In the theorems and lemmas that follow, let $V_0$, $V_1$ and $V_2$ denote the sets of nodes (excluding the root) with zero, one, or two children, respectively, in a rooted binary tree of $|V|$ nodes. Let $|V_0|$, $|V_1|$, and $|V_2|$ denote the sizes of these sets and let $d(r)$ be the degree of the root.

The first lemma shows that in a binary tree, the number of nodes with two children (excluding the root) is equal to the number of leaves plus the degree of the root.

**Lemma 6** $|V_2| + d(r) = |V_0|$ ▮

The next lemma provides a lower bound on the probability that a discrete random variable with a finite upper bound will be larger than some fixed value.

**Lemma 7** *Let $X \leq b$ be a discrete random variable with expected value $\mu$. For $w < b$,*

$$\Pr(X \geq w) \quad \geq \quad \frac{\mu - w}{b - w} \, . ▮$$

The final lemma presents a bound on the tail end of a binomial distribution. Consider a set of $t$ independent Bernoulli trials, each occurring with probability $p$ of success. The probability that fewer than $s$ successful trials occur is

$$B(s,t,p) \quad = \quad \sum_{k=0}^{s-1} \binom{t}{k} p^k (1-p)^{t-k} \, .$$

The lemma bounds that probability $B(s,t,p)$ that fewer than $s$ successes occur in $t$ trials when $t > 2s$ and $p < 1/2$.

**Lemma 8** *For $t > 2s$ and $p < \frac{1}{2}$,*

$$B(s,t,p) \quad \leq \quad \left(\frac{1-p}{1-2p}\right) \left((1-p)^t\right) \left(\frac{et}{s}\right)^s \, . ▮$$

We now prove that with high probability, Algorithm TC takes $O(\lg n)$ steps to contract a rooted binary tree to a single node. The key observation in the proof is that for each node that pairs with its parent, the number of nodes in the tree decreases by one.

**Theorem 9** *With high probability, Algorithm TC takes $O(\lg n)$ contraction steps to contract a rooted binary tree of $n$ nodes to a single node.*

**Proof:** The proof has three parts. We use Lemma 6 to show that that if a rooted binary tree has $|V|$ nodes, the expected number of nodes pairing with a parent is at least $|V|/4$. Next, we call a pairing step "successful" if at least $|V|/8$ nodes pair with a parent. In the resulting contraction, the size of the tree decreases by at least a factor of 7/8. We use Lemma 7 to prove that the probability that a pairing step is successful is at least 1/3. Finally, we use Lemma 8 to show for any constant $k$ that after $\alpha \log_{8/7} n$ steps, for some constant $\alpha > 2$, the probability that fewer than $\log_{8/7} n$ successful steps occur is $O(1/n^k)$.

We first show that the expected number of nodes pairing with a parent is at least $|V|/4$. A node is picked by its parent with probability 1 when its parent is a degree 1 root, and 1/2 otherwise. Thus a leaf pairs with its parent with probability at least 1/2, and a node (other than the root) with one child picks its parent with probability at least 1/4. Let $P$ be the number of nodes pairing with a parent. Apply Lemma 6 to the simple bound on the expected value of $P$,

$$\mathrm{E}(P) \quad \geq \quad \frac{|V_0|}{2} + \frac{|V_1|}{4}$$

to yield the desired result:

$$\mathrm{E}(P) \geq \frac{|V_0| + |V_1| + |V_2| + d(r)}{4} \geq \frac{|V|}{4} .$$

Now we show that the probability that a pairing step is successful is at least 1/3. At most half of the nodes pair with their parents. Using Lemma 7 with $b = |V|/2$, $w = |V|/8$, and $\mu \geq |V|/4$ we have

$$\Pr(P \geq |V|/8) \geq \frac{\frac{|V|}{4} - \frac{|V|}{8}}{\frac{|V|}{2} - \frac{|V|}{8}} = \frac{1}{3} .$$

Finally, we show that with high probability, Algorithm TC takes $O(\lg n)$ contraction steps to contract the input tree to a single node. In the contraction following a successful pairing step, the size of the tree decreases by a factor of 7/8 or more. After $\log_{8/7} n$ successful steps, the tree must consist of a single node. By Lemma 8 with $p = 1/3$, the probability that fewer than $s = \log_{8/7} n$ successful steps occur in $\alpha s$ steps is

$$B(\log_{8/7} n, \alpha \log_{8/7} n, 1/3) \quad \leq \quad 2\left(\left(\frac{2}{3}\right)^{\alpha} \alpha e\right)^{\log_{8/7} n} .$$

For any value $k$, we can choose $\alpha$ so that $B(\log_{8/7} n, \alpha \log_{8/7} n, 1/3)$ is $O(1/n^k)$. In particular, for $k = 1$, setting $(2/3)^{\alpha}\alpha e \leq 7/8$ yields $\alpha \geq 8$. ∎

We now prove that Algorithm TC is conservative.

**Theorem 10** *Algorithm TC is conservative.*

**Proof:** The key idea is that each active element in the contracted tree is a "representative" of a subgraph of the input tree that has been contracted to a single node. The contracted subgraphs, which are trees, are disjoint in the input tree. The representative and spare of a subgraph are either elements in or mates of elements in the subgraph. The pairing strategy ensures that each subgraph is adjacent by an edge to at most one subgraph which is higher in the input tree, and to at most two subgraphs which are lower. The representative of the subgraph has pointers to the representatives of these subgraphs, and to the spare of the subgraph.

As in the list contraction algorithm, memory accesses in a step of the tree contraction algorithm corresponds to a set of disjoint paths in the input data structure. Since each subgraph is connected, the pointers between representatives and spares correspond to disjoint paths in the input tree. Similarly, any set of pointers between each representative and the representative of at most one of the two adjacent subgraphs lower in the input tree corresponds to a set of disjoint paths in the input tree. The memory accesses in a step correspond to a set of pointers between representatives and spares or to a set of pointers between each representative and the representative of at most one of the two adjacent subgraphs lower in the input tree. ∎

Tree contraction can be performed conservatively and deterministically in $O(\lg n \lg^* m)$ steps on a DRAM with $m$ processors using the deterministic coin tossing algorithm of Cole and Vishkin [5]. The key idea is that in Algorithm TC, the nodes in the tree that can pair form chains, and by Lemma 6 these chains contain at least half the tree edges. The chains can be oriented from child to parent in the tree, and deterministic coin tossing can be used to perform the pairing step in $O(\lg^* m)$ steps.

## 5. Treefix computations

This section presents a generalisation of the parallel prefix computation to binary trees. We present two kinds of *treefix* computations—*rootfix* and *leaffix*—and show how they can be implemented by an $O(\lg n)$-step conservative algorithm in linear space. As we shall see in Section 6, treefix computations can greatly simplify the description of many parallel graph algorithms in the literature, and moreover, treefix computations can be performed by conservative algorithms.

We begin with a definition of treefix computation.

**Definition 11** *Let $\mathcal{D}$ be a domain with a binary associative operation $\oplus$ and an identity element $\varepsilon$. Let $T$ be a rooted, binary tree in which each vertex $i \in T$ has an assigned value $x_i \in \mathcal{D}$. The rootfix problem is to compute for each vertex $i \in T$ with parent $j$, the value $y_i = y_j \oplus x_i$, where $y_j = \varepsilon$ if $i$ is the root. The leaffix problem is to compute for each vertex $i \in T$ with left child $j$ and right child $k$, the value $y_i = x_i \oplus y_j \oplus y_k$, where $y_j = \varepsilon$ if $i$ has no left child and $y_k = \varepsilon$ if $i$ has no right child.*

Simple examples of treefix problems are computing the depth of each vertex in a rooted binary tree and computing the size of each subtree. These and other examples appear in the next section.

Like the prefix computation on lists, treefix computations can be performed directly on the contraction tree. To simplify the description here, however, we describe a recursive version. We execute one contraction step and then recursively perform a treefix computation on the new tree. The treefix values for the input tree can be computed immediately from the treefix values for the new tree. The recursion level of a node in the contraction tree can be maintained by recording the step in which it was created.

**Theorem 12** *A rootfix or leaffix computation can be performed by a conservative randomized algorithm which, with high probability, takes $O(\lg n)$ steps, or by a conservative deterministic algorithm which takes $O(\lg n \lg^* m)$ steps, where $m$ is the number of processors in the DRAM.*

**Proof:** We first describe the computation for rootfix. First the input binary tree $T$ is transformed to a new tree $T'$ by one contraction step. Each new node $u$ in $T'$ resulting from the pairing of parent $p$ and child $c$ in $T$ passes input value $x_c$ to the child in $T'$ that $u$ inherited from $c$. Node $u$ passes $\varepsilon$ to its other child. Each unpaired node $v$ in $T'$ passes $\varepsilon$ to each of its children. Each node in $T'$ receives a value from its parent, call it $z$. Each new node $u$ computes $x'_u \leftarrow z \oplus x_p$. Each unpaired node $v$ computes $x'_v \leftarrow z \oplus x_v$. A rootfix computation is performed recursively on $T'$ using the $x'$ values as input and yielding $y'$ values as output. The contraction step from $T$ to $T'$ is then undone. Each new node $u$ passes $y'_u$ to $p$ and $c$. Node $p$ computes $y_p \leftarrow y'_u$ and $c$ computes $y_c \leftarrow y'_u \oplus x_c$. Each unpaired node $v$ computes $y_v \leftarrow y'_v$.

We now describe a computation of which leaffix is a special case. Each node $i$ in $T$ is assigned input values $x_i$, $l_i$, and $r_i$. Node $i$ with left child $j$ and right child $k$ computes output value $y_i = x_i \oplus y_j \oplus l_i \oplus y_k \oplus r_i$, where $y_j$ and $l_i$ are $\varepsilon$ if $i$ has no left child and $y_k$ and $r_i$ are $\varepsilon$ if $i$ has no right child. For the special case of leafix, $l_i$ and $r_i$ are both $\varepsilon$. First, a contraction step transforms $T$ to $T'$. Consider each new node $u$ in $T'$ resulting from the pairing of parent $p$ and left child $c$ in $T$ with input values $x_p$, $l_p$, $r_p$ and $x_c$, $l_c$ respectively. (The cases where $c$ is a right child, or where $c$ has a right child or is a leaf, are similar.) Node $u$ computes $x'_u \leftarrow x_p \oplus x_c$, $l'_u \leftarrow l_c \oplus l_p$, and $r'_u \leftarrow r_p$. Each unpaired node $v$ computes $x'_v \leftarrow x_v$, $l'_v \leftarrow l_v$, and $r'_v \leftarrow r_v$. The computation is performed recursively on $T'$ using the $x'$ values as input and yielding $y'$ values as output. Each node passes its $y'$ value to its parent in $T'$. Each node receives values from its left and right children, call these values $z_l$ and $z_r$. Each new node $u$ passes $z_l$ to $c$ and both $z_l$ and $z_r$ to $p$. The contraction step from $T$ to $T'$ is undone. Node $c$ computes $y_c \leftarrow x_c \oplus z_l \oplus l_c$. Node $p$ computes $y_p \leftarrow x_p \oplus x_c \oplus z_l \oplus l_c \oplus l_p \oplus z_r \oplus r_p$. Each unpaired node $v$ computes $y_v \leftarrow y'_v$. ∎

## 6. Conservative algorithms

This section presents a collection of conservative DRAM algorithms, all of which use treefix computations. The algorithms use two processors per edge of an input graph $G = (V, E)$ and require constant extra space in each processor. Since the algorithms are based on shortcutting pointers in the input data structure, they are independent of the underlying DRAM or embedding of the data structure.

We represent each vertex in an undirected graph $G = (V, E)$ by a doubly linked *incidence ring* of processors, one for each edge. Each element of the incidence ring contains pointers to the next and previous elements in the ring, and one pointer for a graph edge. For each edge $(u, v) \in E$ the element in the incidence ring for $u$ contains a pointer to an edge element in the incidence ring for $v$, and vice versa. A directed graph is represented in the same doubly linked fashion, but the graph edges are labeled with their directions.

We represent trees with arbitrary vertex degrees by an incidence ring structure as well. If the tree is directed, each ring has a unique *principal element* that points toward the root. Breaking the incidence ring before the principal element yields the standard binary tree representation of the tree [10, pp. 332–333].

We now present brief descriptions of the algorithms. The performance is given terms of the number of steps on a DRAM when the input representation has size $n$. We assume the implicit tree contractions in the algorithms are performed by the randomized Algorithm TC. Deterministic bounds can be obtained by multiplying the number of steps by $O(\lg^* m)$, where $m$ is the number of processors. An upper bound on the actual performance can be obtained by multiplying the number of steps by the load factor of the input.

**Generalized treefix.** *Perform a treefix operation on a directed tree with arbitrary vertex degree. The input values $\{x_i\}$ are stored in the principal elements of the tree, which is where the output values $\{y_i\}$ are to be placed. The leaffix value at a node $i$ whose children have values $y_1, y_2, \ldots, y_k$ is $y_i = x_i \oplus y_1 \oplus y_2 \oplus \cdots \oplus y_k$.* Each element that is not principal stores the identity element $\varepsilon$ for its value. A binary treefix computation performed on the binary tree representation underlying the tree computes the desired values. *Performance:* $O(\lg n)$.

**Tree functions.** *Given a directed tree, compute for each node the number of descendents, its height, or its depth.* The number of decendents for each node can be computed by a leaffix computation with $\oplus$ as integer addition and $x_i = 1$ for all nodes. The height of a node can also be computed by a leaffix computation where $a \oplus b = \max(a + 1, b + 1)$, the identity is $\varepsilon = -\infty$, and $x_i = 0$ for all nodes. The depth of a node can be computed by a rootfix computation with $\oplus$ as addition and $x_i = 1$ for all nodes except the root which has value 0. *Performance:* $O(\lg n)$.

**Rooting an undirected tree.** *Pick a root of a tree with undirected graph pointers and orient the graph pointers toward the root.* Form an "Eulerian tour" of the pointers of the representation [20] by directing each element of the tree to link its incoming ring pointer with its graph edge directed outward and its graph edge directed inward with its outgoing ring pointer. Each graph edge is used twice in the tour, once in each direction, but each ring pointer is used only once. Using the variant of Algorithm LC which works for circular lists, form a contraction tree of the tour. Choose the root of the contraction tree to be the root of the tree, and break the tour so that it begins with the root. Use parallel prefix to number each node according to its first occurrence in the tour. Use contraction trees to distribute the smallest value in each incidence ring to the elements of the ring. Orient each graph edge from the larger value to the smaller. *Performance:* $O(\lg n)$.

**Rerooting a directed tree.** *Given a directed tree and another distinguished vertex $k$, reorient the graph edges of the tree to point to $k$.* The algorithm for rooting a tree can be used by picking $k$ as the root instead of the root of the contraction tree, but a single treefix computation suffices. Perform a leaffix computation with $x_k = 1$ and $x_i = 0$ if $i \neq k$, and use Boolean OR for $\oplus$. Each principal element whose leaffix value is 1 lies on the path from $x_k$ to the root. Reverse the direction of the graph pointers of these elements. (Note: rerooting a tree changes the principal elements.) *Performance:* $O(\lg n)$.

**Tree-walk numberings of a binary tree.** *Number the nodes of a binary tree according to the order they would be visited in a preorder/inorder/postorder tree walk.* For each of the walks, we will compute $y_k$, the number of nodes visited before the left subtree of $k$. Use a leaffix computation to compute the number $size_k$ of the subtree rooted at $k$. We first compute the preorder numbering. (For the purposes of these numbering algorithms, we consider the root to be a left child.) If node $k$ is a left child, set $x_k$ to 1. If node $k$ is a right child, set $x_k$ to 1 plus the size of its sibling subtree. A rootfix computation with + yields $y_k$, which is the preoder numbering of node $k$. The inorder numbering can be computed similarly. If node $k$ is a left child, set $x_k$ to 0. If $k$ is a right child, set $x_k$ to 1 plus the size of its sibling subtree. Compute $y_k$ for each node using a rootfix computation with +. The inorder numbering of node $k$ is 1 plus $y_k$ plus the size of its left subtree. The postfix numbering can be computed by setting $x_k$ to 0 if node $k$ is a left child, and by setting $x_k$ to the size of its sibling subtree if $k$ is a right child. After computing $y_k$ using a rootfix computation with +, the postfix numbering of node $k$ is 1 plus $y_k$ plus the sizes of its two subtrees. *Performance:* $O(\lg n)$.

**Prefix/postfix numbering of a directed tree.** *Number the edges of an arbitrary directed tree according to the order they are visited in preorder/postorder tree walk.* The problem reduces to prefix/postfix numbering on the underlying binary tree representation. *Performance:* $O(\lg n)$.

**Diameter and center of a tree.** *The diameter is the length of the longest path in the tree. A center is a vertex $v$ such that the longest path from $v$ to a leaf is minimal over all vertices in the tree.* The diameter can be determined by rooting the tree and using rootfix to find the furthest leaf from the root. Reroot the tree at this leaf. The distance from the new root to the furthest leaf is the diameter. (Based on an analog algorithm attributed to J. Wennmacker [6].) A center of the tree can be determined by finding a median element of the path that realizes the diameter. *Performance:* $O(\lg n)$.

**Centroid of a tree.** *A centroid is a vertex $v$ such that the largest subtree with $v$ as a leaf is minimal over all vertices in the tree.* A centroid can be determined by rooting the tree and computing the size of each subtree. By broadcasting the size $m$ of the tree from the root, each graph edge in each incidence ring can determine the number of elements on the other side of the edge. For each incidence ring, compute the maximum of these values. A vertex with the minimum of these maximum values is a centroid. *Performance:* $O(\lg n)$.

**Separator of a tree.** *A separator* [15] *is a partition of the vertices of an $m$-vertex tree into three sets $A$, $B$, and $C$, with $|A| \leq \frac{2}{3}m$, $|B| = 1$, and $|C| \leq \frac{2}{3}m$, such that no edge of the tree goes between a vertex in $A$ and a vertex in $C$.* Determine a centroid of the tree. This vertex is the separator vertex in $B$. It remains to partition the remaining vertices between $A$ and $C$. For each graph edge in the incidence ring, count the number of vertices in the subtree on the other side of the edge. Put the largest subtree in $A$. Use parallel prefix on the incidence ring to compute a running sum of the sizes of the other subtrees. Put all subtrees whose prefix value is at most $\frac{2}{3}m$ in $C$, and put the remainder in $A$. *Performance:* $O(\lg n)$.

**Subexpression evaluation.** *Given a directed tree in which each leaf has a value and each internal node has an operator from $\{+, -, \cdot, \div\}$, compute for each internal node the subexpression rooted at that node.* A single leaffix computation suffices using the ideas of Brent [2] and Miller and Reif [17]. *Performance:* $O(\lg n)$.

**Minimum cost spanning tree.** *Given an undirected input graph $G = (V, E)$ and a cost function $w : E \to \mathbf{R}$, determine a set $F \subseteq E$ of edges such that each vertex in $V$ is incident on an edge of $F$, and the sum of the weights of the edges in $F$ is minimal.* We give a conservative DRAM implementation of Sollin's algorithm [8, section 5.5]. We assume without loss of generality that the edge weights are distinct—otherwise, we can assign the weight of a graph edge $e$ between two incidence ring elements with addresses $a$ and $b$ to be $(w(e), \max(a, b), \min(a, b))$ and then compare weights lexicographically. We determine $F$ by marking edges in $G$. Initially, no edges are marked. At each step of the algorithm, the currently marked graph edges form a subforest of $F$. Break each incidence ring by removing a single ring pointer and direct the resulting linear list. At each step of the algorithm, the marked graph edges and the ring pointers form a set $\{T_i\}$ of rooted trees, where the index $i$ of the tree is the address of the root. The algorithm proceeds as follows. For each tree $T_i$, use a rootfix computation to broadcast $i$ to all of the elements in $T_i$. Use a leaffix computation on $T_i$ to determine an edge $e \in E$ with the smallest weight $w(e)$ connecting an edge element $u \in T_i$ with an edge element $v \in T_j$, where $i \neq j$. If no such edge exists, the algorithm terminates. If $T_j$ picks the same edge as $T_i$, the tree with smaller index does nothing. Otherwise, mark $e$ as a member of $F$, directing it into $T_j$, and reroot $T_i$ with $u$ as the new root. Repeat this procedure until the algorithm terminates. *Performance:* $O(\lg^2 n)$.

**Connected components.** *Given an undirected input graph $G = (V, E)$, determine a labeling $l : V \to \mathbf{Z}$ such that such that $l(v) = l(v')$ if and only if $v$ and $v'$ are in the same connected component of $G$.* The algorithm is the same as the minimum spanning tree algorithm, choosing the weight of a graph edge $e$ between incidence ring elements with addresses $a$ and $b$ to be $\max(a, b), \min(a, b)$. The label of a vertex is the index of its tree. *Performance:* $O(\lg^2 n)$.

**Biconnected components.** *Two edges of an undirected graph $G = (V, E)$ are in the same biconnected component if they lie on a common simple cycle. Determine a labeling $l : E \to \mathbf{Z}$ such that $l(e) = l(e')$ if and only if $e$ and $e'$ are in the same biconnected component of $G$.* We give a conservative DRAM implementation of the biconnectivity algorithm of Tarjan and Vishkin [20]. We assume that the reader has some familiarity with that algorithm. Find a (directed) minimum spanning tree $T = (V, F)$ of $G$. Number the vertices in the minimum spanning tree in preorder. Use leaffix computations to compute for each vertex $v$ three values: $\mathrm{nd}(v)$, $\mathrm{low}(v)$, and $\mathrm{high}(v)$. Here $\mathrm{nd}(v)$ is the number of descendants of $v$, while $\mathrm{low}(v)$ and $\mathrm{high}(v)$ are the lowest and highest vertices (with respect to the preorder numbering of $T$) that are either a descendant of $v$ or adjacent to a descendant of $v$ by an edge of $E - F$. Build a new graph $G'$ where the edges of $F$ are the vertices of $G'$. Let $e$ be an edge from $u$ to $p(u)$, where $p(u)$ is the parent of $u$ in $F$. The adjacency ring for $u$ in $G$ acts as the adjacency ring for $e$ in $G'$. Add two kinds of edges to $G'$. For each edge $\{w, v\}$ in $E - F$ such that $v + \mathrm{nd}(v) \leq w$, add an edge $\{\{v, p(v)\}, \{w, p(w)\}\}$ to $G'$. For each edge $(v, p(v))$ of $F$ such that $v \neq 1$ and $p(v) \neq 1$, and $\mathrm{low}(v) < \mathrm{low}(p(v))$ or $\mathrm{high}(v) \geq p(v) + \mathrm{nd}(p(v))$, add an edge $\{\{v, p(v)\}, \{p(v), p(p(v))\}\}$ to $G'$. It can be verified that the representation of $G'$ is conservative with respect to the representation of $G$. Find the connected components of $G'$. Two edges of $F$ are in the same block if as vertices in $G'$ they are in the same connected component. Finally, for each edge $e = \{w, v\}$ in $E - F$, let $l(e) = l(\{w, p(w)\})$. *Performance:* $O(\lg^2 n)$.

**Eulerian cycle.** *An Eulerian cycle of an undirected graph $G = (V, E)$ is a cycle containing each edge in $E$ exactly once.* If any vertex has odd degree, then no Eulerian cycle exists. Form a set of disjoint cycles of the pointers of the representation of $G$ as in the algorithm for directing a tree. The cycles can be merged using an algorithm similar to the minimum spanning tree algorithm. *Performance:* $O(\lg^2 n)$.

## 7. Concluding remarks

The efficiency of a DRAM algorithm depends on how well its input is embedded in the DRAM, but this embedding problem must be faced by algorithm designers in any bandwidth-limited distributed network. In general, the problem of determining the best embedding is NP-complete, but for many common situations, good embeddings can be found. For example, any of our polylogarithmic-step conservative algorithms can be run on planar graphs properly embedded in an area-universal fat-tree, and they will exhibit polylogarithmic time performance.

As another example, a subproblem in switch-level simulation of a VLSI circuit is the finding of electrically equivalent portions of the circuit. A naive divide-and-conquer embedding of the circuit on an area-universal fat-tree [12] yields small load factors for every cut. Thus, our conservative connected components algorithm will never cause undue congestion in communicating messages in the underlying network, and the algorithm will run effectively as fast as on an expensive, high-bandwidth network.

Many other classes of algorithms can be implemented in a conservative fashion on a DRAM. Any algorithm that communicates olny across pointers in an input data structure is conservative. Passing a single datum between two processors, however, can require time linear in the diameter of the data structure, whereas our algorithms all run in a polylogarithmic number of steps. As another example, systolic array algorithms for matrix problems

[11,14] can be implemented efficiently if the matrices are properly embedded. In general, any fixed-connection network algorithm will run well on a DRAM if the communication required by the network can be supported by the underlying DRAM network.

As a final comment, it may well be that the notion of a conservative algorithm is too conservative. A contraction tree is not conservative with respect to its input tree (though the levels of the contraction tree are), but the load factor of the contraction tree is at most $O(\lg n)$ times the input load factor. As a practical matter, it is probably not worth worrying whether every set of memory accesses is conservative with respect to the input, as long as the load factor of memory accesses is polylogarithmically bounded. Algorithms with this looser bound are somewhat easier to code because of the relaxed constraint, and they should perform comparably.

**ABSTRACT** New efficient techniques for manipulating linked structures in parallel are presented. These techniques work on the EREW machine, which is the weakest shared memory machine. Using these techniques we develop algorithms for connected components, spanning trees, minimum spanning trees, and other graph problems. All of these algorithms achieve linear speed-up for all but the sparsest graphs. We also present a new parallel radix sort algorithm that is optimal for keys taken from a small range.

## 1. INTRODUCTION

We present new parallel algorithms for several important graph problems including spanning forest, connected components, biconnected components, and (undirected) minimum cost spanning tree (MST). All of the algorithms are improvements over the best results known in several respects: they assume the weakest model of shared memory parallel computation, i.e. the EREW (exclusive read, exclusive write) model; they are deterministic; they are fast on all graph densities. In addition, the input is not required to be in any prearranged order, such as adjacency lists; the input can consist of an unordered list of edges. When the problem size is large relative to the number of processors and the graphs are not extremely sparse (i.e. as long as $n = o(e)$), the algorithms achieve a linear speedup, which means they have optimal processor-time product. As a by product, we obtain a parallel version of radix sort that is optimal as long as the range of the elements sorted is at most polynomially larger than the number of processors.

The algorithms employ a set of useful techniques for efficient parallel manipulation of data structures to avoid conflicts between processors. The most powerful and original technique is a recursive two-step, block-based algorithm. It is used in an algorithm for solving the "parallel prefix" problem on a linked list of elements. In quite a different way, it is used to convert an edge list representation of a graph into an adjacency lists representation. The former representation is how a graph is often defined; the latter representation is often required for efficient parallel access to edges of the graph. Variants of the technique are shown to be useful for performing table lookup, update without conflicts, and radix sort.

Sections 2, 3, and 4 describe basic building blocks. Section 2 reviews the model and some work on solving linked list problems in parallel. In Section 3, we show how a graph can be converted from an edge list representation to an adjacency list representation efficiently in parallel. We also present the parallel radix sort algorithm. Section 4 shows how tree problems can be solved efficiently in parallel. We then use the basic building blocks in Section 5 to obtain parallel algorithms for finding spanning trees, connected components, biconnected components, and minimum spanning trees. A chart at the end of the paper summarizes our results and shows how they compare to the current best.

## 2. PRELIMINARIES

### 2.1. The Model

We assume the PRAM computation model: a PRAM consists of $p$ autonomous processors, all having access to a common memory. At each step, each processor performs one operation from its instruction stream. Instructions accessing shared memory are also assumed to be accomplished in one cycle. Borrowing the notation of [12], we distinguish three variants of the PRAM family: In a Concurrent Read, Concurrent Write (CRCW) model, processors may simultaneously access the same memory location; there are various schemes for resolving write conflicts. In a Concurrent Read, Exclusive Write (CREW) model, several processors may simultaneously read the value of a memory location, but exclusive access is required for write. Finally, in the Exclusive Read, Exclusive Write (EREW) model, a memory location cannot be simultaneously accessed by more than one processor. Our algorithms can be implemented on the weakest of these three models: the EREW PRAM.

### 2.2. Linear Linked List Problems

We now review our algorithm for solving problems on linear linked lists [7]; it will be extended in the following sections to more general linked structures. Although our results for linear linked lists have since been improved by Cole and Vishkin [4], their technique does not seem to extend to more general linked structures.

The *product computation* problem is to compute the product $a_0 \, o \, a_1 \, o \cdots o \, a_{n-1}$, given $n$ elements $a_0, a_1, \ldots, a_{n-1}$, and a binary, associative operation, denoted $o$, e.g. ordinary, matrix, and Boolean addition and multiplication. The *initial prefix* problem is to compute all $n$ initial prefixes $a_0$, $a_0 \, o \, a_1$, ..., $a_0 \, o \, a_1 \, o \cdots o \, a_{n-1}$. The initial prefix problem when solved in parallel is known as *parallel prefix*. When the elements are laid out in known memory locations there are well known methods to solve both problems in time $O(n/p + \log p)$ [9].

The problem is harder to solve when the elements are stored in a linear linked list. The locations of the elements is given, but it is not known which element is which. Only the location of the first element is given along with a map *Succ* from the $i$th element to the $(i+1)$st element, and a map *Pred* from the $i$th element to the $(i-1)$st element (the second mapping can be computed from the first in $O(n/p)$ time).

Part of the work was done while the first author was at the University of Illinois, Urbana-Champaign, the second author was at Carnegie-Mellon University, and the third author was at the Courant Institute of Mathematical Sciences, New York University.

0190-3918/86/0000/0869 $01.00 © 1986 IEEE

It is easy to solve the product and initial prefix problems sequentially in $O(n)$ time by starting at the first element and following the links. Wyllie [15] shows that this problem can be solved with $p < n$ processors in $O(n \log n / p)$ time, using a recursive doubling technique. The algorithm never achieves linear speedup.

An efficient parallel solution to this problem has the following general form.

```
General Parallel Prefix Algorithm
  if the list contains more than one element then
  begin
    pick a set $S$ of nonadjacent elements in the list;
    for each $a \in S$ do
    begin
      {replace a pair of adjacent elements by one
        element}
      $val(succ(a)) := val(a) \; o \; val(succ(a))$;
      $succ(pred(a)) := succ(a)$;
      $pred(succ(a)) := pred(a)$
    end;
    apply algorithm recursively to the list;
    for each $a \in S$ do
    begin
      {expand element back into a pair}
      $val(a) := val(pred(a)) \; o \; val(a)$;
      $succ(pred(a)) := a$;
      $pred(succ(a)) := a$
    end
  end
```

The first part of the algorithm solves the product problem, successively compacting the list until only one item is left; the second part, where the recursion unfolds, expands the list back, and computes the missing partial products. Any parallel algorithm that solves the product problem by successive compaction can be used to create a parallel prefix algorithm, that expands the list back by matching step by step the compression operations done by the parallel product algorithm. The resulting algorithm will have twice the running time of the original algorithm. We shall henceforth consider only the product part.

It is not obvious how to pick at each iteration a set $S$ of $\Omega(p)$ nonadjacent element, while devoting only constant time per element. Assume w.l.o.g. that both $n$ and $p$ are powers of 2 (this affects the result only by a constant factor), and that $p \leq n/2$. The product algorithm consists of $\Theta(\log n)$ iterations. At each iteration the elements are partitioned into $n/p$ blocks, each block containing $p$ elements. The processors visit the blocks one by one; the $i$ th processor always visits the $i$ th element within a block. It pairs this element with its successor, only if the element is not marked as deleted, and its successor belongs to another block. It takes $O(n/p)$ time to process all $n/p$ blocks.

After visiting the blocks, every element has formed the product with a neighbor, provided it and its neighbor were in different blocks; all pairings remaining to be done at this phase are internal to a block. Since there are $n/p$ blocks and $p$ processors, $p^2/n$ processors can be assigned to each block.

If $p^2/n > 1$, then we recursively apply the same routine within each block. If $p^2/n \leq 1$, assign each processor $n/p^2$ blocks, and pair elements sequentially with each block. Note that $p$ and $p^2/n$ are powers of 2.

After this, if an element has not been paired with one of its neighbors, then both of its neighbors must be paired (except for the first and last elements of the list), so at most $2n/3 + O(1)$ elements are left.

Let $H_p(n)$ be the number of steps required by one iteration on a list of length $n$.

$$H_p(n) = O(\frac{n}{p}) + H_{p^2/n}(p) \qquad \text{if } p > 1,$$

$$H_p(n) = O(n/p) \qquad \text{otherwise}.$$

It is easy to check that

$$H_p(n) = O(\frac{n}{p}\frac{\log n}{\log(n/p)}).$$

After each iteration, the remaining elements are packed to the top of array, being careful to maintain the integrity of the pointers (which can be done by first determining the location of each element, then updating pointers to point to the new locations, and finally moving the elements). Once there are less than $2p$ elements, the $O(n \log n / p) = O(\log p)$ parallel algorithm is used to complete the algorithm.

Let $T_p(n)$ be the number of steps it takes to solve a problem of size $n$, i.e. the execution time of the procedure Product. If $n < 2p$, $T_p(n) = O(\log n)$ using the standard parallel algorithm. Otherwise,

$$T_p(n) = O(H_p(n) + \frac{n}{p} + \log p) + T_p(\frac{2n}{3}).$$

It is not hard to show that

$$T_p(n) = O(\frac{n}{p}\frac{\log n}{\log(2n/p)}).$$

We obtain

**Theorem 2.1:** The parallel prefix problem for items represented by a linked list can be solved on an EREW machine in $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$ time for $p < n$.

**Note:** This yields, for any constant $0 < \epsilon \leq 1$, a linear speedup when $p \leq n^{1-\epsilon}$ (or equivalently when the time $T_p(n) \geq n^{\epsilon}$).

This algorithm can be used to solve the *linked list packing problem*: Given a list of $n$ items, a subset of which are *active*, pack the active elements to contiguous locations of memory (starting at some specified location). We can use the parallel prefix algorithm to rank the active elements, and then move each one to the location indicated by its rank plus the starting location. As a by product, the elements are packed in order so that the $i$ th element is contiguous to the $(i-1)$st and $(i+1)$st elements.

A slight variation of the parallel prefix algorithm can be used to assign to each node on the list the value $a_1 \, o \, \cdots \, o \, a_n$. The second (list expansion) phase is modified so as to broadcast the product computed in the first phase. We call this the *product broadcast* algorithm. For example, we can use this algorithm to label each node in a list with the name of the first node in the list, or with the name of the least node in the list. The product broadcast algorithm can also be run on a linked circular list, provided that $o$ is a commutative operation.

If the parallel prefix algorithm is applied to a union of disjoint lists, than it will compute initial prefixes in parallel in each list. Similarly, if the product broadcast algorithm is applied to a union of disjoint lists (circular lists), then it will assign to each node the product of the elements in the list it belongs to.

## 3. GRAPH ADJACENCY LIST CONSTRUCTION

The adjacency lists representation of a (directed) graph is particularly useful for many parallel graph algorithms. Unfortunately, this is not always the input format of a graph. The *graph adjacency list construction* problem has as input the list of the edges of the graph (presented as pair of nodes). The edges are stored in an arbitrary order in an array. One constructs an adjacency lists representation of the graph, that is an array $L[1..n]$ of linked lists, where $L[i]$ is the list of nodes adjacent to node $i$.

Constructing the adjacency lists for a graph with $n$ nodes and $e$ edges requires only $O(e+n)$ serial time and $O(e+n)$ space. The array $L[1..n]$ is initialized to nil in time $O(e)$. The adjacency lists are then constructed in time $O(e)$ by inserting edges successively in the adjacency lists.

The parallel version using $p$ processors is not so simple. When the graph is dense, i.e. $e=\Theta(n^2)$, a matrix can be used to avoid interference. When the graph is sparse one must be careful to insure that multiple processors do not try to add elements to the same adjacency list at the same time.

Assume w.l.o.g. that $p$ and $e$ are powers of 2, and that $p \leq n/2$. We create an adjacency list representation, where each entry in the array $L[i]$ has a pointer to the head and a pointer to the tail of the $i$th list. Each entry in the edge list will point to to the corresponding entry in an adjacency list. Each adjacency list is doubly linked.

If $p^2 \leq e$ then the edges are split into $p$ blocks each of size $e/p$. Each processor is assigned a block and it sequentially creates adjacency lists for the edges in its block. This has to be done with some care: since $e/p$ might be much less than $n$, one cannot afford to pay the $O(n)$ overhead of initializing the array entries to nil. Instead we initialize correctly only those entries that are going to be used. There are two passes over the data. In the first pass no insertions are made; for each edge, (the header of) the list the edge is to be inserted into is initialized to nil. In the second pass the insertions are actually made. We create a structure where nonempty adjacency lists have valid format, whereas empty adjacency lists may contain garbage. This phase requires $O(e/p)$ time and $O(pn+e)$ space.

Next all the partial adjacency lists are linked up: We start with an empty structure and serially link to it the adjacency lists of the $p$ blocks, one at a time. All $p$ processors always process the same block at the same time. As above this is done in two passes. In the first pass each processor picks an edge, and if this edge is the first in its list then the processor initializes the corresponding array entry in the new structure to nil. In the second pass each processor picks an edge, and if this edge is the first in its list then the processor links that list at the head of the corresponding adjacency list in the new structure. Since each block structure contains one entry per node there are no conflicts.

The time to process a block in the second phase is $O(e/p^2)$. There are $p$ blocks, so the total time for the second phase is $O(e/p)$. The total time for the algorithm is $O(e/p)$ and the space is $O(pn+e)$.

If $p^2 > e$ then the edges are split into $e/p$ blocks of size $p$. The algorithm is recursively applied to each block in parallel, with $p^2/e$ processors per block. Note that $p^2/e$ and $p$ are powers of 2. Next the $e/p$ partial adjacency lists are linked up, with each block being processed one at a time by the $p$ processors. The same two-pass method is used to avoid initialization overheads. This part of the algorithm takes $O(e/p)$ time and $O(pn+e)$ space.

Let $T_p(e,n)$ be the running time of this algorithm, and let $S_p(e,n)$ be the space used by the algorithm. Then if $p^2 \leq e$,

$$T_p(e,n) = O(e/p) .$$

If $p^2 > e$, we get

$$T_p(e,n) = T_{p^2/e}(p,n) + O(e/p) .$$

This recursion solves to

$$T_p(e,n) = O(\frac{e}{p}\frac{\log e}{\log(e/p)}) .$$

It is easy to modify the above algorithm to set the empty list headers to nil at an additional expense of $O((n+e)/p)$ time.

There are at most $p$ graph adjacency list construction tasks running in parallel, with a total number of edges $e$. Thus, the space used is $O(pn + e)$.

**Theorem 3.1:** The edge list to adjacency list conversion problem can be solved on an EREW machine with $p \leq e/2$ processors in $O(\frac{e}{p}\frac{\log e}{\log(e/p)} + \frac{n}{p})$ time and $O(pn+e)$ space.

**Note:** This yields a linear speedup when $p \leq e^{1-\epsilon}$ for any constant $1>\epsilon>0$; the space requirement is no more than for an adjacency matrix.

**Corollary 3.2:** A list of $e$ numbers in the range $1..n^k$ can be sorted with $p \leq e/2$ processors in time $O(k(\frac{e}{p}\frac{\log e}{\log(e/p)} + \frac{n}{p}))$ and space $O(np + e)$.

**Proof:** Assume $k=1$. For each key value $i$ in the range $1..n$ we create a linked list containing the items with key value $i$. This is done in the same manner an adjacency list was created in the previous algorithm. It requires time $O(\frac{e}{p}\frac{\log e}{\log(e/p)} + \frac{n}{p})$.

We then pack the list of nonempty buckets, in time $O(n/p + \log p)$. A sorted list can now be created in time $O(n/p)$.

The result for general $k$ is obtained by running $k$ phases of a radix sort algorithm, with radix $n$. □

**Corollary 3.3:** A list of $m$ numbers in the range $1,...,R$ can be sorted with $p \leq m$ processors in time $O(\frac{m}{p}\frac{\log R}{\log(m/p)})$.

**Proof:** We use the previous corollary, with $R = n^k$. The time is minimized when $n \approx \frac{m}{p}\frac{\log m}{\log(m/p)}$. Thereby, the sort takes time $O(\frac{m}{p}\frac{\log R}{\log(m/p)})$. □

The sorting time is optimal when $p \leq R^{O(1)}$.

**Corollary 3.4:** Given an adjacency lists representation of a graph with $e$ edges and $n$ nodes, the adjacency lists representation of the reversed graph (i.e. the graph where the direction of each edge is reversed) can be computed in time

$O(\frac{e}{p}\frac{\log e}{\log(e/p)} + \frac{n}{p})$.

These results can also be used to compute the composition of mappings. Let $f$ be a function with domain $1...m$ and range $1...n$, and let $g$ be a function with domain $1...n$. Assume that $f$ is given as a (not necessarily sorted) list of pairs $<i,f(i)>$, and $g$ is represented by an array of values, with the $i$th entry storing $g(i)$. We compute a representation of $g\,o f$ as a list of pairs $<i,g(f(i))>$ using the following steps.

(1) The pairs $<i,f(i)>$ are stored in bucket lists, indexed by the value of the second coordinate $f(i)$.

(2) The first element of each list is marked.

(3) Each marked element $<i,j>$ $(j=f(i))$ performs a look-up for the value of $g(j)$, and stores this value.

(4) The value of $g(j)$ is broadcast to all elements in the bucket, using the product broadcast algorithm.

Empty buckets are never accessed, so that it is not necessary to initialize them. We obtain

**Theorem 3.5:** The composition problem can be solved with $p$ processors on an EREW machine in time $O(\frac{m}{p}\frac{\log m}{\log(m/p)})$ and space $O(np+m)$.

If the function $g$ is also represented by an unsorted list of pairs, the the composition can be computed in time $O(\frac{m+n}{p}\frac{\log(m+n)}{\log((m+n)/p)} + \frac{n}{p})$, using the composition algorithm given in [11].

## 4. TREE PROBLEMS

### 4.1. Tree Recursions

The parallel prefix algorithm can be extended to "parallel prefix" computations on a tree. This has been independently noted for mesh connected computers [1,13].

Let $T$ be tree represented by its adjacency list (each child has an edge directed to its parent). For each node $u$ of $T$ let $val(u)$ be a value stored at that node. Let

$$F(u) = \sum_{v \text{ descendant of } u} val(v)$$

(where a node is taken to be descendant of itself). The addition is an arbitrary associative and commutative operation. The function $F$ can also be defined by the recursion

$$F(u) = \sum_{v \text{ child of } u} F(v) + val(u)\ .$$

We wish to compute the value of $F$ at each node of the tree. The parallel prefix problem is a particular case of this general problem, when the tree degenerates into a linked list. Other interesting cases are

(1) Computing $d(u)$, the number of descendants of each node, including itself. We take $val(u)$=1, and + is usual addition.

(2) Computing the path length of the tree. We take $val(u)=d(u)$, and + is usual addition.

(3) Computing the height of each node in the tree. We have $val(u)$=1, and + is the minimum operation.

An efficient parallel algorithm for solving tree recursions has the following form

**General Parallel Tree Recursion Algorithm**

```
if Tree contains more than one element then
begin
   Pick a set $S$ of nodes such that
     (1) no two nodes in $S$ are adjacent or have
           the same parent
     (2) each node of $S$ has at most one child;
   for each node $u \in S$ do
   begin
      add the value of $u$ to the value of $parent(u)$;
      delete $u$;
      if $u$ has a child then
     link the child to $parent(u)$
   end;
   execute algorithm recursively;
   for each node $u \in S$ do
   begin
      link $u$ to $parent(u)$;
      if $u$ has a child then
      begin
         add the value of $child(u)$ to $u$;
         link $child(u)$ to $u$
      end
   end
end
```

It is easy to see that this algorithm solves the tree recursion problem correctly. One has to show that a set $S$ containing a fixed fraction of the nodes can be picked at each iteration, while spending only constant time per node.

Assume that the tree $T$ has degree bounded by two. We shall divide each iteration in the execution of the algorithm in two stages, one where left children are active, the second where right children are active. This guarantees that children of the same parent do not conflict. Conflicts between a child and its parent are handled exactly as in the parallel prefix algorithm, by dividing the edges into blocks that are handled one at a time.

At least half of the nodes of $T$ have no more than one child. At least 1/3 of the nodes with no more than one child are paired at each iteration. We thus obtain that the recursion can be solved with $p$ processors for a binary tree with $n$ nodes in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$ in the EREW model.

Let $T$ be now a general tree. The tree $T$ can be mapped onto a binary tree $T^b$, as described in [6, § 2.3.2]. The mapping is readily computed from the adjacency list representation of $T$, with edges going from parent to child: $v := left(u)$, if $v$ is the first child in the adjacency list of $u$; $v := right(u)$ if $v$ follows $u$ in the adjacency list of their common parent.

Let $F^b$ be the function computed on the binary tree $T^b$ by solving the tree recursion problem on this tree. Then $F^b(u)$ is the sum of $val(v)$, taken over all descendants of $u$ and descendants of elder siblings of $u$. We have

$$F(u) = \begin{cases} F^b(u) & \text{if } right(u)=nil \\ F^b(left(u)) + val(u) & \text{otherwise} \end{cases}$$

Thus, $F$ can be easily computed from $F^b$. We obtain

**Theorem 4.1:** Given an adjacency list representation of a valued tree with $n$ nodes, the tree recursion problem for the tree can be solved on an EREW machine with $p$ processors in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$ for $p<n$.

### 4.2. Tree Traversals

Given a tree with $n$ nodes represented by an adjacency list (with edges going from parent to child) a linear linked list of the nodes arranged in preorder can be produced by $p$ processors in time $O(n/p)$. A similar construction is given by Wyllie [15] for binary trees.

Let $u_L$ and $u_R$ be two copies of the node $u$ in the tree. Define the mapping *next* as follows.

$$next(u_L) = \begin{cases} v_L & \text{if } v \text{ is first child of } u \\ u_R & \text{if } u \text{ has no children} \end{cases}$$

$$next(u_R) = \begin{cases} v_L & \text{if } v \text{ follows } u \text{ in the adjacency list of } parent(u) \\ parent(u)_R & \text{if } u \text{ is last child of } parent(u) \end{cases}$$

This mapping corresponds to a traversal of the tree in the order Root-Children-Root ($u_L$ represents the first traversal of $u$, and $u_R$ represents the second traversal).

Each node of the tree (with the exception of the root) occurs exactly once in an adjacency list. The linked list defined by the relation *next* can be created by $p$ processors in the time it takes to traverse a linked list in parallel: Each processor is assigned $n/p$ entries from the adjacency list; the processor creates those nodes of the list corresponding to the nodes of the tree it was assigned. The linked list traversal is required for each last child to determine its parent.

A preorder list of the nodes can be obtained in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$ from this list by deleting all the "$u_R$" nodes, and shrinking the list accordingly. This is done by running the parallel product algorithm.

Applying parallel prefix to this list will provide the preorder number of each node with linear speedup for $p \leq n^{1-\epsilon}$.

If we apply this algorithm to a forest then we shall obtain a preorder list for each tree in the forest, and compute the preorder number of each node in the tree it belongs to. Postorder on trees or forests and inorder on binary trees can be handled in a similar manner. Note too that the adjacency list of a tree can be recreated from the list defined by the *next* relation in time $O(n/p)$.

### 4.3. Unicycular Graphs

In this section we show how a "unicycular" graph can be converted to a forest with the same connected components. Although algorithms on unicycular graphs are not by themselves particularly important, this routine is useful in later sections. A *unicycular graph* is a tree with one cycle; it consists of a set of $n$ nodes, each with a parent pointer to another node in the set. Since each node in a unicycular graph has a unique parent, one can define on such a graph the mapping *next* used in the last section.

**Lemma 4.2:** Let $G$ be a unicycular graph, and let *next* be the mapping defined above. Let $G_{next}$ be the graph defined by this mapping: The nodes of $G_{next}$ consist of two copies of each node of $G$, and $uv$ is an edge of $G_{next}$ iff $v = next(u)$. Then

(1) The graph $G_{next}$ consists of exactly two cycles.

(2) The nodes $u_L$ and $u_R$ occur in distinct cycles of $G_{next}$ iff $u$ is on the cycle of $G$.

**Proof:** Each node has exactly one successor and one predecessor in $G_{next}$, so that this graph is a union of cycles. The node $u$ is on the cycle of $G$, iff a traversal starting at $u$ reaches $u$ again before it backtracks. Hence $u$ is on a cycle of $G$ iff the path in $G_{next}$ starting from $u_L$ returns to $u_L$ before it reaches $u_R$. The graph $G$ can be transformed in a tree by deleting one edge from its cycle. This causes the deletion of one edge, and the change of one edge in $G_{next}$, thereby obtaining a linear graph. It follows that $G_{next}$ contains exactly two cycles. □

Let $G$ be a graph that is the union of disjoint unicycular components. The graph $G'$ is a *forest decomposition* of $G$ if $G'$ is obtained from $G$ by deleting one edge from each cycle, thereby replacing each unicycular component with a tree.

**Theorem 4.3:** Let $G$ be a graph with $n$ nodes that is the disjoint union of unicycular components, represented by its adjacency list. The adjacency list of a forest decomposition of $G$ can be computed with $p$ processors in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$ in the EREW model.

**Proof:** The following algorithm will do.

(1) Construct the linked structure defined by the *next* relation.

(2) Assign a distinct label to each circular list (e.g. the least name, in lexicographic order, of an item in the list); label each item with the label of the list it belongs.

(3) Mark those items $u_L$ such that $u_R$ occurs in a list distinct from the list containing $u_L$.

(4) Mark on each list the least item $u_L$ that was marked in the previous phase.

(5) Delete from the original adjacency list the edge leading to $u$, for each item $u_L$ that was marked at the previous stage.

Each of these phases can be implemented to run within the required time. □

## 5. SPANNING FOREST AND CONNECTED COMPONENTS

Connected components can be derived from a spanning forest by creating a preorder list for each tree, and marking each node with the label of the first node in its list. This can be done with $p < n/2$ processors in the EREW model in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$.

Our algorithms for finding a spanning forest are in the spirit of most of the previous algorithms for this problem: (super) nodes are continually combined into super nodes. When no more combining is possible, each super node will represent a connected component, and a spanning tree will also exist for each component.

Eckstein [5] has shown that a spanning forest can be found in $O(e/p + n)$ time using either depth-first or breadth-first search [5]. This is optimal when the number of processors is small relative to the denseness of the graph, i.e. $p = O(e/n)$).

Let $G$ be an (undirected) graph with $e$ edges and $n$ nodes. Our algorithms use two auxiliary graphs: the graph $G_f$ is a forest that is a subgraph of $G$; the graph $G_s$ consists of the supernodes of $G$. Each connected component (tree) of $G_f$ is represented by one supernode in $G_s$. Two supernodes are connected if the corresponding trees are connected by an edge in $G$. Initially $G_f$ contains all the nodes of $G$ and no edges; $G_s$ is initially identical to $G$. At each iteration supernodes that are connected in $G_s$ are combined into a new supernode; edges are added to $G_f$ to merge the corresponding trees into a new tree. The algorithm terminates when $G_s$ does not contain any more edges. At that point $G_f$ is a spanning forest for $G$.

The graph $G_f$ is represented by marking in the adjacency list of $G$ those edges that belong to $G_f$. Separate adjacency lists represent $G_s$. In order to achieve the desired running time, the number of accesses to each edge entry in this list must be bounded by a constant. Therefore, it is not possible to update the edge entries at each iteration. Instead, each edge in an adjacency list of a supernode of $G_s$ is represented by an entry with the name of the incident node in $G$. Some of the edges in this adjacency list may be self loops, i.e. entries in the list of a supernode with the name of a node belonging to this supernode.

We keep a membership list for each supernode, i.e. a list of the nodes belonging to each supernode. Each supernode has a *weight* count, which is the number of nodes belonging to it. We also keep an inverse directory, i.e. an array that indicates for each node the name of the supernode it belongs to.

At the end of each iteration we pack the adjacency list of $G_s$ so that nodes with nonempty lists of incident edges are in the first locations. As we do not want to modify the edge entries, the packing is actually done on a separate array of pointers to the supernodes.

The initial adjacency list for $G_s$ can be created in $O((n+e)/p)$ steps; it can be packed in time $O(n/p + \log p)$. The membership list and inverse directory for supernodes can be created in $O(n/p)$ time.

We terminate the "graph compaction" iterations when the number of nonisolated supernodes is $O(\max(n/p, p^{1+\epsilon}))$. We can then use Eckstein's algorithm to terminate in time $O(n/p + p^{1+\epsilon} + e/p)$.

Assume that the number of supernodes with nonempty adjacency lists is at least $p^{1+\epsilon}$. At each iteration we serially perform the following steps.

(a) Pick the first edge from each nonempty adjacency list of $G_s$. Delete these edges from the graph $G_s$.

(b) Delete from this set of edges those edges that are self loops.

(c) Create an adjacency list for the graph consisting of the remaining edges, and their endpoints. This graph consists of a union of unicycular components.

(d) Create a generating forest $F$ for the graph, by deleting edges from the new adjacency list. Each tree in this forest will be replaced by one new supernode.

(e) Mark the edges of $F$ as belonging to $G_f$.

(f) Select in each tree of $F$ the supernode of largest weight (this is the new supernode), and label all the supernodes in the tree with the name of the selected supernode. Mark all supernodes with the exception of the new supernodes $F$ as inactive.

(g) Update the membership list and inverse directory for supernodes.

(h) Link the adjacency lists of supernodes marked inactive in (f) to the adjacency list of the new supernode they belong to.

(i) Pack the list of supernodes with nonempty adjacency lists.

It is easy to check that this iteration performs a valid compaction of the graph. We shall now estimate the running time of each step. Let $a$ be the number of active supernodes (i.e. supernodes with nonempty adjacency lists) at the start of the iteration.

The edges picked in (a) are <supernode,node> pairs. We compute the <supernode,supernode> edge represented by this pair by composing the mapping represented by the pairs picked in (a) with the mapping represented by the supernode inverse directory. This is done in time $O(\frac{a}{p}\frac{\log a}{\log(a/p)}) = O(a/p)$. Self loops can then be deleted in time $O(a/p)$.

Thus, step (b) can be performed in time $O(a/p)$. It is easy to see that each of the remaining steps, with the possible exception of step (g) can also be executed within the same time bound. As $a$ edges are deleted from $G_s$ at this iteration, it follows that the total time spent executing these steps is $O(e/p)$. We shall now estimate the time spent in updating membership lists and inverse directories for supernodes.

Let $m$ be the number of nodes that change supernode during the iteration. The number of affected supernodes is bounded by $a$. Using the membership list it is possible to create a list of affected nodes in time $O(a/p)$. This can be used to update the inverse directory in time $O(m/p)$. The membership list (and the weights associated with it) is updated by moving the member lists of inactivated supernodes in time $O(a/p)$

Let $u_i$ be the number of times node $i$ changes supernode membership. The last discussion shows that the total amount of time spent while executing step (g) is $O(\frac{e}{p} + \frac{1}{p}\sum_{i=1}^{n} u_i)$.

Since smaller supernodes are merged into larger ones, the size of the last supernode node $i$ belongs to is at least $2^{u_i}$. When the last merge is performed we have more than $n/p$ components. This implies the inequality

$$\sum_{i=1}^{n}\frac{1}{2^{u_i}} > \frac{n}{p} .$$

The maximum of $\sum_{i=1}^{n} u_i$ under the above constraint is equal to $n\ lg\ p$. Thus

$$\sum_{i=1}^{n} u_i < n \log p .$$

Hence, the total time spent performing step (g) is $O(\frac{e}{p} + \frac{n \log p}{p})$.

It follows that the total time taken by the algorithm is $O(\frac{e}{p} + \frac{n \log p}{p} + p^{1+\epsilon})$.

**Theorem 5.1:** A spanning forest for a graph with $n$ nodes and $e$ edges can be computed by $p < n/2$ processors in the EREW model in time

$$O(\frac{e}{p} + \frac{n \log p}{p} + p^{1+\epsilon}).$$

and space

$$O(pn + e) .$$

**Corollary 5.2:** The connected components of a graph with $n$ nodes and $e$ edges can be computed with $p < (n+e)/2$ processors in the EREW model in time $O(\frac{n+e}{p}\frac{\log(n+e)}{\log((n+e)/p)})$ and space $O(pn+e)$.

### 5.1. Biconnected Components

Tarjan and Vishkin [14] developed a parallel algorithm to compute the biconnected components of a connected graph. Their algorithm, however, required that the graph be dense, the input already be in the form of an adjacency list, and that the model of parallel computation allow concurrent reads and writes. Given our algorithms to compute the spanning forest of a graph as well as the ability of construct preorder and postorder numberings and lists of a tree, we can use their method but improve the result:

**Corollary 5.3:** The biconnected components of a graph can be computed in $O(\frac{e}{p} + \frac{n \log p}{p} + p^{1+\epsilon})$ time, provided $p \leq n$.

**Proof:** The algorithm of Tarjan and Vishkin requires the computation of a spanning tree for the graph, the computation of the preorder number of each node in this spanning tree, and the solution of several tree recurrences. We can perform each of these operations within the claimed time bound. □

### 5.2. Minimum Spanning Tree

The spanning forest algorithm can be modified to give a minimum spanning tree algorithm. A sequential algorithm for minimum spanning tree merges supernodes iteratively. At each iteration a supernode is chosen; the least cost edge outgoing this supernode is used to merge it with another supernode. The order the supernodes are chosen is arbitrary (see [3]).

We can merge supernodes in parallel provided that the merging is consistent with some serial execution of the algorithm above. Let $G_s$, the supernode graph, and $G_f$, the spanning forest graph, be defined as in the previous algorithm. A general parallel algorithm that finds a minimum cost spanning tree for a connected graph $G = <V,E>$ has the following form.

```
General parallel algorithm for MST
$G_f = <V, empty>$; $G_s = G$;
while $G_s$ has more than one node do
begin
    1. pick least cost outgoing edge from each node of $G_s$;
       let $U$ be the subgraph of $G$ containing these edges
       ($U$ is the disjoint union of unicycular graphs);
    2. delete from each cycle of $U$ an edge with largest
       cost; let $F$ be the resulting graph ($F$ is a forest);
    3. add the edges of $F$ to $G_f$;
    4. combine supernodes of $G_s$ that belong to the same
       tree of $F$ into one supernode
end
```

The number of supernodes is at least halved at each iteration, so that at most $\lg n$ iterations are performed.

We implement this general algorithm using data structures similar to those used for the spanning tree algorithm: We keep an adjacency lists representation of $G_s$, and represent $G_f$ by marking edges in the adjacency list of $G$. We assume that $p < n, e$.

(1) A least cost edge is picked in each adjacency list of $G_f$ by running a product broadcast algorithm on the lists of edges. This can be done in time $O(\frac{e}{p}\frac{\log e}{\log(e/p)})$.

(2) A trivial modification of the algorithm of Theorem 4.3 can be used to delete from each cycle of $U$ an edge of highest cost (rather than an edge with least index, as done in the original algorithm). This is done in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$.

(3) The new edges can be added to $G_f$ in time $O(e/p)$.

(4) A supernode is selected from each tree of $F$, and each node of the tree is marked with the label of this supernode, by running a product broadcast algorithm in time $O(\frac{n}{p}\frac{\log n}{\log(n/p)})$. The edges can be now updated to point to the new supernodes in time $O(\frac{e}{p}\frac{\log e}{\log(e/p)})$. This is done by computing the composition of two mappings: the mapping that maps an edge to the old incident nodes, and the mapping that maps these nodes to the new supernode they belong to. A new adjacency lists representation is built from these updated edges in time $O(\frac{e}{p}\frac{\log e}{\log(e/p)})$. While the new list is created self-loops can be deleted.

Each iteration takes time

$$O(\frac{e}{p}\frac{\log e}{\log(e/p)} + \frac{n}{p}\frac{\log n}{\log(n/p)}) .$$

Since there are at most $\lg n$ iterations we obtain

**Theorem 5.4:** A minimum cost spanning tree of a connected graph can be computed with $p \leq e, n$ processors on an EREW machine in time

$$O(\frac{(e+n)\log n}{p}\frac{\log(e+n)}{\log((e+n)/p)}) .$$

**Note:** This algorithm is efficient relative to Kruskal's algorithm provided that $p = O((e+n)^{1-\epsilon})$.

A minimum cost spanning forest for a general graph can be computed withing the same time bounds: the algorithm is modified so that supernodes with no outgoing edges are not visited. This is done by packing the list of nodes at each iteration.

## 6. CONCLUSION

Many simple and fast serial algorithms are often hard to parallelize. In many cases there is enough work that can be performed in parallel, but the challenge is to ensure that the processors do not conflict when performing this work, and that different processors do not replicate the same computation. The problem is harder when sparse structures are handled: If a compact data representation is used then the data layout is irregular, and it is hard to distribute work efficiently among processors. If, on the other hand, a regular data structure is used then superfluous work is performed.

We have presented techniques for working with sparse, irregular structures, and used these techniques to solve several important graph problems. We believe these techniques are generally applicable to other sparse problems. We still do not know whether large, extremely sparse graph problems can be solved efficiently, i.e. when $p << n$ and $e = \Theta(n)$.

**Abstract** -- We present a fast parallel algorithm for computing the dominators of a directed acyclic graph. The model of computation used is a parallel random access machine which allows simultaneous reads but prohibits simultaneous writes into the same memory location. Let $P_t(n)$ be the processor complexity of computing the transitive closure of an n-vertex directed acyclic graph on this model. Our algorithm for computing the dominators requires $O(\log^2 n)$[†] time using $O(P_t(n))$ processors. The only known parallel algorithm for this problem [6] requires $O(nP_t(n))$ processors. Our algorithm therefore improves the processor complexity of this algorithm by a factor of n, but has the same time complexity.

## 1. Introduction

Computing the dominators of a directed acyclic graph (DAG) is a very important code optimization step in compilers (see [2] for details). Consequently, this problem has attracted widespread attention and several excellent sequential algorithms have been developed for it (see [1]). Of late, growing interest in parallel computation has led to a proliferation of parallel algorithms for graph problems on a model of synchronous parallel computation [6, 7]. Surprisingly, despite the importance of the dominator problem the only known parallel algorithm for it is due to Savage [6]. This algorithm computes dominators using a parallel random access machine which allows simultaneous reads but prohibits simultaneous writes into the same memory location. We refer to this model as R-PRAM. A powerful variation of this model that allows simultaneous writes into the same memory location by more than one processor, is referred to as W-PRAM.

Let $G = (V, E)$ be a DAG rooted at r, and $|V| = n$, and $|E| = m$. We say that vertex i is a *dominator* of vertex j if i is on every path from r to j. For each vertex k, Savage first constructs a graph $G_k$, by deleting from G all edges leaving k. Next, the transitive closure of each of these graphs is computed in parallel. Let $G^*$ and $G_k^*$ denote the transitive closures of G and $G_k$ respectively. Dominators are then computed by using the simple observation that if i is reachable from r in $G^*$ and not in $G_k^*$, then k is a dominator for i. Savage's algorithm requires $O(\log^2 n)$ time and uses $O(nP_t(n))$ processors, where $P_t(n)$ is the processor complexity of computing the transitive closure. The two known parallel algorithms for doing so are due to Hirschberg [4] and Chandra [3], and require $O(n^3/\log n)$ and $O(n^{2.81}/\log n)$ processors respectively.

In the following section we will describe our algorithm for computing the dominators on a R-PRAM. Our approach is radically different from both Savage's as well as those used in sequential algorithms. The time complexity of our algorithm is $O(\log^2 n)$, and it uses $O(P_t(n))$ processors. Observe here that the processor requirement our algorithm has decreased by a factor of n over Savage's algorithm.

It is interesting to note that computing the transitive closure seems to be an important step in parallel algorithms for various properties of directed graphs, and hence their processor complexities are determined by that of the transitive closure algorithm. Our algorithm does achieve this bound for processor complexity. This is similar to computing properties of undirected graphs in parallel, where the processor complexities are determined by the connected component algorithm [7].

## 2. Preliminaries

We begin with a review of graph-theoretic terms.

Let $G=(V,E)$ denote a *graph* where V is a finite set of vertices and E is a set of pairs of vertices called *edges*. If the edges are unordered pairs then G is *undirected* else it is *directed*. Throughout this paper we assume that V consists of the set of vertices $\{1,2,...,n\}$ and $|E|=m$. We denote the undirected edge joining the vertices u and v by (u,v) and the directed edge from u to v by $<u,v>$. An *adjacency* matrix A of G is an $n \times n$ boolean matrix such that $A[u,v]=1$ if and only if $(u,v) \in E$. A *directed path* in G joining two vertices $i_0$ and $i_k$ is defined as a sequence of vertices $(i_0,i_1,i_2,..i_k)$ such that all of them are distinct and for each $0 \leq p < k$, $<i_p,i_{p+1}>$ is an edge of G. An undirected path is defined similarly. If $i_0 = i_k$ then the path is called a *cycle*. A *directed acyclic graph* (DAG) has no cycles. We denote a directed path from u to v by $[u \rightarrow v]$. We say that an undirected graph G is *connected* if for every pair of vertices u and v in V, there is a path in G joining u and v. A *tree* is a connected undirected graph with no cycles in it.

[†] Throughout this paper, we use log n to denote $\lceil \log_2 n \rceil$

A *rooted* directed tree has a distinguished vertex called *root* from which every other vertex is reachable via a directed path. We say that vertex u is an *ancestor* of vertex v if u is on the path from the root to v. The father of a vertex is its immediate ancestor. A *descendant* of a vertex is defined similarly. The *lowest common ancestor* (LCA) of vertices x and y in T is the vertex z such that z is a common ancestor of x and y, and any other common ancestor of x and y in T is also an ancestor of z in T.

A directed graph is *rooted* at r if there is a path from r to every vertex in V. For the rest of this paper, without loss of generality we shall assume that G is a directed acyclic graph rooted at r. We say that vertex i is a *dominator* of vertex j if i is on every path from r to j. In particular, for every i in V, r and i are dominators of i. Dominators exhibit transitivity, that is, for vertices i,j and k in V, whenever i is a dominator of j and j is a dominator of k, then i is a dominator of k. Therefore it is easy to see that the set of dominators of a vertex j can be linearly ordered by their order of occurrence on a path from r to j. The dominator of j closest to j (other than j) is called the *immediate* dominator of j. It follows from the definition that immediate dominator of every vertex is unique. We can now express the dominator relation as a directed tree $T_d$ rooted at r called the dominator tree. If u is the immediate dominator of v then <u,v> is an edge of $T_d$. Note now that i is a dominator of j if i is an ancestor of j in $T_d$.

The transitive closure matrix $A^*$ is a boolean matrix such that $A^*[i,j] = 1$ if there is directed path from i to j in G, else $A^*[i,j] = 0$. For completeness, we first describe the parallel algorithm for the transitive closure.

It has been observed in [4] that the transitive closure of a directed graph be computed in $O(\log^2 n)$ time on a R-PRAM by straightforward parallelization of the known sequential algorithm that is based on repeated multiplication of the adjacency matrix. In this parallel algorithm (see Algorithm 2.1 below) *and* and *or* operations replace multiplication and addition operations of an inner product step. We refer to this as the *and-or* multiplication of two matrices. The algorithm initializes the transitive closure matrix $A^*$ to the adjacency matrix A and then performs (log n) iterations of the and-or multiplication of $A^*$ by itself. The matrix DD is used as temporary storage for clarity.

```
// All steps involving i and j are executed for all i, j,
$1 \leq i \leq n$ and $1 \leq j \leq n$ //
1.   $A^*[i,j] := A[i,j]$     //Initialize//
2.   for t:=1 to log(n-1) do
         2a.  $DD[i,j] := \overset{n}{\underset{x=1}{or}} \{ A^*[i,j], A^*[i,k] \text{ and } A^*[k,j] \}$
2b.       $A^*[i,j] := DD[i,j]$
```

Algorithm 2.1

**Lemma 2.1:** The above algorithm computes the transitive closure $A^*$ in $O(\log^2 n)$ time using $O(n^3/\log n)$ processors.

**Proof:** The proof is immediate from the steps (1) and (2) of Algorithm 2.1. If Chandra's [3] parallel algorithm for matrix multiplication is used in step (2a), then the processor complexity of this algorithm is $O(n^{2.81}/\log n)$. Throughout this paper we refer to the processor complexity of this algorithm as $O(P_t(n))$. □

We now describe our algorithm for computing dominators.

## 3. The Algorithm

In order to compute the dominator tree we first construct a spanning tree for G that is rooted at r. We then compute the set of dominators for each vertex in a matrix DOM such that DOM[i,j] = 1 if i is a dominator of j otherwise DOM[i,j] = 0. The computational steps are as follows.

1. Compute the transitive closure matrix $A^*$ for G. By Lemma 2.1, this computation requires $O(\log^2 n)$ time and uses $O(P_t(n))$ processors.
2. Construct a directed spanning tree $T_s$ from the adjacency matrix A and the transitive closure matrix $A^*$. This is done by specifying the father of each vertex i, the smallest vertex j such that <j,i> is an edge of G. This selection can be done in O(log n) time by assigning n processors to each vertex. Since there are n vertices in G, we need $n^2$ processors for this step.
3. For every vertex, mark all its ancestors in $T_s$ as its dominators. That is, set DOM[i,j] = 1, if i is an ancestor of j, else set DOM[i,j] to 0. Ancestor computation can be done in O(log n) time using $O(n^2)$ processors (see [7]). Initialization of the matrix DOM requires constant time and $O(n^2)$ processors.
4. For every vertex v, consider the non-tree edges incident on it. For all such edges <x,v>, compute the lowest common ancestor of x and v in $T_s$. Among these LCAs, select h(v) = LCA(u,v) be the vertex closest to the root r (h stands for highest). The lowest common ancestors for all vertex pairs can be computed in O(log n) time using $O(n^2)$ processors (see [7]). For each vertex v, h(v) can be determined in O(log n) time using n processors.
5. Now, the edge <u,v> provides a path from h(v) to v passing through u, other than the path present in $T_s$. Therefore all vertices on the path [h(v)→v] are not dominators of v. For all such vertices j, set DOM[j,v] = 0. Since the number of vertices on any path is at most n, we need $O(n^2)$ processors to do this step in constant time.
6. For every vertex y, if i is not a dominator of y then i is not a dominator of any vertex reachable from y. Therefore for every vertex j, i is not a dominator for j if there exists at least one vertex x, such that i is not a dominator for x and j is reachable from x. Therefore set DOM[i,j] = 0, if

$$\mathop{or}_{x=1}^{n} \{ (\text{DOM}[i,x] = 0) \text{ and } (A^*[x,j] = 1) \}$$

evaluates true. This computation is equivalent to *and-or* multiplication of DOM and $A^*$. Therefore this step requires O(log n) time and $O(P_t(n))$ processors.

This completes the description of our algorithm for dominators. We now provide the proof of its correctness.

**Lemma 3.1:** If vertex u is not a dominator of vertex v then at the end of our algorithm DOM[u,v] will be set to 0.

**Proof:** If u is not on the path from r to v in $T_s$ then DOM[u,v] is set to 0 in step 2 of our algorithm and it stays 0 for all following steps. If u is on the path from r to v in $T_s$ but it is not a dominator of v then there must exist a path from r to v that does not pass through u. There are two types of paths to be considered. First, v has a non-tree edge <x,v> incident on it such that u is on the path from the LCA(x,v) to v. In step 5 of our algorithm, we select h(v) to be the closest LCA to the root r. Therefore u must be on the path [h(v)→v], and DOM[u,v] will be set to 0. Second, v is reachable from some vertex y such that y has a non-tree edge incident on it, providing another path to y from r that does not use u. In step 5 of our algorithm DOM[u,y] will be set to 0, and since v is reachable from y, in the next step, DOM[u,v] will be set to 0. Hence the Lemma. □

**Theorem 3.1:** The above algorithm computes the dominator matrix DOM in $O(\log^2 n)$ time using $O(P_t(n))$ processors.

**Proof:** The correctness of our algorithm is proved in Lemma 3.1 and the processor and time complexities are immediate from steps 1 to 6 of our algorithm. □

Given the matrix DOM, the dominator tree can be constructed by determining the immediate dominator for each vertex. Recall that the immediate dominator of a vertex is unique, and it is the closest dominator of that vertex. In the dominator tree, the closest dominator of a vertex is its father. The steps for construction of the dominator tree are as follows.

1. For every every vertex i, count the number of dominators of i by summing the entries in the $i^{th}$ column of DOM. This summation requires $n^2$ processors and O(log n) time.
2. For every vertex i, determine the immediate dominator of i. If i has d dominators then the immediate dominator of i is a dominator of i that has (d-1) dominators. This can be done in constant time using $n^2$ processors.
3. The father of every vertex i in the dominator tree is its immediate dominator. The root of the tree is r.

The above procedure constructs the dominator tree from the matrix DOM in O(logn) time using $n^2$ processors. The time and processor complexities are immediate from the steps given above, and the correctness is direct from the following lemma.

**Lemma 3.2:** Let d be the number of dominators of i. A dominator j of i is the immediate dominator of i iff j has (d-1) dominators.

**Proof:** The number of ancestors of any vertex in the dominator tree is equal to its dominators. Since the dominator tree is unique, the immediate dominator, which is the father of i in the dominator tree, must have (d-1) dominators. □

## 4. Conclusions

We have described an $O(\log^2 n)$ time algorithm for dominators of a DAG that uses $O(P_t(n))$ processors, where $P_t(n)$ is the processor complexity of computing the transitive closure of a directed graph. This improves the processor complexity of Savage's [6] algorithm, by a factor of n. Finally, it is worth mentioning that the algorithm presented here would require O(log n) time on a W-PRAM that allows simultaneous writing in the same memory location by more than one processor. The only step in our algorithm that requires $O(\log^2 n)$ time is computing the transitive closure matrix. All other steps require O(log n) time. Since the transitive closure can be computed in O(log n) time on a concurrent write model [5], our algorithm would therefore require O(log n) time on a W-PRAM.

# A Graph Model for Parallel Computations Expressed in the Computation Structures Language*

Ashok K. Adiga & James C. Browne
Department of Computer Science
University of Texas at Austin,
Austin, Texas 78712

## Abstract

The design of parallel computations involves numerous decisions whose effect on execution efficiency is not immediately clear. A Petri Net based model is presented which has the representational power to model a wide range of computations while retaining the flexibility to alter configuration parameters with ease. The model can be used to predict optimal values for configuration parameters such as degree of parallelism and task granularity on the efficiency of the computation.

## 1 Introduction

This paper describes a model for representing and evaluating the performance of parallel computations. An implementation of the model is being used to analyze the behavior of programs expressed using the Computation Structures Language (CSL), a language designed and implemented at the University of Texas.

The model can be used as a vehicle for studying the configuration space of a computation. A parallel computation [1] consists of a collection of programs (called *tasks*) and the specification of dependencies between them. The dependencies could be simple synchronization or sequencing relationships, constraint relationships such as mutual exclusion for shared resources, or communication relationships signifying data transfer between two or more tasks. The performance of a parallel computation is therefore architecture dependent, since different architectures would support these dependencies with varying degrees of efficiency. The basis for a model for parallel computations is to be able to predict the efficiency of execution of a parallel computation on a given architecture, and to study the effect of varying different configuration parameters of the computation. The configuration space of interest includes the following parameters:

- shared memory/ message model: the interaction between the tasks of a computation can be specified using a message model, a shared memory model, or a mixture of the two. This choice is based on the support provided by the host architecture and the volume and size of the information being exchanged.
- granularity of a unit: the efficiency of the computation is directly dependent on the size of each schedulable unit of computation. Larger units would usually reduce the amount of parallelism possible, while smaller units could entail additional overheads of data movement.
- computation structure: this includes the specification of synchronization and sequencing of the units composing the computation.
- underlying or host architecture: all the earlier parameters are implicitly dependent on the choice of the host architecture.

The model described here was initially designed to represent computations specified using the Computation Structures Language (CSL) ([2], [3]). CSL is a language that allows specification and programming of multitype, multiphase parallel computations. It supports dynamic structuring of computations through multiple phases, each of which may display different types and degrees of parallelism and differing requirements for sharing of data and interprocess communication. The model is a direct abstraction from CSL. Each instance of a computation expressed in CSL has an equivalent representation using our model. CSL programs are directly derivable from the Petri Net model and vice versa.

The proposed model is based on Petri Nets with extensions to allow the representation and performance evaluation of parallel computations. The extensions are predicated upon a performance evaluation viewpoint rather than a theoretical view of Petri Nets. Performance statistics for a computation are achieved by first expressing the computation in terms of the model, and then simulating the behavior of this net instance. The choice of a Petri Net based model allows most of the communication and synchronization primitives of the computation to be directly modeled. Any non-determinacy in the computation can also be easily captured in the model. Extensions are provided to allow dynamic structuring and scalability of the modeled computation.

The rest of this paper is organized as follows. Section 2 gives a brief introduction of Petri Nets and highlights some of the previous work in this area. Section 3 contains the definition and details of the proposed model, while the implementation is briefly described in Section 4. The

* This research was sponsored by the Department of Energy under grant number DE-AS05-81ER10987 and grant number DE-FG05-85ER25010.

utility of the model is demonstrated by means of an example in Section 5.

## 2 Petri Nets

Informally, a Petri Net [4] consists of two sets of vertices (called *places* and *transitions*) in a bipartite, directed graph. Arcs connect places to transitions or transitions to places. If an arc exists from a place to a transition, the place is an *input* place for that transition. Similarly, if an arc exists from a transition to a place, the place is an *output* place for that transition. Places can contain *tokens*. One interpretation given to Petri Nets is that places represent conditions, transitions represent actions, and the presence of a token in a place represents the presence of that condition. The set of input places for a transition signifies the conditions that should be present for that event to occur. The occurrence of an event is represented by the *firing* of a transition. For a transition to fire, all its input places must contain tokens, and upon firing, the transition removes one token from each of its input places and puts one token each in its output places. The state of the net is simply the distribution of tokens in the places of the net. Petri Nets are represented graphically as shown in Fig. 1 with the places shown as circles, the transitions as bars, and the tokens as dots.

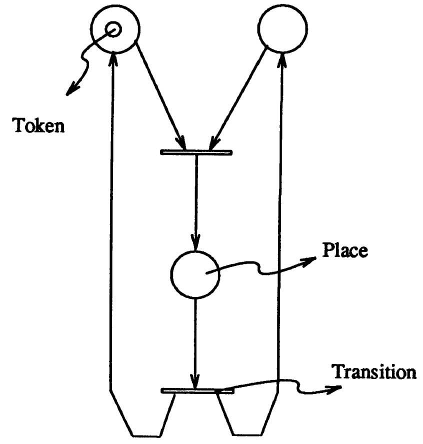

**Figure 1:** A Petri Net

Extensive work has been done to include timing information in Petri Nets. The most common addition is that of associating delays with transitions. When a transition begins to fire, it removes its input tokens as before, but places tokens in its output places only after a period of time equal to its delay value. E-nets [5] had fixed delays associated with transitions, Timed Petri Nets [6] allowed arbitrary delays; while extensions to their model in [7] allowed state dependent delays. While these models are suitable for modelling parallel systems, they lack the ability to model data-dependent control flow with ease.

An extension was proposed by Keller [8] to help model this control flow. His model included a set of program variables. Each transition had a transition procedure and predicate based on the program variables. In addition to requiring tokens on all input places, a transition was now considered enabled only if its predicate was true. Also, when a transition fired, its procedure was executed, thus altering the program variables. This model was designed for verifying correctness properties of parallel algorithms, and did not include the notion of time.

The model proposed in this paper attempts to combine these ideas, while also including additions to support features such as dynamic structuring and scalability of computations.

## 3 PCM: A model for parallel computations

This section contains a description of the model, along with some details of the simulation procedure used to do the performance evaluation.

### 3.1 Definition

The Parallel Computation Model (PCM) is defined by the three-tuple

$$\mathrm{PCM} = (\ \mathrm{PN},\ \mathrm{V},\ \mathrm{TA}\ )$$

where

PN = (P, T, I, O), a Petri Net, where
  $P = \{p_1,\ldots,p_n\}$, a set of places, $n \geq 0$
  $T = \{t_1,\ldots,t_m\}$, a set of transitions, $m \geq 0$
  $I \subseteq P\mathrm{x}T$, the transition input function
  $O \subseteq T\mathrm{x}P$, the transition output function
where P and T are disjoint

$V = \{v_1, v_2, \ldots, v_r\}$, a set of program variables

TA = is a three-tuple $<\Pi,\ \Phi,\ T>$;
  and
    $\Pi(V) = \{\pi_1(V),\ \pi_2(V),\ldots,\pi_m(V)\}$,
      a set of predicates,
    $\Phi(V) = \{\phi_1(V),\ \phi_2(V),\ldots,\phi_m(V)\}$,
      a set of procedures,
    $T(V) = \{\tau_1(V),\ \tau_2(V),\ldots,\tau_m(V)\}$,
      a set of delays.

The basic underlying structure is the standard Petri Net PN. In addition, the model allows a set of program variables (V), and attributes associated with each transition.

Each transition $t_i$ in the model defined above has a corresponding predicate $\pi_i(V)$ and a transition procedure $\phi_i(V)$. The predicates are defined on program variables, and are used to enable transitions under the modified firing rules. The transition procedures also operate on elements of V and can be used to modify them. The function $\tau_i(V)$ specifies the delay associated with transition $t_i$, and can also be a function of the set of program variables.

### 3.2 Firing Rules

The definition of the model is completed by specifying the modified firing rules. Each place in the net is conceptually divided into an *enable* and a *hold* region (Fig. 2). This division helps in describing the behavior of the net. A transition can be in one of three states: ***disabled***, ***enabled***, and ***firing***. The rules governing transition state changes are as follows.

- A disabled transition $t_i$ is enabled if each of its input places contains at least one token in its enable region and the predicate $\pi_i(V)$ corresponding to the transition is true.
- An enabled transition $t_i$ enters the firing state by moving one token in each of its input places from the enable to hold region. If this transition shares input places with other enabled transitions, they must satisfy rule 1 to remain enabled, failing which they become disabled.
- A transition $t_i$ remains in the firing state for a period of time specified by its delay function $\tau_i(V)$. A the end of this period, it removes one token from the hold region of each of its input places, and places a token in the enable region of each output place, and executes its associated procedure $\pi_i(V)$. It then returns to the disabled state.

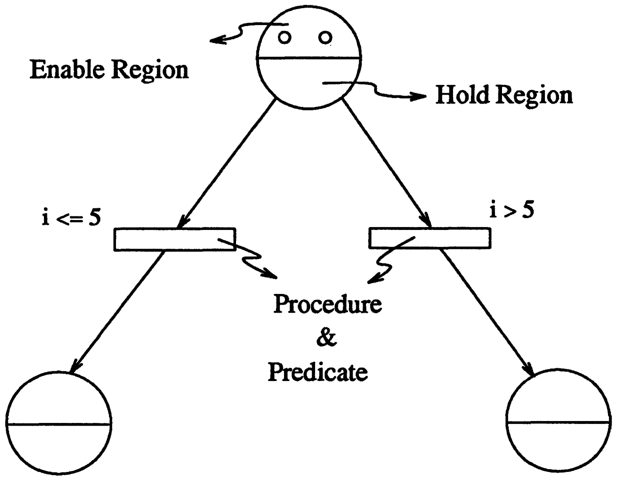

**Figure 2:** Execution of Net

Transition firings are no longer instantaneous, as in the case of standard Petri Nets. When a transition starts firing, it removes its enabling tokens , which can no longer contribute to the firing of any other transition. Tokens appear on the transition's output places only after a certain delay. There are two ways in which the firing of a transition can effect other transitions. When a transition starts firing, the removal of tokens from its input places could cause other enabled transitions to become disabled. Also, when a transition completes firing, it modifies the marking as well as the state of the program variable vector, thereby causing other transitions to be either enabled or disabled.

Transition predicates, procedures and program variables provide the means to represent standard looping and branching constructs with ease. Figure 2 shows the branching construct where the enabling of the two transitions is dependent on the current value of the program variable *i* - both transitions can not be enabled simultaneously.

The state of this system at any time is given by the current marking along with the vector of program variables and the vector of 'remaining firing times' for the transitions. The marking expresses the 'control' state, while the program vector specifies the 'data' state. If a transition is in the process of firing, its remaining firing time specifies the period of time after which firing will be complete. If the transition is not firing, its RFT is zero.

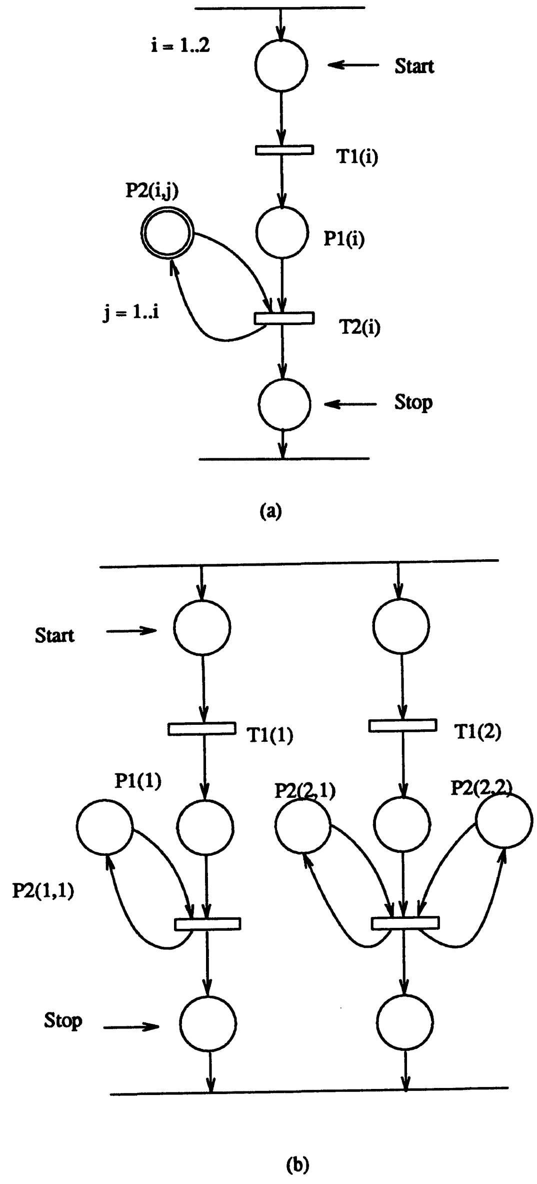
### 3.3 Hierarchical Modelling

PCM supports hierarchical modelling by allowing transitions to be designated as subnets. A subnet transition is constrained to begin and end with special places called the start and stop places (Figure 3a). When the subnet transition begins firing, a token is placed in its start place, and the subnet becomes active. When a token appears in the stop place, the subnet ceases to be active. Only transitions in active subnets can fire..

In addition, subnets can be parameterized in two ways. A subnet can have a set of parameters which cause the entire subnet to be replicated upon its activation. Subnets can also contain special places which have parameters associated with them. When the subnet becomes active, these places, along with their connecting arcs, are expanded to produce simple places. In Figure 3a, P2(i,j) is a parameterized place with j ranging from 1 to i. When this net becomes active, all parameters are applied to the nodes of the net, resulting in the net shown in Figure 3b. Dynamic structuring of the graph can be achieved by using program variables as parameter ranges.

## 4 Model Behavior

The PCM simulator package has been implemented in C on a SUN workstation. A menu-driven graphics front-end is provided to create and modify net instances. The current implementation supports a wide range of net attributes. Transition delays can be specified either as instantaneous (zero delay), fixed delay, or random based on exponential or uniform distributions. In addition, the delays can be expressed as functions of the program variables. The transition procedures and predicates are specified as standard C functions, which are precompiled. Places have types associated with them to specify the kind of performance values expected from them. For example, a place modelling a queue would yield figures on throughput, mean wait and service times, etc. The length of the simulation run is specified by the user. The simulation proceeds by moving time-stamped tokens through the net and collecting timing



(a)

(b)

**Figure 3:** Subnets

information at the places. Alternately, a state history of the execution of the net is maintained, which can be used to determine the sequence of events in the computation. The simulator has been validated using analytical results obtained using the Stochastic Petrinet Analyzer [9].

## 5 An Example

In this section, the utility of the model is demonstrated by means of an example. The computation, suggested by J. Dongarra and D. Sorensen of Argonne National Laboratories, is the solution of a lower triangular matrix:

$$Tx = b$$

where T is an nxn lower triangular matrix, x and b are n-vectors. The algorithm used is to decompose the matrix into blocks as illustrated in Figure 4. There are three types of tasks in the computation: *init*, *solve* and *matvect*. The tasks are described next:

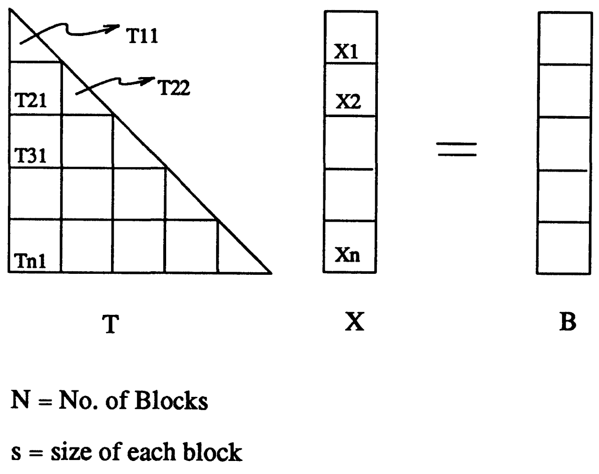


**Figure 4:** A Triangular Solver

init(i) initializes one block row of the system.

solve(i) triangular solver for the *i*th triangular diagonal block. It solves for $x_i$ in the system:

$$T_{ii}x_i = b_i$$

This can be done only after all matvect tasks for row i have completed. Observe that solve(1) (solve for block 1) can begin immediately after initialization, and does not depend on any matvect tasks.

matvect(j, i) executes the transformation

$$T_{ji}x_i - b_j \text{ --> } b_j$$

on the *j*th block in column i. This step can only be executed if solve(i) has been completed.

Figure 5 shows the CSL program which specifies the above computation. The CONSTRUCT statement contains declarations of the tasks, shared variables and communication channels involved in the computation. The declaration of Solve, for example, specifies N tasks Solve(1), Solve(2)...Solve(N). All Solve tasks are identical, and their compiled (object) code is found in file C2. A list of shared objects accessible to each task completes the specification of the Solve tasks. The Matvect tasks process the non-diagonal blocks of the matrix. Associated with each Matvect is a boolean task condition which is set after each execution of the task.

The program starts off N parallel streams, as denoted by the outer COBEGIN. Each parallel stream begins by executing a diagonal (solve) task first, and then all non-diagonal (matvect) tasks in that column in parallel (inner cobegin). The WAIT statement ensures that the execution of each solve task begins only after all matvect tasks in its row

```
JOB Triangle;

VAR N : integer;

BEGIN
  N := 4;
  CONSTRUCT
      TASKS
        Init(i)  : C1 [ T(i,j), X(i) ]
                  RANGE j = 1 to i,
                        i = 1 to N;
        Solve(i) : C2 [T(i,i), X(i) ]
                  RANGE i = 1 to N;
        Matvect(i,j) : C3[T(i,j), X(i), X(j)]
                       CONDITION C(i,j)
                  RANGE j = 1 to i-1,
                        i = 1 to N;
  END; { CONSTRUCT }

  WITH T(i,j), X(i) DO
    EXECUTE Init(i)  RANGE j = 1 to i,
                           i = 1 to N;

  COBEGIN
    ( // WAIT C(i,j) RANGE j = 1 to i-1;
         WITH X(i), T(i,i) DO
             EXECUTE Solve(i);
         COBEGIN
           (// WITH T(j,i), X(j) : X(i) DO
                  EXECUTE Matvect(j,i)
           ) RANGE j = i+1 to N;
         COEND
    ) RANGE i = 1 to N;
  COEND;
END.
```

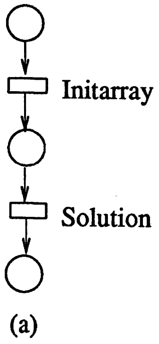
**Figure 5:** CSL Program for Triangular Solver

signal their completion by setting their task conditions. The statement:

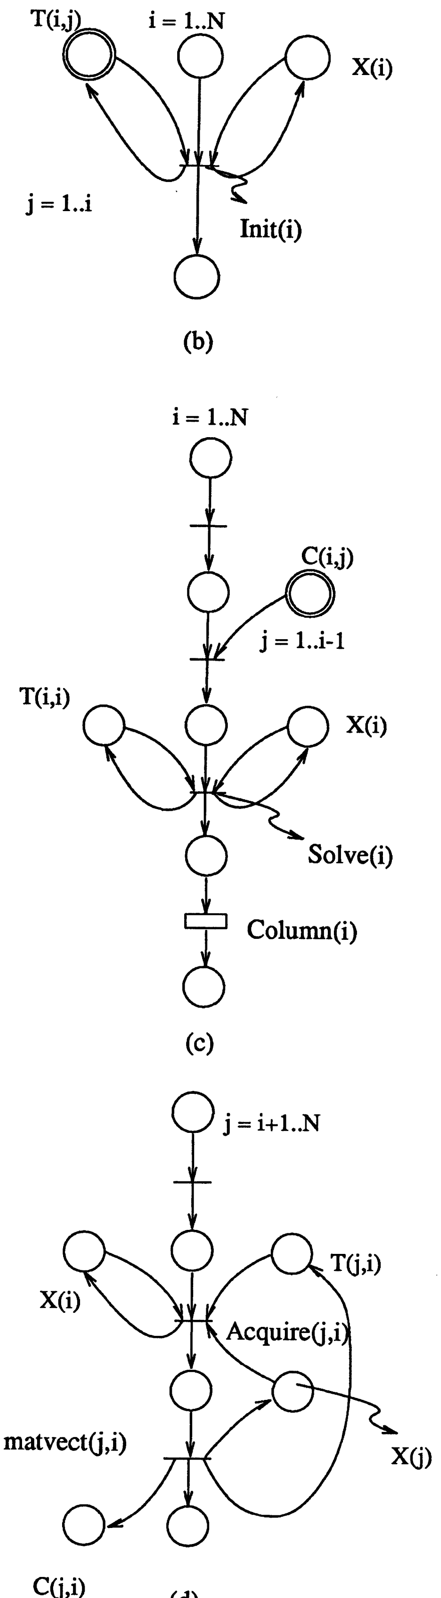
```
WITH T[j,i], X[j] : X[i] DO
   EXECUTE  Matvect (j,i);
```

specifies that the task matvect requires exclusive access to shared objects T[j,i] and X[j]; and wishes to use X[i] in read-only, or non-exclusive mode. Finally, the CSL program demonstrates the power of the RANGE statement as a construct for parameterizing the computation.

The equivalent representation of the computation in the PCM model, shown in Figure 6, consists of four subnets.



(a)



(d)

**Figure 6:** PCM solution

Figure 6(a) shows the top level decomposition of the computation into the initialization phase (Initarray), and the solution phase (Solution). *Initarray* (Figure 6(b)) models N parallel streams, with each stream containing one execution of Init. The place T(i,j) is parameterized, and is expanded when the subnet becomes active. For example, if i is 3, T(i,j) would be expanded to T(3,1), T(3,2) and T(3,3). The subnet *Solution*, shown in Figure 6(c) models the rest of the computation. Each solve task solve(i), requires exclusive access to T(i,i) and X(i), and can execute only after conditions C(i,1), C(i,2)..C(i,i-1) are set. After completion of solve(i), subnet *Column* is activated, which models the matvect task executions. The transition Acquire is used to gain exclusive access to shared objects T(j,i) and X(j), and non-exclusive access to X(i). The non-exclusive access is modelled here by merely copying the contents of X(i) into local memory. A more elaborate reader-writer scheme could be modelled by means of auxiliary program variables and appropriate transition predicates and procedures.

To calculate the delays in the model, the following architectural model is assumed. The system contains several independent processors, each with sufficient local memory. In addition, all processors can access a shared memory, and can set locks on parts of this memory. Access times are assumed to be equal for both local and remote accesses. The only overhead for remote accesses is for setting or releasing locks. Figure 7 shows the delays assumed for some operations. Also shown are delays associated with the transitions of the model, in terms of the size of each block.

The simulation results presented here are for a 48x48 system. The execution speed is measured for different values of N, the number of blocks. Figure 8 shows the various execution speeds as N is varied from 1 to 6. The structure of the computation is such that the parallelism is mostly contained in the concurrent executions of the matvects for a column. This explains the limited speedup when N is increased from 1 to 2. The small speedup that does appear seems to be due to the parallelism in the initialization tasks. As N is increased to 3 and 4, a substantial decrease in execution time is observed. Eventually, the bottleneck is due to conflicts for access to X(i) by all matvect tasks in column i.

| Operation | No. of Cycles |
|---|---|
| multiply + add (V) | 30 |
| acquire/release shared memory (c) | 10 |
| local store in memory (l) | 5/element |
| copy from shared memory (r) | 10/element |
| For block size s, | |
| matvect | $s^2V + 2c$ |
| Solve | $s^2V/2 + 4c$ |
| Acquire | rs + 4c |
| Init(i) for ith row | ls(s(i+1/2) + 1)<br>+ 2(i+1)c |

**Figure 7:** Delays associated with some operations

Using the powerful parameterization features provided in this model, the simulations can be repeated for various values of N with no changes to the net itself. The model is also capable of evaluating resource utilizations for communication channels and throughputs at various points in a computation, which can be used to determine bottlenecks in the computation.

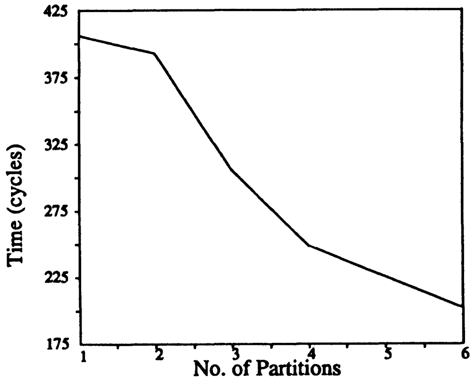


**Figure 8:** Execution Time vs No. of Partitions

## 6 Conclusions

In this paper, we have presented a model for representation and performance evaluation of parallel computations. In addition to modelling the algorithm behavior, the model incorporates features to study the execution overheads such as synchronization and communication delays. The model provides a vehicle for studying the configuration space of a given parallel computation, and deciding which configuration is most suitable for a given computation and architecture.

The parameterization mechanism described here leads to a powerful and compact representation which is extremely flexible. Dynamic graph structures can be represented using this parameterization scheme. Only small changes need to be made to a model instance to vary parameters like the granularity of a task or the degree of parallelism.

The model has been designed to provide a straight forward mapping from CSL programs to net instances. This mapping could be automated, providing a useful tool for analyzing and debugging CSL programs. A unique element of this modelling system is that it models the execution of programs, thus capturing the effects of different representations of algorithms. The Petri Net model is directly coupled to CSL constructs and vice versa.

*Abstract.* We show that a one-way two-dimensional iterative array of finite-state machines can recognize and parse strings of any context-free language in linear time. What makes this result interesting and rather surprising is the fact that each processor of the array holds only a fixed amount of information (independent of the size of the input) and communicates with its neighbors in only one direction. This makes for a simple VLSI implementation. Although it is known that recognition can be done on such an array, previous parsing algorithms require the processors to have unbounded memory, even when the communication is two-way.

## 1. Introduction

The parallel recognition of context-free languages by iterative arrays of finite-state machines was first considered in [11], where it was shown that context-free languages can be recognized by two-way two-dimensional iterative arrays in linear time. The construction in [11] is a parallel implementation of the well-known Cocke-Younger-Kasami (CYK) dynamic programming algorithm for recognizing the strings generated by a context-free grammar in Chomsky normal form [1]. Later in [10], the problem of computing the cost of an optimum binary search tree was shown to be solvable by a one-way two-dimensional array of unbounded-memory processors in linear time. It follows from the construction in [10] that context-free language recognition can also be done on a one-way two-dimensional iterative array (see, e.g., [3]). A recognition algorithm akin to the CYK algorithm is Earley's algorithm [1]. The advantage of the latter algorithm is that it does not require the context-free grammar to be in Chomsky normal form. A parallel implementation of Earley's algorithm was recently reported in [2]. Both recognition and parsing were considered, and detailed VLSI implementations were described. The structure of the iterative array implementation of the recognition algorithm is similar to that in [10] with each processor of the array being finite-state. However, the array implementation of the parsing algorithm required the processors to store and manipulate data which grow with the length of the input string being parsed. This is because of the way the parse is generated: the "indices" specifying the decompositions of the input string in the dynamic programming method are stored in the processors. Moreover, each processor must be capable of comparing index values, thus making the "control mechanism" (for transmitting and distributing data) of the array more complex. Thus, the parallel parser in [2] is not finite-state and its VLSI hardware implementation is not as simple as the one for recognition.

In this paper, we show that we can produce the parse without storing the "indices". In fact, we show that both recognition and parsing can be carried out on a one-way two-dimensional iterative array of finite-state machines (2DIA) in linear time. Because the array is finite-state, the processor's logic is simple and independent of the input size. This, together with the one-way communication, makes VLSI implementation simpler.

A 2DIA [4] is shown in Figure 1-(a). It consists of an n×n array of identical finite-state machines (nodes) that operate synchronously at discrete time steps by means of a common clock (not shown in the figure). The node at the upper right hand corner receives the serial input $a_1a_2 \cdots a_n\$$ beginning at time 0. The serial output $b_1b_2 \cdots b_k\$$ is observed from the node at the lower left hand corner, and is output beginning at time 2n-1. Thus, $b_i$ occurs at time 2n-2+i. (Note that all nodes generate outputs, but only the output of the node at the lower left hand corner is observed.) The $a_i$'s and $b_j$'s come from finite input and output alphabets $\Sigma$ and $\Delta$, respectively. Both input and output strings are terminated by a special endmarker \$, which is not in $\Sigma \cup \Delta$. We assume that, unlike the $a_i$'s, \$ is not "consumed" when read by the array, and is always available for rereading. The state and outputs of a node at time t are functions of its state and the states of its neighbors (or the external input in the case of the node at the upper right hand corner) at time t-1. At time 0, each node is in a distinguished quiescent state $q_0$, with its outputs set to the blank symbol $\lambda$. It remains in this state until one of its neighbors enters a non-quiescent state. The 2DIA has time complexity T(n) on input $a_1a_2 \cdots a_n\$$ if it outputs \$ after at most T(n) steps. Clearly, $T(n) \geq 3n-1$. We note that the 2DIA and the triangular array of Figure 1-(b) are equivalent. Clearly, the former can simulate the later. For the converse, the triangular array simulates in parallel the computations of the nodes that overlap when the 2DIA is folded along its diagonal. Our algorithms will be carried out on 2DIA's, since they are more convenient to use in our constructions. It is clear, however, that they can also be carried out on triangular arrays.

The 2DIA, being finite-state and one-way, is not so easy to program. Concurrency and synchronization of

* This research was supported in part by NSF Grant MCS 83-04756. O. H. Ibarra was also supported by a John Simon Guggenheim Memorial Foundation Fellowship.

processes are not easy to handle. Thus, for the proofs, we use an equivalent formulation of the 2DIA in terms of a restricted type of uni-processor sequential machine called 2DSM [7,8] (see Figure 2). The 2DSM consists of a finite-state control, with an input terminal from which it receives the serial input $a_1a_2 \cdots a_n\$$ and an output terminal from which the serial output $b_1b_2 \cdots b_k\$$ is observed. As in a 2DIA, we assume that \$ is not consumed when read by the machine and is always available for rereading. The 2DSM operates on a two-dimensional worktape of $n \times n$ cells. Initially, all cells of the worktape are set to $\lambda$. The 2DSM operates in sweeps as shown in Figure 3. A sweep begins with the machine in a distinguished start state $q_0$ and the read-write head (RWH) scanning the rightmost cell of the first row. The machine then reads an input symbol and scans the first row from right to left. For each cell scanned, the machine rewrites the cell, outputs a symbol, and changes state (except into $q_0$). When the machine has processed the leftmost cell, the RWH is reset to the rightmost cell of the next row in state $q_0$. The operation is repeated for all other rows. After scanning the bottom row, the RWH is reset to the rightmost cell of the first row to begin the next sweep. (Thus, a sweep begins at the rightmost cell of the first row and ends at the leftmost cell of the bottom row.) The RWH has the following capability: when scanning a cell in some row, it can also read (but not rewrite) the content of the cell directly above the cell currently scanned. The output symbols $b_1, \ldots, b_k, \$$ are the outputs produced by the leftmost cell of the bottom row. The 2DSM has sweep complexity S(n) on input $a_1a_2 \cdots a_n\$$ if it outputs \$ after at most S(n) sweeps. Clearly, $S(n) \geq n+1$.

In [7,8], the following result was shown:

**Theorem 1.** Let $T(n) \geq 3n-1$. If $M_1$ is a 2DIA with time complexity T(n), then we can effectively construct an equivalent 2DSM $M_2$ with sweep complexity $T(n)-2n+2$, and conversely.

Thus, we need only show the constructions on a 2DSM, since automatic conversion to the corresponding 2DIA is guaranteed by the constructive proof of this result.

## 2. Context-free Language Recognition and Parsing on a 2DIA

Our construction is based on the CYK algorithm [1]. The same techniques should apply to Earley's algorithm [1].

Let $G = (N, \Sigma, S, P)$ be a context-free grammar (CFG), where N and $\Sigma$ are finite nonterminal and terminal alphabets, respectively, $S \in N$ is the start symbol, and P is a finite set of productions (or rules) in Chomsky normal form. Thus, the productions in P are of the form $A \rightarrow BC$ or $A \rightarrow a$, $A,B,C \in N$ and $a \in \Sigma$. Let L(G) denote the language generated by G. For any string $x = a_1a_2 \cdots a_n$, $n \geq 1$ and $a_i \in \Sigma$, let $Q(i,j) = \{A \mid A \in N \text{ and } A \Rightarrow a_ia_{i+1} \cdots a_j\}$, $1 \leq i \leq j \leq n$. Then, $Q(i,i) = \{A \mid A \in N \text{ and } A \rightarrow a_i \in P\}$, $1 \leq i \leq n$, and $Q(i,j) = \bigcup_{i \leq k < j} Q(i,k) \cdot Q(k+1,j)$, $1 \leq i < j \leq n$, where $X \cdot Y = \{A \mid (\exists B,C)\ (B \in X, C \in Y, \text{and } A \rightarrow BC \in P)\}$. The CYK algorithm builds table Q by dynamic programming. Then, $x \in L(G)$ if and only if $S \in Q(1,n)$.

The above algorithm can be modified so as to also output a parse of x if $x \in L(G)$. This is accomplished by associating with each Q(i,j) another set R(i,j) containing "rules" of the form $[A \rightarrow BC]$ or $[A \rightarrow a]$, $A,B,C \in N$ and $a \in \Sigma$. The R(i,j)'s are computed as follows. Suppose that A becomes a member of Q(i,j), $i<j$, as a result of the rule $A \rightarrow BC$, $B \in Q(i,k)$ and $C \in Q(k+1,j)$, for some $i \leq k < j$. Then $[A \rightarrow BC]$ is in R(i,j). Similarly, if A becomes a member of Q(i,i) as a result of the rule $A \rightarrow a_i$, then $[A \rightarrow a_i]$ is in R(i,i). Note that, in fact, the Q(i,j)'s need not be computed, since they can be derived from R(i,j)'s. (Q(i,j) is simply the set of all nonterminal symbols appearing on the left-hand sides of rules in R(i,j).)

Figure 4-(a) gives an example of a CFG G. For input x = *baaba*, the table R of R(i,j)'s is shown in Figure 4-(b) (ignore the *'s for now). Observe that *baaba* is in L(G) since R(1,5) contains at least one rule whose left-hand side is S. The same table, with the entries relabeled, is shown in Figure 4-(c).

If $x \in L(G)$, a parse tree of x can be obtained by backtracking. That is, one starts by choosing from R(1,n) a rule of the form $[S \rightarrow AB]$. Then, for $k = 1, \ldots, n-1$, R(1,k) and R(k+1,n) are searched for rules of the form $[A \rightarrow CD]$ and $[B \rightarrow EF]$, respectively. (If the search is successful for more than one value of k, one is chosen arbitrarily.) The process is repeated for each newly found successor until the R(i,i)'s are reached. Figure 4-(d) gives a parse tree of the string x = *baaba*, obtained by backtracking on the table R of Figure 4-(b). In each node, the number below the rule represents the set from which the rule was chosen. (The chosen rules are also marked * in Figure 4-(b).) The parse itself can be specified in several ways. For our purposes, we shall output the *right parse* of the input string, which is obtained by traversing the parse tree in reverse preorder. For the given example, the right parse is $[S \rightarrow BC]$, $[C \rightarrow AB]$, $[B \rightarrow CC]$, $[C \rightarrow a]$, $[C \rightarrow AB]$, $[B \rightarrow b]$, $[A \rightarrow a]$, $[A \rightarrow a]$, $[B \rightarrow b]$. Thus, the right parse is obtained from the sequence of nodes 15-14-12-5-8-4-3-2-1.

We now show that the above parsing algorithm can be carried out on a 2DSM operating in O(n) sweeps. It then follows that the corresponding 2DIA also operates in linear time. The construction is complicated by the fact that the 2DSM is finite-state, since in this case it cannot store numbers whose values grow with n. As we shall see, this restriction makes the generation of the parse quite difficult. To simplify the presentation, we only illustrate the construction by means of an example, using table R of Figure 4-(b).

Let M be a 2DSM. Without loss of generality, assume that M has a worktape consisting of $3n \times 3n$ cells. (The worktape can always be reduced to $n \times n$ by simulating a $3 \times 3$ subarray in one cell.) Each row of the worktape is divided into three tracks. M operates in several phases: Table Construction, Tape Reversal, Regeneration, Parse-Tree Extraction, and Outputting of the Right Parse.

**Table Construction.** M starts by constructing table R on the first track of the worktape. The operation of M during this phase is a modification of that given in [8] (where only context-free language recognition was considered). The idea is to compute the entries on the ith diagonal of the table (Figure 4-(c)) during the ith sweep of M. Figure 5 shows the pattern we wish to achieve. The jth row of sweep i, $1 \leq j \leq i$, computes the jth entry of diagonal i of the table (starting with the topmost entry). For instance, during sweep 3, M computes *3*, *7* and *10* in rows 1, 2 and 3 of the worktape, respectively. Note that an entry is computed only after forming the "convolving" pairs on which it depends. For example, in the third sweep, *10* (represented by the pair *(10,10)*) is computed by first forming the pairs *(7,1)* and *(3,6)* on the first two cells of the row.

A careful study of the profile will reveal how M should generate the pairs. Except for the leftmost pair of each row, the left element of each pair is propagated diagonally downwards (i.e., one row down and one cell to the left). The right elements of the pairs are obtained by shifting them one row down during each subsequent sweep. The leftmost pair of each row is simply the value of the entry computed on this row. All of these actions can be performed by M. However, a problem arises when generating the left element of the first cell of each row. For instance, consider rows 3 and 4 of sweep 4 of the profile. The pair *(11,1)* in row 4 can only be formed by propagating *11* of the pair *(11,11)* in row 3 into this pair. However, M cannot pass information from left to right since it changes states only during a right-to-left row scan. This problem is overcome by using the following "folding technique". The idea is to fold the profile of each sweep along the dotted lines shown in Figure 5. The folded profile is shown in Figure 6. As a result of the folding, all the necessary propagation and shifting of elements can now be performed by M. For instance, in sweep 4 of the profile, pair *(11,1)* is now directly below pair *(11,11)*. Hence, *11* can be propagated from the latter pair to the former during a right-to-left row scan of M. Figure 7 gives the rewriting rules necessary to achieve the folding. In the figure, the boxed cell is the cell currently being rewritten; the solid (dotted) arrow means: copy the current (previous) contents. Thus, the right element of a pair is obtained from the *previous* right element of a pair in the row above it. The second track is used to hold these previous values.

While performing the above steps, M also creates, on the third track, a table T whose ith row, $1 \leq i \leq n$, is simply the bottom row of sweep i of M (see Figure 8). Thus, at the end of n sweeps M has the last sweep profile of Figure 6 on the first track and table T on the third track of the worktape. When $ is first read (on the (n+1)st sweep), M can then check whether *15* has a rule whose left-hand side is S (the start symbol). If no such rule exists, M outputs "error" and halts. Otherwise, it chooses one such rule, marks it by *, and proceeds to the next phase.

**Tape Reversal.** During this phase, M reverses the tape contents by first reversing the rows, then the columns of the worktape. To reverse the rows, M proceeds as follows. When $ is first read (on the (n+1)st sweep), M rewrites the rightmost cell of the first row by '-' and stores the previous contents of this cell on the left end of the row (i.e., after the last 'B'). (M in fact stores the previous contents in reverse. That is, if the previous contents were (a,b)(c,d), then M stores (d,c)(b,a)). M also marks the left end of the row by @. The same is done for all other rows. In succeeding sweeps and for each row, M moves past the '-'s and rewrites the first cell encountered by '-'. It then stores the previous contents of this cell in the cell marked @, while shifting the tape contents to the left. M repeats the process until the next cell to be rewritten is the one marked @. The tape profile of M after reversing the rows is shown in Figure 9-(b). Next, M reverses the columns. The steps carried out are the same except that they are done vertically (see Figure 9-(c)). M also marks the bottom row of the table by @. This phase takes 2n sweeps to complete. The configuration of the worktape after reversal is shown in Figure 10.

Once the tape contents have been reversed, M generates a parse tree of the input string by backtracking. It does this by performing the next two phases simultaneously.

**Regeneration.** During this phase, M regenerates the sweep profiles shown in Figure 6 in reverse order starting with sweep 5. In general, M can regenerate the profile of sweep i from the profile of sweep i+1 and from table T. For instance, to regenerate the profile of sweep 4, M starts by erasing the top row of the current profile and replacing the ***right*** elements of the pairs in the second row by the corresponding elements in the second row of table T. The left elements of the second row and the pairs of the remaining rows are obtained by shifting and propagating the entries according to the rules given in Figure 12, which are essentially the "inverses" of the rules given in Figure 7. Again, the boxed cell represents the cell currently being rewritten; the solid (dotted) arrow means: copy the current (previous) contents. The same steps are carried out to regenerate the remaining sweeps. In each case, the top row of the current profile is erased, and the right elements of the next row is replaced by the right elements in the corresponding row of table T. The left elements of the row and the pairs of the remaining rows are formed using the rules in Figure 12. The regeneration phase terminates after the bottom row of the table has been erased. To know when this happens, M does the following. At the start of the regeneration phase, M initializes a marker on the rightmost cell of the top row (*(15,15)(15,15)* in Figure 11). In each subsequent sweep, it shifts the marker one cell to the left. The regeneration phase terminates when the marker moves past the leftmost column of the table.

**Parse-Tree Extraction.** While executing the regeneration phase, M simultaneously performs a marking phase through which it extracts a parse tree of the input string. Recall that at the end of the table construction phase, M has marked by * a rule in *15* which has S (the start symbol) on its left-hand side. This rule is the root of the parse tree generated by M. The rest of the tree is generated as follows. When scanning a row, M checks if the rightmost (non-'B') entry has a rule marked *. If no rules are marked, M writes '-' at the left end of the row. Otherwise, the rule is either of the form [A→a] or [A→BC]. In either case, M remembers the rule in its state and writes the rule at the left end of the row. In addition, if the rule is of the form [A→BC], M does the following. While moving left on the worktape, M searches for the first pair of entries (X,Y) in which B appears on the left-hand side of a rule in X and C appears on the left-hand side of a rule in Y. Let the two rules be [B→DE] and [C→FG]. M then marks both [B→DE] and [C→FG] by *.

During the regeneration phase, the entries (along with any marked rules) are shifted and propagated according to the transition rules given in Figure 12. Thus, at some point an entry with a marked rule will reach the rightmost (non-'B') cell of some row.

The execution of the above steps results in the generation of a matrix of rules, as shown in the last sweep profile of Figure 11 (to the left of the dotted vertical line). This represents essentially a parse tree of the input string (see Figure 4-(d)). This phase terminates at the same time as the regeneration phase.

**Outputting the Right Parse.** What remains to be done is to output the right parse itself. Intuitively, this can be done by scanning the matrix of rules one column at a time, starting with the rightmost column. Within each column, the rules are output one at a time, starting with the topmost one. However, a problem arises because M cannot tell when it has exhausted one column and proceed to the next. To overcome this problem, M performs a "shift-and-accumulate" phase during which the matrix is shifted downwards and the rules are accumulated on the bottom row of the matrix. (The bottom row of the matrix is marked @ at the end of the column-reversal phase.) The details of this phase are shown in Figure 13. The bottom cells can hold at most two rules. The cell acts as a queue so that when a rule is shifted into a cell which is already full, the first rule shifted in is taken out and passed to the next cell. Note that there are exactly 2n-1 rules in the matrix, and these can all be accommodated in the bottom cells. This "shift-and-accumulate" phase can be performed by M in n sweeps. Once completed, M can then output the right parse of the string by outputting the rules from right to left. (Note that the output is observed at the bottom row of the worktape, which is different from the bottom row of the matrix. In this case, M simply outputs the same rule in each of the remaining rows of the tape.) We leave it to the reader to verify that outputting the rules in this order does indeed give the right parse of the input string.

M takes 7n sweeps to complete the computation. The corresponding 2DIA has time complexity 9n-2. Thus, we have

**Theorem 2.** Context-free language recognition and parsing can be carried out on a 2DIA in linear time.

**Remark 1.** The 2DSM described above can be made to operate in time (n+1)+$\epsilon$n for any real number $\epsilon$>0, by simulating k sweeps in one sweep and allowing the machine to output k symbols at a time. It follows from the characterization that the 2DIA can be made to operate in time (3n-1)+$\epsilon$n.

**Remark 2.** Strings of length less than n can also be recognized/parsed by the 2DSM. This follows from the fact that the length of the input determines the size of the table built by the 2DSM during the table construction phase. Moreover, during the outputting of the parse, the answer is propagated to all rows lying below the table.

## 3. Conclusion

We have shown that context-free language recognition/parsing can be carried out on a 2DIA in linear time. One can show that a (one-way) 2DIA operating in linear time can be simulated by an unbounded two-way 2DIA (Figure 14) also operating in linear time. Moreover, the computation of the two-way 2DIA can be sped up to operate in time (n+1)+$\epsilon$n, for any real number $\epsilon$>0 [7]. It follows that CFL recognition/parsing can be carried out on a two-way 2DIA in (n+1)+$\epsilon$n time.

Our techniques are applicable to other problems involving dynamic programming, e.g., to the problem of finding approximate patterns in strings [14,15], the string-to-string correction problem [12,16], the longest common subsequence (LCS) problem [5,6,12,16], dynamic time warping, optimum generalized alignment, error-correction, etc. [13]. For these problems, we are interested in the "parse", rather than the value, of an optimal solution. For example, for the LCS problem, what we require as output is an LCS of the two given strings, not its length. If only the value of an optimal solution is required, the problems can be carried out in linear time on a one-dimensional array of non-finite-state processors [9].

## ABSTRACT

The recent advances in computer architecture for image processing will provide unprecedented systems capabilities in the upcoming decade. Among the most significant aspects of the architectures will be their increasing ability to process image data in a parallel fashion. This paper presents a new computing architecture called "DRAFT" (Dynamically Reconfigurable Architecture for Factoring Things) used in parallel processing of image data structures. Furthermore, we show that quadtree data structures can be processed efficiently on this new parallel computing architecture. Algorithms are given for constructing and pruning the quadtree structure and for findings neighbors in a parallel fashion. The computational requirements of the "DRAFT" system in image processing are examined and their analysis is presented in detail.

## INTRODUCTION

The quadtree has received much attention in recent years as an efficient data structure for a variety of image processing applications. Recursively defined a quadtree may be empty or it may consist of a root with either none or exactly four sons consisting of quadtrees. For this paper a region will be the BLACK portion of a 2**n x 2**n array made up of a unit square pixels colored BLACK or WHITE. A sample region is presented in Fig. 1 and its quadtree is given in Fig. 2. We define a node in a quadtree to be a record containing the following fields. If P is a (pointer to a) node and D is in the set of directions {NW,NE,SW,SE}, then we may define the fields as follows. **COLOR(P)** has value WHITE or BLACK for a leaf, GRAY for an interior node. **SON(P)** (pointer to) a collection of four nodes which are the sons of P in each direction; NIL if no such node exists. **FATHER(P)** (pointer to) the father of P; NIL if P is the root. **PATH(P)** a path code recording the position of the node as an encoded series of directions from the root to the node as proposed by Jones, Raman and Iyengar [1, 2]. The (pointer to the) root of the quadtree will be denoted by ROOT. In our figures, the offspring of a node are drawn in the canonical order NW-NE-SW-SE.

Many algorithms have been written to process patterns stored as quadtrees. Important to these algorithms are procedures which allow determination of the neighbors of any given nongray node. These "neighbors" are the closest nodes in any of four directions, referred to as N,E,S, and W. An algorithm for traversing a quadtree to find these neighbors is given in Samet[3]. For a broader treatment of quadtree related research see [4, 5, 6, 7, 8].

Research supported in part by the National Science Foundation and the National Security Agency under grants NSF DCR 83-115-80 and NSA MDA904-85-H-0006.

This paper presents a scheme for performing quadtree functions in parallel on a new type of architecture called the DRAFT architecture. We begin with a brief overview of the architecture in section two. Section three outlines several programming concerns designed to maximize parallelism. Next a parallel data structure for representing quadtrees in a DRAFT machine is presented in section four, followed by an algorithm for building these structures from raster input in section five. Section six demonstrates parallel operation in the DRAFT environment with a sample neighbor find algorithm. An analysis of the expected performance improvement for common quadtree operations is provided in section seven.

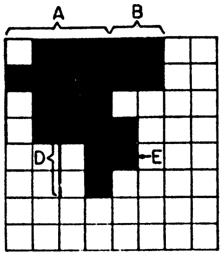

Figure 1

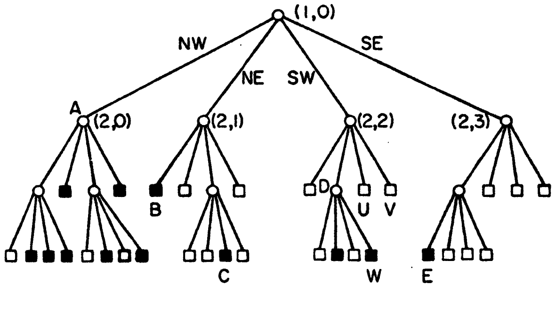

Figure 2

## A HORIZONTALLY RECONFIGURABLE ARCHITECTURE (DRAFT)

The DRAFT is an extended word length machine, 256 bits in the current implementation. This 256-bit word is constructed of 32-bit slices. A switching network is placed between each of the slices and is controlled by an 8-bit field in the microinstruction word. By setting or resetting the bits in this field the microprogrammer can at the micro-instruction level join one or more adjacent slices into a single processing unit or separate them into independently operating parallel processors. Thus the machine is horizontally reconfigurable along its word length into any combination of processing elements which can be constructed by joining adjacent slices. Possibilities range from a single 256-bit processor to eight 32-bit processors. For clarity we will refer to processing elements constructed in this manner as segments and the underlying 32-bit building blocks as slices. Figures 3 - 5 illustrate the details of the DRAFT architecture machine.

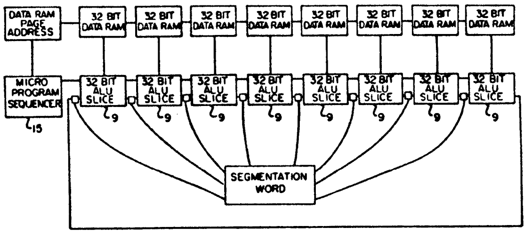

Figure 3

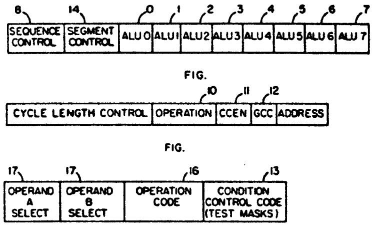

Figure 4

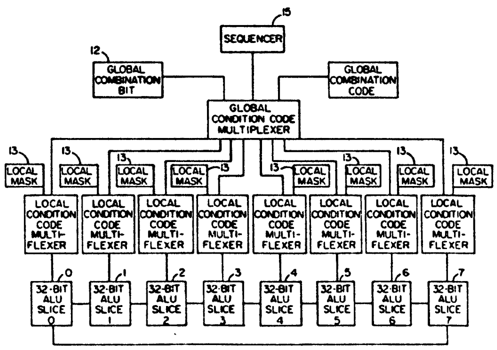

Figure 5

As stated, the slices and hence the segments configured from the slices are independently programmable. The major components of each slice include a control RAM and instruction pipeline, a 32-bit ALU built from VLSI bit-slice devices, a 64k-by-32-bit data RAM, and the switching circuitry necessary for constructing segments. The local control and data RAMs provide each segment with an instruction and data stream separate from the other segments in a given configuration. When combined into a segment, the control RAMs of each slice are simply programmed with the same instruction. The data RAMs of adjacent slices combine into higher- and lower-order 32-bit pieces of the segment data word.

Two components of the DRAFT machine which are global to the slices are the microinstruction sequencer and the global condition multiplexer. The microinstruction sequencer broadcasts a common next instruction address to all segments and is itself programmed with a separate sequencer instruction. The resulting program structure is unique in that a single control structure encloses parallel operations taking place within different processors of the same machine.

To provide for conditional execution of the segments, a slice level control mechanism is added by the global condition multiplexor. Between the slices and the global sequencer is a hierarchical arrangement of condition codes. At the bottom of this hierarchy is the slice level condition code bit. This bit is set by a combination of inputs, including the status output from the ALU, a slice level condition mask which selects the appropriate status output, and the segmentation word which propagates condition codes from the high-order to low-order slices within a segment.

The sequencer requires a single binary condition code to control branching within the global control structure. The function of the global condition mux is to generate the logical AND and logical OR combination of the local condition codes and to select under program control the appropriate combination for use by the sequencer. Thus, transfer of control instructions for the sequencer have, instead of the conventional conditional and unconditional analogs, unconditional, conditional all slices, and conditional any slice versions. The slice level control structure is implemented as conditional and unconditional analogs of all slice operations. Unconditional versions operate as normal instructions, while conditional analogs execute only so long as the local condition code is false. Once the local condition becomes true, these instructions become NOPs, and the slice essentially drops out of any parallel computations occurring within the global iterative or conditional structure. It is also notable that each segment has the ability to directly set or reset the local condition code independent of the actual status. This mechanism completes the condition code structure by adding the capability to mask out a given slice from consideration in a conditional all or conditional any decision for the global control structure. For a broader treatment of the DRAFT machine see[9].

## DRAFT PROGRAMMING PARADIGMS

What most distinguishes DRAFT based parallel algorithms from other types of parallel algorithms is the unique mix of global and local control structures. Because of the common instruction word address, each segment must wait until all segments have finished with a block of code before continuing. The conditional execute option allows a slice to shut itself off while waiting. At the programming level, this provides an excellent environment for converting sequential algorithms into parallel algorithms. The parallel algorithm is written as though it were sequential, with the added specification on conditional branching instructions indicating whether the branch is dependent on the condition testing true for all of the segments or just one of the segments.

Obviously it is possible to lose parallelism if some of the segments are shut off. This is the cost one must pay for the simplicity of the DRAFT programming environment. However, there are several ways in which can parallelism can be maximized by the programmer.

**Paradigm 1:** Since each slice processor includes its own local slice of the DRAFT memory word, the arrangement of data structures in memory is key to parallel operation. As the slices combine into segments of longer word length so do the memories. If a data item is to be considered as a

256 bit item, it should be right justified in the memory of the 256 bit segment to be used. Conversely if eight items are to be used in parallel they should be placed adjacent to one another in the slice level store of each segment.

**Paradigm 2:** Whenever possible, replace a block of code involving a conditional branching operation with a functionally equivalent block without conditional branching. Conditional branches depend on the status of all segments either ANDed or ORed together to generate global transfers of control. It is possible that when a conditional structure is executed, some of the segments will invoke conditional execution and shut themselves off. Since the objective is to maximize parallelism and minimize non-executing conditional code, the substitution of logical operations for conditional control structures such as if-then and case is advised wherever possible. If the function can be implemented without any type of conditional branching, this insures that all segments will remain active throughout. Although this seems to be a restriction on the programmer, examination of code and judicious selection of internal representations for data will reveal some branches that are the result of programming style and which can be eliminated without undue cost.

**Paradigm 3:** DRAFT micro-code allows parallel programming of the global micro-sequencer concurrently with the operation of the slices. The programmer has the opportunity to test condition bits at each instruction and branch out of redundant or useless operations. Although this branching is usually done at the end of a block of code on a sequential machine, it is possible to speed up an algorithm on the DRAFT by redundant testing in the microprogram sequencer.

## A PARALLEL DATA STRUCTURE FOR QUADTREES

The data structure used by Samet and others [4, 1, 2, 7, 8] for image quadtrees contains a color value and pointers to each of the four sons representing the NW,NE,SW, and SE quadrants of the image section. The structure proposed here is similar but includes additional fields for a parent pointer and a path code to be used in neighbor finding. The major difference in the DRAFT implementation is that the son quadtree nodes will be processed in parallel and reside adjacent to one another in a single segmented location of DRAFT memory. Thus the parent requires only a single pointer to this location. Figures 6 and 7 show a 4 x 4 raster scan and its corresponding full (worst case) quadtree representation. Figure 8 illustrates how the quadtree representation can be partitioned in a the prototype DRAFT machine.

<table>
<tr><td colspan="8">1</td></tr>
<tr><td colspan="2">2</td><td colspan="2">3</td><td colspan="2">4</td><td colspan="2">5</td></tr>
<tr><td>6</td><td>7</td><td>10</td><td>11</td><td>14</td><td>15</td><td>18</td><td>19</td></tr>
<tr><td>8</td><td>9</td><td>12</td><td>13</td><td>16</td><td>17</td><td>20</td><td>21</td></tr>
</table>

**Figure 8**

The layout parallels the segmentation to be used in processing at each level: 256 bit uni-processing at the root, four segments of 64 bits each at the next lowest level, etc. Since the current DRAFT prototype is an eight-slice machine, nodes at levels three and below must be arranged as might be expected in a single processor environment. This amounts to a data partitioning between the slices, so that one eighth of the total area represented is handled by each processor and each of eight image octants will be processed in parallel. However, the DRAFT architecture imposes no limit on the number of slices. The current prototype has eight, but since only neighboring interconnections are required, it is feasible to string together a large number of slices to meet the requirements of some particular imaging task.

Note how this arrangement of the quadtree into DRAFT memory greatly increases the available parallelism in quadtree algorithms. Assuming that the number of slices is sufficient to hold all leaf nodes in a quadtree of depth N. It is possible by successive reconfigurations to access each node in a full quadtree in N steps, compared with the 4**N-1 steps required for traversals in a sequential environment. If the number of slices is not sufficient to hold every leaf node, the access time degenerates to that of a sequential access in all levels below log4(P) where P is the number of slices. In such a case, each slice is executing a sequential traversal with all slices running in parallel.

Other quadtree operations work well in this data partitioned format. Rotation of the image in 90 degree increments can be achieved by changing the order in which the child nodes are accessed; the pointer to the NW quadrant becomes the pointer to the SW quadrant, etc. No actual movement of data is required and pointer updates proceed in parallel. The same is true for a transposition of the image across some axis inside the plane of the image. Since superimposing one quadtree image upon another is a task which requires traversing two quadtrees simultaneously while constructing a third, one can expect timing improvements for this operation to be proportional to the improvements in traversal time. The time complexity for finding the intersection of two images should also be improved from 4**N to N, assuming a processor slice is available for every pixel.

## QUADTREE CONSTRUCTION FROM RASTER INPUT

For testing on the DRAFT prototype, two implementations of the quadtree structure were proposed: a vertical storage, where each field is placed in a different data location with the color at the base of the data page, and a horizontal packing where all fields are kept in a single data location. Vertical storage assigns one node to every data page; therefore horizontal packing is 16 times more memory efficient. However, horizontal packing has a disadvantage that extra code is required to extracted each field from the data word before it can be used. The procedures below were coded assuming horizontal packing.

Having chosen a representation scheme for the quadtree nodes the next problem is loading image data for an input device, such as a raster scanner into the DRAFT memory. This operation is important since the arrangement of pixels in the proper slice order is critical in constructing the parallel quadtrees as shown in Figure 8. For a DRAFT machine implementation sufficiently wide to provide a slice for each pixel this problem is relatively trivial. More difficult is the arrangement of nodes for the case of a limited number of slices, each processing a sub-quadrant of the image. Such was the case with the following test algorithms designed for the eight slice prototype. For loading an N x M pixel raster the data must be divided into eight octants of size N/2 x M/4. As the raster is scanned pixels from lines 1 to M/4 are placed in slice one for n < N/2 and slice three for n >=N/2. The next quarter for m are placed in slices two and four, then five and seven, and the remaining quarter loads into slices six and eight. Shown below is a sample implementation of this algorithm for the DRAFT machine host processor. The routine *get_pixel* reads the next pixel from the scanner and *store_pixel* places the pixel into the memory of the second parameter "slice".

```
/* sample algorithmfor loading an N x M
  raster into an 8 slice DRAFT machine */
int slice[4] = 0,1,4,5;

for m = 1 to max_lines
{/* lower half of line */
 for n = 1 to pixels_per_line/2;
 {
 pixel = get_pixel;
 store_pixel(pixel,slice[int(m/4)]);
 }
 for n = 1 to pixels_per_line/2;
 { /* upper half of line */
 pixel = get_pixel;
 store_pixel(pixel,slice[int(m/4)]+2);
 }
}
```

The store_pixel routine also performs an additional function to ease the construction of quadtrees for each of the octants in the next step. For this construction step the sequence of pixels in sequential memory locations will need to be the ordering from left to right of the leaves in the full quadtree to be constructed. This is not the order in which the pixels are received from the scanner. To achieve the required shuffling of the pixel locations the loading program uses an M/4 by N/2 translation raster. Each location in the translation raster holds the offset from raster base into which the pixel is to be stored. Figure 9 illustrates a translation raster for an eight-by-four octant processed at the slice level in a 16-by-16 raster.

**Input Raster**

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 |
| 25 | 26 | 27 | 28 | 29 | 30 | 31 | 32 |

**Translation Raster**

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| 1 | 2 | 9 | 10 | 3 | 4 | 11 | 12 |
| 17 | 18 | 25 | 26 | 19 | 20 | 27 | 28 |
| 5 | 6 | 13 | 14 | 7 | 8 | 15 | 16 |
| 21 | 22 | 29 | 30 | 23 | 24 | 31 | 32 |

**Figure 9**

The final step in preparing a raster for DRAFT quadtree operations is to construct and color the parent nodes ascending upwards to the root. Phase one scans in parallel the pixels of each of the eight octants. Every fourth pixel generates a new node colored black if all four pixels are black, white if all four are white, and grey if a mixture of black and white exists. Also during this scan the parent field of each pixel is filled with the address of the new node and the son field of the new node is set to the base address of the group of four. After scanning the pixel level nodes the process is repeated for each of the new parent parent nodes created until in the final iteration a single root node is generated for the octant quadtree processed by each slice. The procedure below shows the code for each slice. The actual code is implemented in DRAFT microcode.

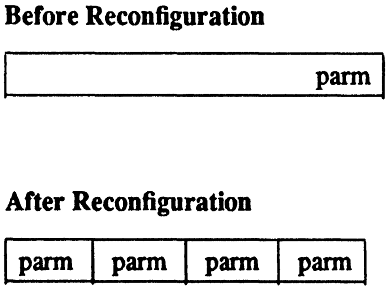
```
/* sample slice level algorithmfor generating
  quadtreesfor raster octants */
nodecount = n*m/8;
while(nodecount > 0)
 for i = 1 to nodecount by 4
 { new_parent = make_parent_node;
   son(new_parent) = i;
   color(parent) = color(i)
   for j = i to i+3
   { parent(j)=new_parent;
     color(parent)==color(j) : color(parent)=GREY;
   }
 }
```

Note that the conditional testing of child colors appears to be backwards in this algorithm. In fact the statement is an example of conditional execution. The program sequencer will cause the assignment statment to execute in all slices, however in those slices for which the local condition code is true, the assignment statement is converted to a nop and the parent color is unchanged.

Phase two of quadtree construction completes the upper levels of the image quadtree as shown in Figure 7. In the eight-slice prototype this will be two additional levels. Since all of the octant quadtrees roots lie in adjacent slices of the same location, the completion of the address fields is trivial. Each level is executed using a successively larger segmentation until the root executes in single segment mode. Having constructed the quadtree, the next step is the implementation of common quadtree operations. A complexity of analysis of most such operations will inevitably be dependent on the complexity of quadtree traversal. As stated, a sufficiently wide DRAFT implementation reduces such traversals to complexity proportional to the depth. When DRAFT segments must traverse entire subtrees in parallel the single instruction address forces the complexity to the worst case of the eight (for the prototype) subtrees. This is because all other segments must wait for the "slowest" segment to complete its traversal before continuing.

## FINDING NEIGHBORS

One essential quadtree operation that has received a good deal of attention [2, 10] is the neighbor-find operation. The DRAFT implementation of this algorithm is a good example of how varying segmentation can not only assist in quadtree traversal but can also return information such as the size of a neighboring block. The algorithm proceeds recursively with an N bit parameter holding the path code of the node for which the neighbors are to be located. N in this case is the number of bits in the current segment. At each level of the recursion the machine reconfigures to divide the current segment into four new segments which will simultaneously search the four children. Each of these segments is given an N/4 bit copy of the original parameter arranged across the parameter word as shown in Figure 10.



Before Reconfiguration

After Reconfiguration

Figure 10

A identical mechanism is used in reverse for the return parameter. In this case the segment locating a neighbor places an N bit copy of the path code for that neighbor into the corresponding segment of the return parameter word. When the recursion returns to the root the resulting word contains a string of four values representing the four neighbors of the node in question. The segment size of each of this values determine the size of the neighbor block returned. A recursive slice level algorithm for nearest neighbor is shown below. The actual micro-code for nearest neighbor on the DRAFT prototype is a non-recursive implementation using the parent pointers. This is due to the limited size of the stack memory for the sequencer chip used.

```
find_neighbor(node,quadtree)
{
/* locates the neighbors of "node"
   in "quadtree" */

if(color(quadtree) <> GREY)
   then if(is_neighbor(node,quadtree))
           then return(0);
           else return(quadtree);
   else { re_seg(4);
          find_neighbor(node,son(quadtree));
        }
}
```

The *re_seg* procedure above resets the segmentation and regenerates the parameter as above. *Is_neighbor* is a boolean function which compares the path codes of "node" and "quadtree" to determine if they are neighbors.

Algorithms have also been devised for *union* and *intersection* functions of two image quadtrees. For these functions the result quadtree is the union or intersection of the blacks regions of the two inputs Both algorithms are based on a top down traversal like the one discussed in section three and thus have complexity proportional the depth of the inputs.

## ANALYSIS

Analysis of DRAFT algorithms must be made based on two cases. In case one the slice width of the DRAFT implementation is equal the number of nodes in the worst case quadtree to be constructed. For this case quadtree construction, traversal, and neighbor finding reduce to O(N) since each step processes an entire level and N is equal to the depth of the quadtree. While this is not an unrealistic assumption based on current VLSI capabilities, no such machine for non-trivial rasters has been built. For operations on the existing eight slice DRAFT prototype the analysis divides into two phases. Phase one is the analysis above for the upper levels of the quadtree. Phase two, is an eight processor parallel version of essentially sequential operations on the eight octant subtrees. The proposed data structure divides all work evenly so that the time required to execute in parallel is the same as the equivalent sequential algorithm divided by p, where p is some even number of slices. The cost paid for this improvement is log4(p) steps representing those levels which can be fit into adjacent slices. For quadtree construction each quadtree is constructed in with O[(4(N/p)-1)/3] where N is the number of pixels in the raster. The entire quadtree for rasters of N pixels is thus constructed in O[log4(p) + (4(N/p)-1)/3] Assuming an N log4(N) complexity for sequential neighbor finding yields an identical analysis for the DRAFT neighbor find algorithm of complexity O[log4(p) + N/p log4(N/p)]. Traversals and traversal oriented operations improve from O(N) for the sequential case to O[log4(p)+ N/p] in the DRAFT algorithm.

In Iyengar and Moitra [5], a paradigm is given for measuring EPU, the Effective Processor Utilization, is defined as (complexity of the fastest sequential algorithm for a problem)/( the number of processors used * time complexity of the parallel algorithm). Using this measurement, DRAFT algorithms have an EPU of 1.

## FUTURE RESEARCH

The DRAFT machine has great potential for use in an image processing environment. Its quasi-SIMD structure makes it possible to create algorithms which make good use of parallel processing while retaining the familiar programming structures of a sequential environment. In addition to the work in new algorithms for this machine, two other areas are currently being given attention. The first is an attempt to reduce the essential switching functions to custom VLSI. The existence of such a chip set would greatly enhance the ability to apply this new processor design to a wide range of special purpose machines. Second is the development of a high-level programming environment. Whereas the current micro-code environment is well suited to optimizing performance, high-level language to support such operations as the segmented recursion discussed in this paper would be of great advantage.

## Abstract

Given a sequence of numbers which can be mapped into an $m \times n$ array, sorting rows and columns is shown to yield an overall sorted sequence. This unusually simple procedure is proven to require $O(\log_2 m)$ iterations by analysing the data movement in the array under successive row and column sorts. An efficient bubble sort network suitable for VLSI implementation, with near-optimal $area-time^2$ performance is a direct application of the row-column sorting technique. The ease in implementation for practical VLSI chips is also demonstrated.

## I. Introduction

The problem of sorting numbers on a two-dimensional array has been studied by various researchers ([1], [2], [10]) and more recently by Leighton[3], Lang et al.[8] and Tseng et al.[12]. This problem involves routing of each data item to a distinct position of the array predetermined by some indexing scheme. Three different schemes have been considered by Thompson & Kung[1] : row major, shuffled row major, and snake-like row major (see Figure 1). The corresponding column-major forms can be considered equivalent to the schemes above. Most of the above referenced algorithms are based on two dimensional adaptations of very efficient sorting algorithms for linear sequences like bitonic sort[9] in [1] and [2], and odd-even merge sort[9] in [10] and these are essentially recursive in nature. Even though they perform optimally within a constant factor of the lower bound of O(n) for a $n \times n$ array, these algorithms spend most of the time in routing data to appropriate processors. Consequently, the complexity of the execution time is dominated by the number of unit routing steps in a SIMD model. Thompson and Kung[1] derived a 4(n-1) lower bound from an initial configuration where elements on the opposite corners of an $n \times n$ array have to be exchanged.

However, mere figures of time complexity appear to be superficial, when we consider the complexity of the control structure for the complicated data routing during the successive stages of recursion. One hardly needs to overemphasize the cost of the communication overheads in a VLSI implementation. In this context one can be more enthusiastic about the algorithm in [12], which in spite of being recursive in nature gets away with minimal control and achieves a bound within O(log n)[a] of the optimal. In the realm of sorting a two-dimensional array of numbers, a seemingly "nice" way would be to sort rows and columns (since it involves sorting on smaller problems of approximately $\sqrt{n}$ size) and "hope" that somehow a combination of these two operations will terminate in a sorted sequence. Unfortunately, such a procedure doesn't seem to work when implemented in a straight-forward manner and indeed Leighton[3] observes that ".. if the matrix were square, we would essentially be sorting rows and columns which is well known to leave entries arbitrarily away from the correct sorted position". This was in obvious reference to the row-major indexing scheme. Paradoxically things fall into place when one sorts the rows in a snake-like row-major form without increasing the complexity of the procedure. This simple algorithm, which we call **shear-sort** , will be formally introduced in the next section. Section III will provide the analysis of the algorithm. In section IV we discuss very efficient and simple VLSI implementation of the algorithm using only bubble-sort network and in section V we discuss a method to optimize the algorithm by simple manipulations.

## II. Row-column sort

Let Q = [ $q_{i,j}$ ] be an $m \times n$ matrix onto which we have mapped a linear integer sequence S. Sorting the sequence S is then sorting the elements of Q in some predetermined indexing scheme. We suggest an iterative algorithm in which every iteration consist of the two basic operations:

(1) Row-sort - Sort independently all the row vectors of Q such that adjacent rows are sorted in opposite directions (alternate rows in the same direction). In a normal snake-like row-major indexing scheme, sort the first row from left to right (increasing). At the end of this step, $q_{i,j} \leq Q_{i,j+1}$ for all i = 1, 3, 5,..2p+1 and $q_{i,j} \leq q_{i,j+1}$ for all i = 2, 4, 6,..2p.

(2) Column-sort - Sort independently, in an ascending order from top to bottom all column vectors of Q. After this step $q_{i,j} \leq q_{i+1,j}$ for all j = 1, 2, ..n.

The shear-sort algorithm is defined as a repetitive application of steps 1 and 2 until one of the following conditions is satisfied :

(a) all the columns are sorted, i.e. no element has moved in the present column-sort **after a row-sort**, or

(b) no element has moved in the present row-sort **after a column sort**.

A step by step application of the algorithm is shown in Figure 2.

Fig 2 f A snake-like row-major sorted sequence.

The reader may note that the algorithm will terminate into a sorted snake-like row-major sequence from the definition of such an indexing scheme. It is trivial to observe that, if the rows and columns are sorted in the directions corresponding to the algorithm, the array is sorted. Thus conditions (a) and (b) are equivalent and are necessary and sufficient conditions.

To give the reader an insight into the 'mechanism' of this sorting technique and throw some light on how such a simple procedure results in a sorted sequence we will obtain a very loose upper bound using an informal analysis. In the next section we will derive a tight upper bound using an indirect technique.

Consider the n smallest elements in Q and assume they are randomly distributed over the rows and columns of the array. The first column-sort will move these elements to the first row if initially they all happen to be in different columns. However, if all n smallest elements are in the same column (only possible for $m \geq n$), by virtue of alternating sorting direction on rows, a row-sort will have the effect of moving the elements on odd rows to the leftmost column of the array and the remaining half to the rightmost column. *This phenomenon is analogous to normal shear of a column and hence the name of this algorithm* . Clearly, at the beginning of the second iteration the n smallest elements have moved up into the upper half of Q. The second row-sort will then pair the elements on the two leftmost columns for the odd rows and on the two rightmost columns for the even rows. Following the same reasoning, it is not difficult to see that the column sort of the p iteration will move the n smallest elements of Q to the band defined from rows 1.. $\frac{n}{2^p}$. Without loss of generality we can assume n to be a power of 2 and conclude that the n smallest elements of Q will move to their sorted positions in at most log n iterations.

It follows from the above discussion that for m < n, the n smallest elements move into their sorted position in at most log m iterations. It is evident that once the first row is in place, it will continue to do so throughout the remaining iterations. Therefore we now face a problem of sorting the reduced array $Q_{-1}$ of dimension $m-1 \times n$. Each time a row is in its place, we reduce the problem to a smaller array on which the smallest elements are brought to the 'first' row in $\lceil log(m-k) \rceil$ iterations where k is the number of previously discarded 'first' rows. The total number of iterations to sort the array is thus

$$\sum_{k=0}^{k=m-1} \lceil \log(m-k) \rceil$$

which is bounded from above by mlog m.

In this simple analysis we assumed that after the 'first' row of array $Q_{-k}$ is in place all the remaining elements are randomly distributed in the reduced array $Q_{-k-1}$. This is not the case as we will show in the next section which gives a much better bound of O(log m) iterations.

## III. Analysis of the algorithm

We shall prove that shear-sort converges in O(log m) iterations, for an $m \times n$ array, by showing that the elements go within a specified distance of its final sorted row in every successive iteration. It will be seen that an arbitrary element (and hence all elements) goes within $\frac{m}{2^p}$ of its final sorted row after p iterations, from which the O(log m ) bound follows immediately. We will use here an application of the [0-1]principle (Knuth[6]) (for a direct combinatorial proof see Scherson & Sen[13]). For the purpose of applying the [0,1] principle, we will visualize our sorting algorithm as a sorting network of logm + 1 stages, where in each stage we sort all the rows in a row-major snake-like form followed by sorting all the columns (Figure 3).

Consider the simple case of a $2 \times n$ array containing arbitrary number of 0's and 1's.

(a) After the rows are sorted, the 0's in the first row will be packed to the left, while 0's in the second row will be pushed to the right. Let us denote the number of 0's in the first and second rows by $n_1$ and $n_2$, respectively (Figure 4).

(b) Depending on the value of $n_1 + n_2$, sorting the columns (in this case a simple compare exchange), will result in one of the following

Case 1 ( $n_1 + n_2 < n$ ) : the bottom row will contain only 1's and the top row will be a mixture of 0's and 1's.

Case 2 ( $n_1 + n_2 = n$ ) : the top row will contain only 0's and the bottom row will have only 1's.

Figure 4b. Afterthe column sort, one of the two rows(second in this case) contains only 0's or 1's. In a more favorable case, both rows are clean.

Case 3 : ( $n_1 + n_2 > n$) : the top row will contain only 0's and the bottom row will contain an unordered sequence of 0's and 1's.
Out of these cases, Case 2 is the most favorable, since the rows are already sorted and in the other cases we have a sorted row (first in case 1 and second in case 2). Also, the rows are mutually ordered i.e., all the elements of the top row are less than or equal to the elements of the bottom row. In the next row-sort the remaining row is ordered and sorting is complete. Henceforth we shall refer to a row as being 'clean', if it contains identical elements (only 0's or only 1's). Analogously, a row consisting of both 0's and 1's will be called 'dirty'.

The above discussion makes it clear that in a pair of adjacent rows, after the first iteration at least one of the rows is 'cleaned', i.e. it consists of only 0's or 1's. We will now extend the above phenomenon to an $m \times n$ array. Without loss of generality assume m to be a power of 2. After the row-sort of the first iteration we have 0's squeezed to the left on the odd- numbered rows and packed to the right on the even-numbered rows. Consider that a column sort consists of the following two stages
(1) For an element $q_{i,j}$, do a compare exchange with the element $q_{i+1,j}$, for i = 1,3 ..,m-1. For i = 2,4 ..,m, compare exchange $q_{i,j}$ with $q_{i-1,j}$. (This is equivalent to sorting m/2 pairs of adjacent rows independently.)
(2) Sort the columns normally i.e. across the entire columns.

It should be clear that decomposition of a column sort in the above manner is not going to affect the ordering resulting from a normal column sort. The extra (hypothetical) step makes the analysis much simpler. From the previous discussion, we know that following step 1 there is at least one clean row among every pair of odd-even rows. We may now consider an entire 'clean' row as a single entity during the column sort since a 'clean' row continues to be clean throughout the subsequent iterations. This follows from the observation that, when a 'clean' row of 0's is compared with a 'dirty' row across the columns, the clean row bubbles to the top row remaining 'clean'. Similarly a 'clean' row of 1's sinks to the bottom. Clearly, two clean rows, when compared across the columns cannot 'dirty' themselves. It may be easier to visualize this process of column sort being a bubble sort, in which all elements of a row vector are simultaneously compared to the corresponding elements in their adjacent row. The reader should note that the actual algorithm used for sorting columns does not necessarily have to be a bubble-sort since the ordering obtained is independent of the algorithm used. Row-sorts do not affect the clean rows.

Fig 5 b The 'clean' rows of 0's bubble up at the top of the array and the 'clean' rows of 1's settle down. Note that the 'dirty' rows are contiguous somewhere between the bands of 'clean' rows.

It follows, that after the column-sort step of iteration 1, we have at least half (m/2) rows 'clean', with the clean rows of 0's at the top and 'clean' rows of 1's at the bottom. The 'dirty' rows will occupy a band of at most m/2 rows in the middle of the array (Figure 5). Actually we may find less than m/2 'dirty' rows since two 'dirty' rows may mutually 'clean' each other during the column sort. In the course of the second iteration, half of the m/2 'dirty' rows will become clean by applying the same argument to the contiguous band of dirty rows while the clean rows continue to be clean. By a repetitive application of this phenomenon of cleaning half the number of dirty row with every successive iteration, we may conclude that there can be at most one dirty row after log m iterations. An additional row-sort orders this dirty row which actually separates the clean rows of 0's from the clean rows of 1's in the sorted array. Thus, for an initial array consisting of an arbitrary number of 0's and 1's **the shear-sort algorithm terminates successfully in logm +1 iterations.**

The classification of rows as 'clean' and 'dirty' in constructing the complexity analysis was extremely helpful since it reduced the burden of keeping track of every element in the array to only m rows. At this point the implications in a generalized array consisting of elements which may not be only 0's or 1's, is not clear. Nevertheless, we can state the following important result:

**Theorem 1** : An $m \times n$ array of elements can be sorted using shear-sort in time proportional to $\lceil \log m \rceil$+ 1 [m*(time for row-sort) + n*(time for column sort)].

The proof follows immediately from the previous discussion and the [0,1] principle. The tightness of this bound should be obvious from the the informal discussion at the end of the previous section. In the next section we will present an efficient implementation of this algorithm on a mesh-connected processor array.

The **average-case** performance analysis can also be simplified using the [0-1] principle. An important corollary following from the discussion of clean and dirty rows can be summarized as follows:

**Corollary 1** : A 0/1 array consisting of 'd' dirty rows initially, can be sorted using $\lceil logd \rceil$ iterations of shear sort.

Theorem 1 can be stated as a special case, since all m rows can be dirty initially. Consider O(m) 0's uniformly distributed in the $m \times n$ array, the other elements being 1's. Because of the uniform distribution, we may conclude, that on the average, m/2 rows will be dirty. From Corollary 1, the average number of iterations is logm - 2 or O(log m). This shows that the algorithm is optimal within minor variations of the basic shear-sort paradigm.

## IV. VLSI Implementation of shear-sort

In spite of the terrible performance of a normal single processor bubble sort, efforts have been directed towards obtaining efficient VLSI implementations ([5], [6]) because of the inherent simplicity of the algorithm. For this purpose a parallel version of bubble sort viz. odd-even transposition sort([6]) has been adopted. By using crossing sequence techniques, several researchers have shown that the optimal $AT^2$ bound for sorting n elements is O( $n^2$ ) in word model and O( $n^2 \log^2 n$ ) in bit model ([3],[5],[6]). The normal N/2 processor bubble sort where each processor performs one compare-exchange operation during each of the N iterations behaves horribly ( O( $n^3$ ) ) with respect to the $AT^2$ measure. This remains unchanged even by using completely pipelined bit-parallel comparison exchange modules to sort more than one problem instance. The pipelined scheme consists of O ( $n^2$ ) comparators which reduces the effective area by a concurrency factor(n) - the time remaining unchanged ([5]).

**Theorem 2** : The $AT^2$ performance of shear-sort implemented with a bubble-sort network is O($n^4 \log^3 n$) for $n^2$ elements.

Figure 6c shows the implementation of the shear-sort using a pipelined scheme where each of the n rows(columns) are pipelined through this sorting network. The 'Transpose/ Detranspose ' network aligns the array properly for the next column (row) sort. Following Leighton's[3] argument, the Transpose/Detranspose network needs n non-unit length wires and hence occupies $O(n^2)$ area where the transposition is performed in n parallel stages by hardwiring the rows to the corresponding columns (and vice versa- see Figure 6b). The bubble-sort network consists of $n^2$ comparators and thus the total area of the network is O( $n^2 \log n$ ). We will need 2n word steps to sort all n rows (columns). Each comparator is capable of performing a compare-exchange operation of two O(log n) bit numbers

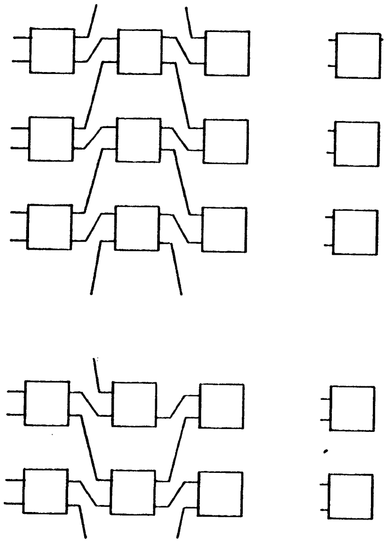

Figure 6a. An N/2 by N comparators Bubble-sorter
Each box represents a compare-exchange module

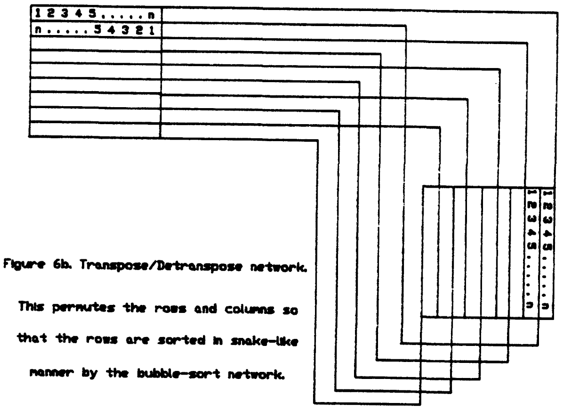

Figure 6b. Transpose/Detranspose network.
This permutes the rows and columns so that the rows are sorted in snake-like manner by the bubble-sort network.

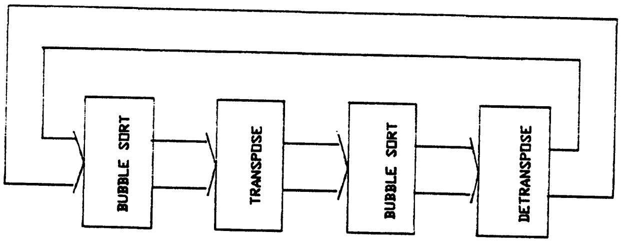

Figure 6c. Block diagram of Shear-sort using Bubble-sort network.
log n + 1 passes through this network will sort any sequence

in O(1) time. As observed previously the Transpose/Detranspose network also needs O(n) time for each iteration. Since we need log n iterations the $AT^2$ performance for this scheme will be

$$O(n^2 logn) \times O((n \log n)^2) = O(n^4 \log^3 n)$$

This is only O( $\log^3 n$ ) away from the lower bound. A similar result can be obtained for the bit model by using bit-serial compare exchange modules. Each compare-exchange module can perform a compare exchange operation every O(log n) time units and can fit into an O(1) by O(log n) unit rectangle. Thus the bubble-sort circuit occupies an area of O( $n^2 \log n$ ) units. The Transpose/Detranspose circuit consists of n non-unit length wires which occupy an area of O ( $n^2$ ) units. Each of these wires routs O(n logn) bits of data and thus takes O(n logn) units of time to complete the operation. The total time is O( $n\log^2 n$ ) and so the $AT^2$ measure for this scheme is O( $n^4\log^5 n$ ). This is only a factor of $\log^3 n$ away from the optimal which is O( $n^4\log^2 n$ ) for O( $n^2$ ), O(log n) bit numbers ([3]).

As noted by Thompson[5], this network needs very little in the way of control as no complicated operations are involved and may be more attractive than its $AT^2$ performance indicates (being a couple of log n factors away from the optimal). There is hardly any need to overemphasize that this scheme of sorting which exploits the powerful property of the algorithm has made bubble-sort comparable to some more sophisticated VLSI sorting networks as far as $area-time^2$ trade-off is concerned.

Figure 7 shows a more regular network for accomplishing the required compare exchanges, though it needs slightly more area (a factor of logn more than the previous approach). We have managed to incorporate the comparators for carrying out row and column sorts within the mesh- connected network, which is very similar to an ILLIAC IV like machine. The horizontal and the vertical compare-exchange modules are used during row-sort and column sort stages respectively. A ROW/COLUMN control line decides which set of the comparators is being used. A ROWDIR control line which controls the direction of compare exchange for the horizontal comparators, achieves alternating sorting directions in rows. A single row/column of elements 'oscillates' between two adjacent row(column) n/2 times, each of which carries out the required compare-exchanges needed for two iterations of odd-even transposition sort. The ROWDIR is changed during every clock cycle of the row-sort stage, so that adjacent rows are sorted in opposite directions. The overlapped comparators in the figure actually represent single comparators multiplexed between the row and column sorts. Each cell is drawn with two inputs, but only one of them is selected according to the row or column sort stages. After O(logm +1) such iterations the array is sorted in a snake-like ordering.

A few comments may be expedient at this point to emphasize the ease in implementation and the expandability of this scheme which are of major concern to any VLSI chip designer. The simplicity in the control structure, which is the result of purely iterative nature of the algorithm, and the regularity of the layout due to use of only nearest- neighbor type operations, make it ideally suitable for systolic implementation. Each chip containing a subset $k \times k$ of the $n \times n$ components will be connected to four similar chips in the four (North, East, South, West) directions, thus presenting no additional complications for chip interconnections. To account for the pin limitations in a chip, and packaging a maximum number of components in a single chip, we can use bit serial communications between the nearest neighbors. This would not change the asymptotic performance since a compare-exchange operation is of the same complexity as a bit-serial communication time of a 'b' bit words ( O(b) time). For example, in a 80 pin package, we need at most 10 pins for the global control signals leaving us with 70 pins for the inter-chip communication. Rounding this to the nearest power of two, i.e. 64, we can integrate a 16 X 16 mesh-connected compare-exchange modules in a single chip (for a $k \times k$ array, we need 4k data pins).

While this scheme is theoretically inferior to Lang et al.[8] by a factor of logn, it may prove to be more feasible for reasonable sized arrays by sacrificing a little time-performance in the bargain.

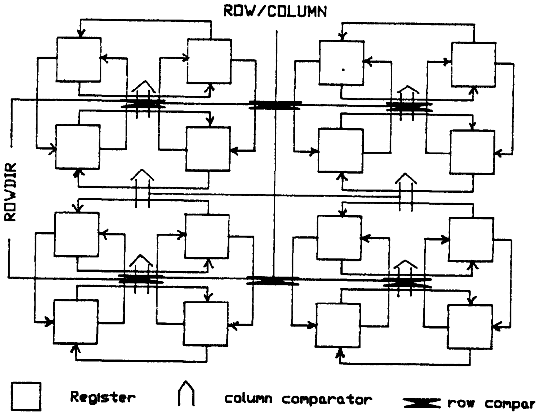

Figure 7. A regular VLSI layout for Shear-sort.

## V. Optimization of the shear sort

A further reduction in execution time for shear-sort is possible for a 'brick-wall' type sorting using a simple manipulation in the dimension of the array of $n^2$ elements. Recall from section III, that the band of 'dirty' elements keeps on shrinking by a factor of 2 in every iteration. This is the basis for an O(log m) (for an $m \times n$ array) iteration convergence. Thus, during the successive stages of the algorithm, it is enough to sort the elements in a column that fall within the 'dirty' band, instead of sorting an entire column during the column-sort stage. Another way of looking at it is that, since all the elements move within $\frac{m}{2^p}$ rows after p iterations (discussed more in [13]), we need to perform only $\frac{m}{2^p}$ steps of the brick-wall sort after p iterations.

For an $m \times n$ array, this means we perform m, m/2, m/4 .. iterations of brick-wall sort in successive column-sort stages. However, no such optimization seems possible for the the row-sort stage since the algorithm is non-adaptive so that we keep on performing all the 'n' compare-exchange steps throughout the course of execution. This yields a complexity of n(logm +1) + 2(m - 1) compare exchange steps. For $n^2$ elements, this can be expressed as

$$\frac{n^2}{m}(logm + 1) + 2(m - 1)$$

By choosing m = $\frac{n\sqrt{logn}}{\sqrt{2}}$, we get a complexity of

$$O(\ 2\sqrt{2}n\sqrt{logn} + \frac{nloglogn}{\sqrt{2logn}}\ )$$

The second term can be approximated to o(n) since $\frac{loglogn}{\sqrt{logn}} = o(1)$, thereby yielding the following result:

**Theorem 3:** A rectangular array of $n^2$ elements can be sorted using shear-sort in time proportional to O( $n\sqrt{logn}$ ).

The behavior of this function is very close to linear since $\sqrt{logn}$ is less than 5 for well over tens of millions i.e. more than the practical size of any sorting chip. In fact it outperforms most of the well-known algorithms for number of elements below a couple of tens of thousands which is not rare in practical situations. The cautious reader may have noticed that an extra compare exchange step is needed during the column sort stage depending on the boundary of the dirty band. If the dirty band starts from an even row during all the iterations of column sort the complexity function will be affected by an additional log m steps, which is negligible.

This improvement can be very easily incorporated into the VLSI implementation shown in Figure 7. The number of iterations of odd-even transposition sort during row and column sort stages can be easily controlled by the number of 'oscillations' between adjacent rows(columns) of comparators.

## VI. Conclusions

The feasibility of sorting a rectangular array of elements by sorting rows and columns was demonstrated. The algorithm was shown to execute in at most O(log m) iterations and in section III we traced the data movement during each iteration. Recall that we showed that all elements moved within O( $\frac{m}{2^p}$ ) rows of their final destination row in O(p) iterations. Also taking advantage of this phenomenon it is possible to optimize a simple algorithm like bubble sort. Sorting a row(column) is actually sorting $\sqrt{n}$ elements in a n element sequence which may be expensive. However this basic operation may be optimized by using a sorting network as was demonstrated in section IV. The complexity of this algorithm is more appropriately expressed as O ( $\sqrt{n} \times k \times \log n$ ) for an 'n' element sequence organized as a square array, where k is the time for sorting $\sqrt{n}$ elements and this is O( $\sqrt{n} \log n$ ) for a single processor sort which was used as a basis for the multiprocessor implementation. For the sorting network allowing pipelining this turns out to be O( $(\sqrt{n} + k) logn$ ) which at the best will give us a time of O( $\sqrt{n} \log n$ ).

This algorithm can be also executed effectively in any MIMD type machine which allows independent access to rows and columns in a shared memory model. A multiprocessor architecture which can implement the algorithm elegantly because of its orthogonal access to the memory banks and originally conceived as a high performance graphics system which can draw very fast vectors of any orientation ([11]) is discussed in Scherson & Sen[13]. In a similar architecture, Tseng et al.[12] propose a combination of bitonic sort and a single processor O(nlogn) sort, which can achieve identical complexity figures when implemented on mesh-connected processors. That process also sorts rows and columns in successive stages though it requires a more complicated control structure being recursive in nature. The direction of sorting in rows change dynamically in successive levels of recursion, as also does the number of independent sequences in the columns.

In an effort to optimize the algorithm further, by trying to reduce the cost of sorting entire rows and columns by partial sorting an interesting variation is mapping a two dimensional odd-even transposition sort on this row-major snake-like indexing scheme. Each iteration will consist of performing compare-exchange on elements ( $x_{2i-1,j}$ , $x_{2i,j}$ ) on all rows independently followed by the same procedure on all the columns ( $x_{i,2j-1}$ , $x_{i,2j}$ ) and then repeating the same with the elements ( $x_{2i,j}, x_{2i+1,j}$ ) in all rows and elements ( $x_{i,2j}, x_{i,2j+1}$ ) in all columns. It is not difficult to see that such an algorithm will result in a sorted sequence. It was speculated in [13] that the upper bound for the number of iterations may be $\sqrt{n}$ giving an optimal and an even simpler algorithm. However it turns out to be totally inefficient running into O(n) iterations like a normal bubble-sort which makes us hopeful about the optimality of shear sort within similar variations.

## Abstract

A methodology to derive trace-driven simulations on a uniprocessor for evaluating the performance of parallel algorithms in multiprocessors is described. Based on the desired degrees of accuracy and speed of the evaluation, we interleave the independent traces, which are obtained by actually running each of the cooperating processes on a uniprocessor and capturing global events. Since only global events are captured, data reduction is very high. Using this trace, we can extract parameters which are applied to a variety of progressively refined analytical and hybrid models to study the impact of algorithmic and architectural features on performance. Finally, design spaces of architectures and algorithms can be explored through successive refinements of the simulations.

## 1. Introduction

Multiprocessor systems are emerging in the commercial world as cost-effective systems for satisfying throughput demands of the mini and supermini markets [ARC85]. It is foreseen that such systems can deliver not only throughput, but also speed-up. Many languages have been developed to take advantage of multiprocessor systems [AND83, BAR83, TED84]. They introduce the notion of a process to the users of these machines. The execution of a program can be implemented by a set of concurrent and cooperating processes running simultaneously on different processors. Speed-up can thus be obtained for a given program and not only for a batch of programs.

Many results have been derived on the computation complexity of parallel algorithms [HEL78, KRU83, GAN84]. However, the interaction between software and hardware is so complex in MIMD machines that simple complexity studies are often inadequate. Some attempts at modeling some algorithms on specific multiprocessors are presented in [DUB82a-b, VRS84, VRS85]. However, concurrency control mechanisms in the algorithm, such as scheduling and synchronization, and data allocation effects are most of the time neglected for reasons of analytical tractability. Moreover, it is not clear how the parameters used in the models can be estimated. Simulation technique is often the method of choice to verify analytical approximations. Of course, the most accurate evaluation method is measurement on an actual prototype[GEH82].

Some major simulators have been implemented to predict the performance of algorithms on multiprocessors. The first one, developed at Lawrence Livermore Laboratory[AXE84], uses a trace-driven approach but traces every instruction with the detailed model of the S-1 multiprocessor. Therefore, the simulation is complex and must contain hardware timing information which is specific to the S-1. The NYU simulator is also an instruction level simulator[ABR84], written in CDC Cyber assembly language. The Cedar simulator[ABU85], written to take advantage of Parafrase[KUC84], allows the user to select statements whose execution may be simulated. A parallel algorithm simulator, called PSIMUL, was written at IBM[SOK86]. This is also an instruction level simulator, but with no timing facility. The trace is produced by interleaving blocks of records of the individual traces of each process, where the size of each block is determined by the time slice interval on the host machine.

In this paper, we present a different methodology for developing trace-driven simulations of the execution of algorithms in multiprocessor systems. It is not specific to any particular architecture and hence can be used to evaluate different machines. The only limitation we impose is on the computational model which is described in the next section. The complexity of the trace-driven simulations as presented here is intermediate between the complexity of analytical models and detailed, cycle-by-cycle simulations. In our methodology, every instruction of the algorithm is executed. However, only global events are traced. Depending on the accuracy desired, the interleaving of the individual traces is derived from virtual or real time components. The trace is then applied to the performance prediction. In our technique, we extract values for algorithmic and architectural features from the trace and apply them to analytical or hybrid simulation models to predict the performance. Of course the detailed simulation with real timing is also accomodated and is necessary for the validation of the more approximate models.

The paper is structured in two parts. In the first part, the computational model and the basic multiprocessor environment we assume is described. In the second part, the architecture for the simulator is analyzed and different levels of complexity of simulations are identified through a careful analysis of the tasks involved in the trace-driven simulation of multiprocessor programs.

## 2. Computational Model and General Hypotheses

Parallel and distributed algorithms can be classified broadly in two classes, with respect to the complexity of analyzing their performance: *data-independent* and *data-dependent* algorithms. In data-independent algorithms the

0190-3918/86/0000/0909 $01.00 © 1986 IEEE

performance is independent of the *values* of the data. These algorithms include many numerical algorithms. The performance of data-dependent algorithms depends on the *values* of the data. Such algorithms which include most symbolic algorithms are more difficult to analyze than data-independent algorithms because of the large number of configurations to consider. Compounding this difficulty is the possibility that the data-dependent algorithm may be non-stationary; that is, the behaviour of the algorithm execution varies with time.

The parallel programming model we will use is based on practical concurrent programming language constructs [AND83]. The model allows the user to specify the concurrency and cooperation between the processes of the program. This technique is different from the compiler generated parallelism which have been shown to be effective for numerical algorithms[KUC84], but performs somewhat poorly on nonnumerical algorithms[LEE85]. The poor performance may be due to the fact that most nonnumeric algorithms are data-dependent and often non-stationary. Therefore, the programming model adopted here is all the more applicable to nonnumeric algorithms.

It is assumed that each processor has a large instruction cache or memory so that accesses to program code and local variables are done locally and do not generate global traffic. This assumption is justified by the fact that the program size for the algorithms considered here is usually very small compared to the total number of data accessed. If an algorithm does not fit this description, then the modeling technique must be refined to include instruction fetches.

In the type of machine envisioned in this study, the operating system is minimum. The multiprocessor is used as an attached multiprocessor. Basic operating system mechanisms supported by the methodology described here are flexible enough to support most, if not all, possible algorithms. These mechanisms are for process scheduling, sychronization, and communication[LIN81,DUB82b]. In addition to these mechanisms, data partitioning and allocation, and process granularity may also affect the performance of the algorithm[JON80, GAJ85]. The effects of these mechanisms can be derived from the global trace events by scanning the event attributes in order to extract statistics for the multiprocessor. The computation homogeneity or heterogeneity of the set of concurrent processes is also an important feature of the algorithm. Analyzing heterogeneous computations analytically is often impractical.

In a multiprocessor system, scheduling may be static or dynamic. Both scheduling mechanisms are therefore supported by the methodology. In the static scheduling policy, the binding between processors and processes is determined at compile time. Static scheduling has low runtime overhead but is less flexible and often results in poor load balancing. In the dynamic scheduling policy the time of binding of processors to processes is delayed until runtime. A process can be executed by any processor that becomes available. Dynamic scheduling results in more runtime overhead but also in better load balancing.

In the attached processors under study, scheduling support is minimum. Therefore, the system relies on self-scheduling by the application program as performed in the HEP multiprocessor via a local or global ready list[GAJ85, SMI81]. In this case, the processes participating in the algorithms execute code to fork other processes and to access the job queues. In the static scheduling, each process is forked on a specific processor, determined at compile time and the process runs to completion on the designated processor. Each processor has a run list. When a process forks a new process on a different processor, it puts a descriptor for the process in the queue of the target processor and executes a static_fork instruction. The effect of this instruction is simply to wake up the target processor in case it is idling. The target processor automatically reads the top of its run list, loads the descriptor and starts execution.

In the more complex, dynamic scheduling case, a run list is shared by several processors. The dynamic_fork procedure is somewhat similar to the static_fork procedure but, the job descriptor is put in the shared run list if an attempt to bind the new process to a processor fails because there is no free processor.

In both static and dynamic scheduling, a processor that terminates a process attempts to get a new descriptor from the private or shared list before entering the idle state. The termination of a process is indicated by the execution of a *terminate* primitive.

Our methodology is applicable to most practical multiprocessor architectures. These include shared-memory multiprocessors and distributed systems with or without cache memories. For multiprocessors with cache memories, the impact of software or hardware-enforced coherence on algorithm performance can be evaluated since only global events may cause *cross-interrogates* [DUB82c].

The basic set of language constructs we have used to support multiprocessing are the process creation and control primitives: *fork/join, suspend, activate, create, terminate and resume.* In addition, we provide simple synchronization primitives such as *spin-lock, suspend-lock* and *unlock*. Knowing that each synchronization primitive has its own advantages and disadvantages, we also provide other data-level primitives such as *fetch-and-add* [GOT83], *full/empty bit* [SMI81]. For distributed systems, message-based primitives such as *send/receive* [SHA84] are used.

## 3. Modeling Methodology

The methodology uses a hybrid and hierarchical approach to modeling by incorporating trace-driven simulations and analytical models[SCH78, KUM80]. In a multiprocessor, the events to trace are accesses to shared data or message-passing through the network. However, the methodology allows for the tracing of *any* selected set of events.

### 3.1. Interleaving of the traces

In order to evaluate the performance of arbitrary parallel and distributed algorithms on proposed or existing multiprocessors, the traces must be generated through the interpretation of the multiprocessor algorithm. This is especially important for algorithms whose behavior is highly sensitive to data values. Therefore the traces are derived *while* the multitasked algorithm is executed.

The events of importance in a multiprocessor system are accesses to shared data (and, in particular, synchronization), message-passing operations, and the creation and purging of processes. In between the execution of such events, processors execute locally and do not affect each other. One problem is to interleave the traces of events generated by each processor. This interleaving is needed because the simulation technique described here is a technique for a uniprocessor system.

This section analyzes three levels of accuracy in trace interleaving: interleaving based on rank, on a virtual time approximation or on physical time.

### 3.1.1 Rank Interleaving

A first approach is to interleave the P traces according to the rank or position of each event in each individual processor trace. Assume that the P processors are ordered in an arbitrary sequence and numbered from 0 to P-1. In the interleaved trace, global event $k$ in processor j occupies position $kP+j$. This interleaving techniques is said to be ***based on rank***. This approach is acceptable for simple multitasked algorithms where the computation is homogeneous, and the real elapsed time between two successive events is approximately the same for all processors at any given time. This is the case for the simple PDE example given in section 5 of this paper. It is an unacceptable approximation for more complex algorithms such as quicksort, in which the execution behavior of the processors is not homogeneous all the time.

### 3.1.2 Virtual-Time Interleaving

To improve the reliability of the simulation, the traces are interleaved according to the rank of each event in its trace and according to a timing estimate such as the instruction count between two events generated by a process. We call this interleaving an interleaving based on a ***virtual time approximation*** [LAM78, JEF83]. The reason is that the timing estimate is not a physical time. In this technique, the trace for each processor is a set of records of the type

$$< pn\ ,\ e\ ,\ \delta t\ ,\ parameters\ >.$$

$\delta t$ is an estimate of the time complexity of the work (in number of instructions, or in number of instruction cycles) performed by the processor since the last global event from the processor. In our facility, we derive this number of instruction cycles from a mechanism first developed at AT&T Bell Laboratories[WEI84] and modified at Rice University[JUM85]. $pn$ is the number of the processor causing the event, $e$ is the event type and *parameters* are the parameters of the event. Examples of event types include fetch, store, test_and_set, block, fork and terminate. Parameters may be, for example, a shared-memory address, a process descriptor, or a run list pointer. Table 1 indicates the various trace events with a definition of their parameters. The virtual time approximation defines a partial ordering of the global events produced by the processors as follows. For processor j there are a total of $n_j$ events numbered $E_{j,1}$, $E_{j,2}$, ..., $E_{n,n_j}$ and the time between events $E_{j,i}$ and $E_{j,i+1}$ is $\delta t_{j,i} = \delta t + t_b$, where $\delta t$ is the virtual time increment given in the trace record and $t_b$ is the virtual time that the processor has been blocked since the last global event. Then, the virtual time for the $k$th event of processor j is denoted by $T_{j,k} = \sum_{i=0}^{k-1} \delta t_{j,i}$. By definition, the partial ordering is such that $E_{j,m} \leq E_{l,n}$ if and only if $T_{j,m} \leq T_{l,n}$. A partial ordering of events is not sufficient for the simulation because events having the same virtual time can only be scheduled one at a time in the multiprocessor simulator implemented on a uniprocessor. In order to define a total ordering of events, a selection algorithm is used to select among trace events having the same virtual-time stamp.

The interleaving based on the virtual time approximation is attractive because it is independent of actual multiprocessor organization, data allocation strategies, and technological parameters. It only depends on the algorithm and on the uniprocessor architecture. If it is valid, the interleaved trace may be reused multiple times to study various system configurations and technology trade-offs. This aspect has been a major advantage of trace-driven simulations for the analysis of uniprocessor systems. In the analysis of multiprocessor systems this advantage may be lost in some cases because of a phenomena called ***trace-shifting*** and explained below.

### 3.1.3 Trace-Shifting Phenomena

In the virtual time approximation, the effect of the multiprocessor environment is not included in the algorithm to interleave the traces. There are many ways in which the system under study may affect the interleaving of the traces. For example, in a cache-based system a cache miss in a processor delays the occurence of the next global event in this processor, and therefore affects the interleaving of events. If this effect is symmetric with respect to all the processors (i.e. if the same type of delay is encountered by all processors at some random times), then the virtual time approximation is valid. When the effect is not symmetric over a long period of the simulation, a long-term phenomena called ***trace-shifting*** may occur in which the traces get out of phase as compared to the order of execution on the real machine. For example, in the cache-based system, some processor may be in a phase in which misses occur in bursts because it is accessing a new data structure; in a distributed global memory system, such as the Cm*[GEH82], trace shifting may occur if the data is allocated asymmetrically, even if all the processors are performing the same work. For example, if all data are stored in the memory of processor 0, processor 0 will access memory faster and therefore, in the real system, it will execute faster than the other processors. In the simulation, however, all processors would execute at the same speed. Therefore, the trace of processor 0 has shifted with respect to the P-1 other traces. Trace shifting may result in considerable errors in some cases. For data-dependent algorithms and dynamic scheduling, it may result in a totally different execution sequence as compared to the execution on the real machine.

### 3.1.4 Physical-Time Interleaving

In general, the only way to avoid trace shifting is to include physical (real) timings in the trace-interleaving algorithm. We call this type of interleaving an interleaving based on ***physical time***. First, the "$\delta t$" provided in the trace record of the individual processor traces must be a physical time estimate as accurate as possible. Second, a penalty must be added to account for data access delays such as cache miss penalty or remote memory access penalty. The penalty depends on various factors including the multiprocessor configuration, data allocation and technology parameters. A fixed penalty for each access type may also result in trace shifting, because of conflicts for shared-resource accesses. If some processors are systematically conflicting while accesses from other processors are conflict-free, the traces will shift in the case where a fixed penalty is added for each access. The penalty should in this case be variable and include conflict delays. A full fledged simulation of the multiprocessor may be needed to determine accurately the total access delays through the interconnection network and through the memory system.

In some cases, when the algorithm interpretation is not affected by the shifting, the problem of trace shifting can be compensated for during the simulation. That is, traces can be realigned periodically: a total penalty is accumulated for each processor during the simulation; when the difference between the penalties becomes too large, the traces are synchronized by subtracting their total penalty from the time stamp of their next event.

### 3.1.5 On-the-fly and Off-line Tracing

Finally, tracing may be done *on-the-fly* or *off-line*. If it is done *on the fly* then the interpretation of the algorithm, interleaving of the traces, simulation and collection of statistics, are done in one single run. No trace file is derived, saved and reused. This mode of operation is desirable if the interleaving must be based on physical time, or if the overhead of handling large trace files (on tape or on disk) is large compared to the overhead of rederiving the trace each time. Note that the trace-driven approach is still applicable in this case even if the trace cannot be reused. Indeed, partitioning the simulation into two parts (the derivation of the trace and the simulation ) removes all local events from the global event list and results in increased efficiency. *Off-line* tracing is done in two phases. In the first phase, the interleaved trace is derived and stored in a trace file. The trace file may then be reused several times for multiple simulations of different system configurations, data allocation and/or technological parameters. The off-line interleaving of traces only makes sense when the trace is re-usable, i.e., when the interleaving is based on rank or on the virtual time approximation.

### 3.2. Description of Simulator Architecture

The simulator is divided into three types of modules (see Figure 1): the trace-generator, trace-scheduler, and MP-simulator. The function of a *trace-generator* module is to generate the trace records as they are requested by the scheduler module. For each algorithm and each partitioning strategy, one must write a set of trace generator modules. The *trace-scheduler* is the driver of the whole simulator: it determines the next process that will generate a trace record according to the trace interleaving strategy and a *selection algorithm,* it requests the next trace record from the selected process, and submits the record to the MP simulator. This last module may be a detailed simulation or a program to gather statistics of the dynamic behavior of the algorithm on the architecture.

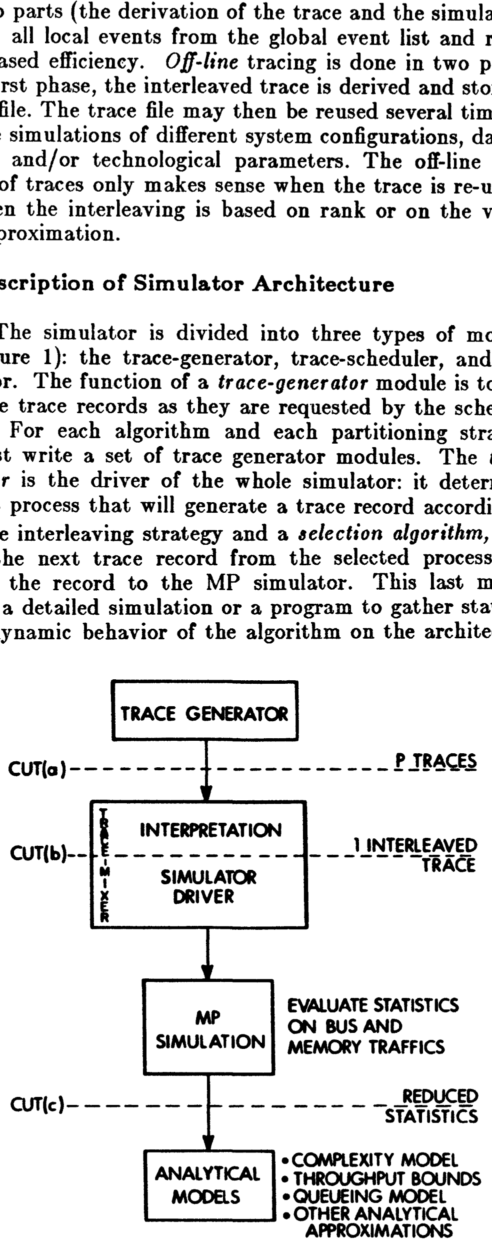

**Figure 1.** Activity flowchart of trace-driven simulation.

These statistics are then used as parameters in simple analytical models such as complexity, throughput or queueing models.

An activity flowchart for the overall performance analysis is also outlined in Figure 1. Several "cuts" are possible in the flowchart. A cut means that the simulation is run in two independent parts, and that intermediate results from the first part must be stored. A cut at (a) requires storing one or several files on tapes or disks, for each processor; a cut at (b) requires storing one single thread of trace records, a cut at (c) reduces the information that has to be stored to statistics such as mean traffic values, variance of memory service time, histogram of execution time between two successive global events.

Cuts at (a) and (b) result from off-line tracing while a cut at (c) results from on-the-fly tracing. Depending on the interleaving strategy, on the algorithm being traced, and on the overhead of file manipulation, a cut at (a) or (b) may be desireable in order to reuse the trace.

### 3.2.1 Trace-Generator Module

A trace-generator module of the simulator executes the process and produces each global event from that process. The process is written as a procedure specifying the task to be performed augmented by statements which log global-trace event records as these events are generated by the process. For each "forked" process there exists a *trace generator.* A trace generator is completely specified by a process and by a descriptor defining the data set to which the process is applied.

The implementation of a trace generator is based on the coroutine principle. Few basic functions are provided to facilitate the "forking", activation and suspension of the trace generators. The first function is called *fork* (proc, $p_1, p_2, \ldots, p_n$). This function creates and activates a process of type "proc" with the associated parameters $p_1, p_2, \ldots, p_n$, and returns a unique process identification number, *pid* . Subsequently, the process can start execution when the trace-scheduler performs a *transfer* (*pid*) to the process. The trace generator suspends itself and transfers control to the scheduler by executing a *suspend* (). This is essentially a coroutine call to the trace scheduler. In the trace generator, a trace event is logged into the event list of the scheduler by *log_event* (pn,event_type, time_incr,parameters). The "time_incr" attribute is the virtual or physical time increment from the last event logged by that processor. The next time the trace scheduler schedules the trace generator for event production it again executes a *transfer* (*pid*). These and other primitives were packaged into a Concurrent C preprocessor[MAD86].

### 3.2.2 Trace-Scheduler Module

The trace scheduler is designed to invoke the trace generators. Its first function is therefore the interpretation of the multitasked algorithm. The second function is to produce a single thread of totally ordered events from the partially ordered set resulting from the interpretation.

The trace scheduler maintains four types of lists: the event list, ready list, run list and the blocking lists. The run list, which could be local or shared, contains the set of forked processes waiting for a processor. The blocking lists support blocking synchronization primitives such as suspend-locks and synchronous message primitives. The event list contains at every time as many nodes as there are active processors in the multiprocessor. A node of the event list includes a processor_number field, an event descriptor field, a time stamp field, and other parameters. The time stamp is computed on the basis of the time increment provided in the trace record and the system time at the arrival of the event. Nodes in the list are ordered according to increasing time stamp values. The scheduler selects the processor whose node is at the top of the list as the producer of the next global event. If several events at the head of the event list have equal time stamps, then these events are moved to the ready list where a ***selection algorithm*** is invoked to schedule the events in the ready list in turn. Possible selection algorithms are round-robin, priority, or random; the choice of an algorithm should reflect the interconnection network arbitration protocol.

At initialization of the scheduler, the first event, "start", and the process identification corresponding to the algorithm to be run is placed in the event-list. While the ready list is not empty one event at a time is selected for event processing based on the event type in the multiprocessor simulator. The processor which issued that event is then resumed to generate the next trace event, which is logged into the event list. When the ready list is exhausted, the scheduler starts a new cycle by moving events with equal time stamps to the ready list for scheduling. Note that if the application has been correctly interpreted, the algorithm terminates when the event list is empty.

The possible event types for the scheduler are given in Table 1. In the following, the implementation of some of these primitives in the trace scheduler are discussed. On a read, write, test_and_set or a reset event type, the scheduler simply submits the request to the MP simulator and then invokes the next trace element. Programs for spin_locks and suspend_locks are given in Figure 2. A suspend_lock is more difficult to implement and requires the additional primitive ***block*** (x) to indicate to the trace-scheduler that the execution of the process is to be suspended. The scheduler puts the processor in a blocking list associated with x, and thereby suspends it from invoking its trace generator. On executing an ***unblock*** (x) in a trace generator, the scheduler randomly selects one of the processors blocked on x for reactivation by placing it in the event list.

**Table 1**

**Possible Trace events and their parameters**

| **Events** | **Parameters** |
|---|---|
| READ, WRITE,<br>TEST_AND_SET, RESET | x |
| BLOCK | x |
| FORK | p_id |
| TERMINATE | pn |
| START_PROCESS | p_id |
| STOP_PROCESS | p_id |
| SYNC_SEND, SYNC_RECEIVE | m, p_id |
| ASYNC_SEND, ASYNC_RECEIVE | m, p_id |
| SYNC_BROADCAST | m |
| ASYNC_BROADCAST | m |
| READF, WRITEE | x |
| FETCH_AND_ADD | x, d |

x: shared memory address; p_id: process identification; pn: processor number; m: message; d: increment.

To illustrate the use of these functions in implementing a trace generator, we consider the simple example of a parallel and dynamic *quicksort* performed on an array A[1....n]. A description of this algorithm is given in [DEM82]. In this paper we present a skeleton of the algorithm in Figure 3 and illustrate a segment of the implementation of the trace scheduler with dynamic forks in Figure 4. For simplicity, we have excluded all the necessary declarations and calls to the MP simulator. The quicksort routine picks up a "descriptor" from the run list via a spin-lock and splits up the array into two subarrays about a pivot elememt A[v] [BAA78]. A new quicksort process is forked to sort one of the subarrays while the current process sorts the other subarray. An array with a number of elements less than "threshold" is sorted by ***insertion sort.*** During the forking of the new process, a "descriptor" is also placed on the run list via a spin-lock.

```
/**********************************/
/* Microcode for spin_lock(x)     */
/* and suspend_lock(x)            */
/**********************************/
spin_lock(x)
{
   repeat y := test_and_set(x);
     until y = 0;
}
suspend_lock(x)
{
   y := test_and_set(x);
   if (y = 1) block(x);
}
/**********************************/
/* Trace generators for           */
/*spin_lock(x) and suspend_lock(x)*/
/**********************************/
gen_spin_lock(x)
{
      y := x;
      if (y = 0) x := 1;
      log_event(pn,"tas",2,x);
      suspend();
      while (y = 1)
      {
         y := x;
         if (y = 0) x := 1;
         log_event(pn,"tas",2,x);
         suspend();
      }
}
gen_suspend_lock(x)
{
    y := x;
    if (y = 0) x := 1;
    log_event(pn,"tas",2,x);
    suspend();
    if (y = 1)
    {
       log_event(pn,"block",b_time,x);
       suspend();
    }
}
```

**Figure 2.** Trace generators for spin_lock and suspend_lock.

The trace generator for the quicksort will include two statements wherever a reference to global data A[*] is made in the algorithm. These are *log_event* (pn,event_type,time_incr,parameters) and ***suspend*** (). Note that the trace generator for spin-lock, shown in Figure 2, will replace the spin-lock in the quicksort process. Complete analysis of the quicksort in multiprocessors with distributed global memory system can be found in [BAL86, PAT86].

### 3.2.3 Multiprocessor Simulator Module

The complexity of the multiprocessor simulator depends on the class of multiprocessor and the level of details of the simulation. We illustrate these complexities by considering single-bus multiprocessor architectures. The simulator collects statistics on the bus and memory traffic generated by the global events transmitted by the trace scheduler. The statistics collection for distributed systems and for systems with distributed global memory merely consists in the updating of traffic counters. The simulator for cache-based machines is by far the more complex. It must keep track of the cache contents and implement cache replacement and coherence algorithms. The cross-interrogate and traffic statistics may then be used in analytical models to compute the degradation on system performance during the execution of the algorithm.

```
quicksort(A,l,u)
{
pn = getmyPE();
dequeue(global_run_list) ;
while (( u-l) > threshold)
{
   v = split(A,l,u,pn);
   forkprocess(quicksort,A,l,v-1,pn) ;
   l = v + 1 ;
}
insort(l,u) ;
terminate(pn) ;
}

forkprocess(proc,A,l,u,pn)
{
pd = fork(proc,A,l,u) ;
enqueue(global_run_list) ;
log_event(pn,"fork",fork_time,pd) ;
suspend();
}

terminate(pn)
{
         log_event(pn,"term",delta_t) ;
         suspend()
}

dequeue(global_run_list)
{

## 4. Hybrid Simulation Models

The traffic estimates obtained through enumeration of bus access or shared memory access events in the simulation trace can be used in analytical models. The analytical model can be as simple as throughput bounds or queueing models. Many models have been developed to analyze the performance of multiprocessors once the traffic and latency values are known[HOO77,DUB82a,MUD84].

In general, the more precise an analytical model is, the more system parameters are needed. Also, the model may become quite complex to exploit. We feel that a great deal of information on the performance of multitasked algorithms can be obtained by simple throughput bounds.

The models in which the parameters are estimated as averages over the entire run of the application is only valid when the computation is approximately *stationary* in time. By stationary, we mean that its execution behavior with respect to causing the global events remains constant during the overall processing. If the behavior varies (such is the case for the sorting algorithm, which is non-stationary because the decomposition varies during the execution), then the models presented above must be applied successively to the different *phases* of the algorithms. During each phase, it is considered that the characteristics of the computation remain constant.

```
trace_scheduler()
{
Initialize ;
pd = fork(quicksort,A,l,u) ;
log_event(NULL,"start",0,pd) ;
while (event_list NOT NULL )
{
   EVENTS_TO_READY_LIST ;
   rdy_ptr = get_next_ready_event ;
   while (rdy_ptr NOT NULL)
         {
         pd_old = bind[rdy_ptr -> pn];
         CASE(rdy_ptr -> type)
"start":pn = get_PE_pool() ;
         pd = rdy_ptr-> parameter ;
         bind[pn] = pd ;
         Q_global_run_list(rdy_ptr) ;
         transfer(pd) ;
         break ;
"fork": Q_global_run_list(rdy_ptr) ;
         pn = get_PE_pool();
         if(pn NOT NULL)
         {
           pd = rdy_ptr -> parameter ;
           bind[pn] = pd ;
           transfer(pd)   ;
         }
           transfer(pd_old) ;
         break ;
"term": transfer(pd_old)    ;
         if (global_run_list NOT NULL)
         {
            pn = rdy_ptr -> pn ;
            rdy_ptr = D_Q_global_run_list ;
            pd = rdy_ptr -> parameter  ;
            bind[rdy_ptr ->pn] = pd ;
            transfer(pd) ;
         }
         else
         {
            bind[rdy_ptr ->pn] = NULL ;
            ret_PE_pool(rdy_ptr ->pn) ;
         }
         break ;
"block":x = rdy_ptr ->parameter ;
         block(rdy_ptr,x) ;
         break ;
"unblock":x = rdy_ptr ->parameter ;
         rdy_ptr = random_select(x);
         pd = search(rdy_ptr ->pn) ;
         transfer(pd) ;
         transfer(pd_old) ;
         break ;
         }
         M_P_Simulator(rdy_ptr) ;
         rdy_ptr = get_next_ready_event ;
         }
   }
}
```

### 4.1 Example

Below a grid relaxation algorithm for solving numerically partial differential equations is described and executed for the hybrid simulation. This example is an illustration of the methodology for a simple algorithm on a complex machine (i.e. a cache-based system). A complete analysis for different cache and coherence mechanisms can be found in [DUB85].

Grid relaxation is an iterative technique to solve partial differential equations (PDEs) numerically. The traditional example chosen to compare algorithms and implementations for PDE solvers is Laplace's equation on a square domain of $R^2$, and is referred to as the *model problem* [YOU71]. The problem is first discretized on a square grid. In the Jacobi iteration, the computation consists in repeatitively computing the average of the four N-, E-, W-, and S-neighbors at each grid point. Therefore, the (K+1)th iterate is computed as

$$x_{i,j}^{K+1} = \frac{1}{4}\left[x_{i+1,j}^{K} + x_{i-1,j}^{K} + x_{i,j+1}^{K} + x_{i,j-1}^{K}\right]$$

Two copies of the grid, U and V, are maintained. In each iteration, a copy is updated by using the iterate values of the other copy. Then the two copies are interchanged. This is an example of a synchronized algorithm. This algorithm can also be implemented as an asynchronous algorithm in which the latest iterate values are used [KUN76]. Let $N^2$ be the size of the square grid. A partition can be described in terms of $P$ blocks, where $P$ is the number of processors. $P=p^2$, where $p$ is the number of blocks on each side. The boundary conditions add a total of $4N$ fixed iterate values to each grid, so that the total number of values for each grid is actually $N^2+4N$.

This algorithm is an example of a data-independent algorithm with homogenenous decomposition. A simple interleaving based on rank was applied for its simulation.

The trace was then used to study the performance of a bus-oriented multiprocessor system caches. For the *write-through* system, the memory is updated on each write, and no space is allocated in the cache on a write miss. Each write cycle on the bus is read by all the processor nodes and caches are invalidated when they contain a copy of the modified block[PAT82].

There are two types of events causing accesses to the bus: read misses and writes. Let $M$ be the total number of misses and $W$ the total number of writes in all the caches for one iteration. Note that $W=N^2$. If $C_{rb}$ and $C_w$ are the number of bus cycles required per cache block read and word write respectively, the total bus traffic due to global data accesses per Jacobi sweep is the sum of the miss traffic and the write traffic and can be written as

$$Traf\ (p,q)=MC_{rb}+N^2C_w \qquad (4.1)$$

This traffic places an upper bound on the execution speed because of the limited bus bandwidth.

Let $T_{rb}$ and $T_w$ be the processor wait time for a read miss and for a write in the absence of conflicts, respectively. Also, let $m_i$ be the total number of misses per iteration in processor $i$. A lower bound on the iteration time is obtained by neglecting all the bus conflicts.

$$T_{ite}\,(p,q)=t_0+\frac{N^2t_1}{P}+T_{rb}\ \underset{0\leq i<P}{Max}[m_i]+\frac{N^2}{P}T_w \qquad (4.2)$$

In (4.2), $t_1$ is the time to update one iterate when all operands are in cache, $t_0$ is a fixed time, independent of the decomposition. The maximum of "$m_i$" is used because the process with the worst case computation time determines the duration of the iteration in a synchronized algorithm[KUN76].

From the trace-driven simulator we can evaluate $M$ and $m_i$ for different values of $P$ and various cache configurations. The values obtained through simulation can then be substituted in (4.1) and (4.2).

## 5. Conclusion

Understanding the behavior and the performance trade-offs of multitasked algorithms in multiprocessor machines is a very difficult task. Many authors have tried to develop stochastic models. But such models are too general to be applicable to specific algorithms. Performance issues such as the impact of synchronization techniques, scheduling methods, and partitioning and allocation strategies cannot easily be mapped onto simple analytical models. This is specially true for data dependent algorithms, heterogeneous decompositions, or dynamic scheduling. Full-fledged cycle-by-cycle simulation of the multiprocessor is very tedious, especially if the goal of the analysis is to understand the performance of the multiprocessor for very large configurations of multiprocessors and very large problem sizes.

In this paper, we have presented an intermediate approach, namely a trace-driven, approximate simulation of the problem on the multiprocessor. The simulation yields results such as the total number of events of given types. These event counts are then introduced in throughput bounds or approximate analytical models to evaluate the approximation to the desired performance measure of the algorithm. The approach presented in this paper provides a general methodology, with which simulations and analytical models may be refined and validated progressively, from the complexity models to the cycle-by-cycle simulation.

The methodology has been applied to the grid relaxation and static and dynamic quicksort problems. These examples were presented here to illustrate the methodology. Extensive results can be found in the referenced technical reports.

# DELTA TRANSFORMATIONS TO SIMPLIFY VLSI PROCESSOR ARRAYS FOR SERIAL DYNAMIC PROGRAMMING†

*Richard J. Lipton*
*Daniel Lopresti*

Department of Computer Science
Princeton University
Princeton, NJ 08544

## Abstract

We introduce a technique for transforming certain dynamic programming algorithms into ones which are in some sense equivalent, but require asymptotically less space and time under a logarithmic cost criterion. When mapped into silicon, these transformed algorithms result in VLSI processor arrays which are significantly smaller and faster. We illustrate the discussion with a general case of serial dynamic programming and briefly describe other, nonserial, applications in pattern matching.

## Introduction

VLSI processor arrays are often application-driven; the structure of the algorithm and the domain of the problem dictate the complexity of the hardware needed. Algorithmic structure has been used to simplify communication requirements. We show how structure in the problem can be exploited to simplify the computation itself.

Throughout the following complexity analysis we shall use the logarithmic cost criterion [1], an appropriate measure for algorithms to be implemented in VLSI. The cost of storing a non-negative integer $i$ under the logarithmic criterion is

$$l(i) = \begin{cases} 1 & if\, i = 0 \\ \lceil log_2(i) \rceil & if\, i > 0 \end{cases}$$

and the cost of evaluating a primitive function $f$ (e.g. addition or comparison) is the sum of the costs of its operands

$$l(f(x_1, x_2)) = l(x_1) + l(x_2)$$

### The Serial Dynamic Programming Problem

The general case of a problem solvable by serial dynamic programming can be expressed as

$$\min_X f(X) = \min_X \sum_{i \in T} f_i(X^i)$$

where

$$X = \{x_1, x_2, \dots, x_n\}$$

is a set of discrete-valued variables, $S_i$ is the definition set of $x_i$ ($|S_i| = \sigma_i$), and

$$T = \{1, 2, \dots, n-1\}$$

are the time instances of the problem. We wish to minimize the objective function $f$ over all schedules $X$ subject to the serializing constraint

$$X^i = \{x_i, x_{i+1}\}$$

The $f_i(X^i)$ are components of the objective function [2].

It may be helpful to observe that this formulation is fully equivalent to the problem of finding a shortest (i.e. lowest cost) path through a multistage graph with edge weights determined by

$$c_{i,j,k} = f_i(x_{i,j}, x_{i+1,k}) \quad 1 \le i \le n-1, 1 \le j \le \sigma_i, 1 \le k \le \sigma_{i+1}$$

where $x_{i,j}$ is the $j^{th}$ value $x_i$ assumes in some standard ordering. We interpret $c_{i,j,k}$ as the cost of traversing the edge from the $j^{th}$ vertex in the $i^{th}$ stage to the $k^{th}$ vertex in the $i+1^{st}$ stage.

### The Problem Restricted

For the development which follows, we make two assumptions which restrict this most general problem. The first, strictly for analytical convenience, is that

$$\sigma_i = 1 \quad i = 1, n \quad and \quad \sigma_i = m \quad 2 \le i \le n-1$$

so that we consider only graphs which have $n$ stages, with one vertex (or "node" or "state") in the first and last stages and $m$ vertices in each of the intermediate stages. Such a graph is shown in figure 1.

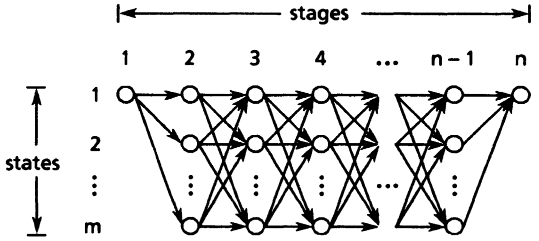

*figure 1.* a multistage graph

The second assumption is a necessary condition for the transformations we present. It is that

$$c_{i,j,k} \in N \quad and \quad 0 \le c_{i,j,k} \le C$$

for all $c_{i,j,k}$. That is, we assume the edge weights can be represented as elements chosen from a finite set of non-negative integers, and we know in advance their maximum value. This is a highly restrictive assumption, but one which reflects real-world conditions. Since programs and processor

† This research was supported in part by DARPA under contract N00014-82-K-0549.

0190-3918/86/0000/0917 $01.00 © 1986 IEEE

arrays have limited resources, we often know (or at least must require) bounds on the edge weights.

### A Dynamic Programming Solution

The shortest path through a multistage graph can be found using a backward recurrence with initial conditions

$$r_{n-1,j} = c_{n-1,j,1} \qquad 1 \le j \le \sigma_{n-1}$$

and iterative step

$$r_{i,j} = \min_{1 \le k \le \sigma_{i+1}} \left[ r_{i+1,k} + c_{i,j,k} \right] \qquad 1 \le i \le n-2,\, 1 \le j \le \sigma_i$$

where $r_{i,j}$ is the length of the shortest path from the $j^{\text{th}}$ vertex in the $i^{\text{th}}$ stage to the lone vertex in the $n^{\text{th}}$ stage. We shall refer to this recurrence as the *standard serial dynamic programming algorithm*.

### Space and Time Complexity

Since the edge weights of the graph lie between 0 and $C$, the cost of a path from a vertex in the $i^{\text{th}}$ stage to the vertex in the last stage can range from 0 to at most $(n-i)C$. We remark that after the optimal costs for the $i+1^{\text{st}}$ stage are used to determine those in the $i^{\text{th}}$ stage they can be forgotten. Thus, the storage required is approximately

$$ml((n-3)C) + ml((n-2)C)$$

bits, which means the space complexity is $O(m\log n)$.

For the time complexity, we note that an addition in the $i^{\text{th}}$ stage requires time $l((n-i-1)C) + l(C)$ and a comparison requires $2l((n-i)C)$. Since determining the cost of the optimal path for each of the $m$ nodes in the second through the $n-2^{\text{nd}}$ stages requires $m$ additions and $m-1$ minimizations, the intermediate stages contribute

$$\sum_{i=2}^{n-2} \left[ m^2[l(n-i-1)C + l(C)] + m(m-1)[2l((n-i)C)] \right]$$

which is $O(m^2 n\log n)$. Determining the optimal path from the vertex in the first stage requires $m$ additions and $m-1$ minimizations, and so contributes

$$m[l(n-2)C + l(C)] + (m-1)[2l((n-1)C)]$$

which is $O(m\log n)$. Hence the time complexity of this algorithm is $O(m^2 n\log n)$.

### Mapping the Recurrence into Silicon

Li and Wah [3] present a VLSI processor array for serial dynamic programming which is quite general, at the expense of failing to exploit all of the potential parallelism. The architecture itself is based on the observation that the inner loop step of the algorithm is equivalent to an inner-product in the closed semiring (N, *min*, +, ∞, 0). Hence, the problem can be solved as a sequence of matrix-vector multiplications, where the additive step is minimization and the multiplicative step is addition. The array is depicted in figure 2.

To determine the shortest paths for vertices in the $n-2^{\text{nd}}$ stage, the multiplicand vector is shifted through the array while the cost matrix for that stage is applied and the product vector accumulates. For the next stage, the product vector is shifted while the multiplicand vector remains stationary. This alternation continues; on the last pass the cost vector corresponding to the first stage is input and the final value of the shortest path is accumulated in the first processor.

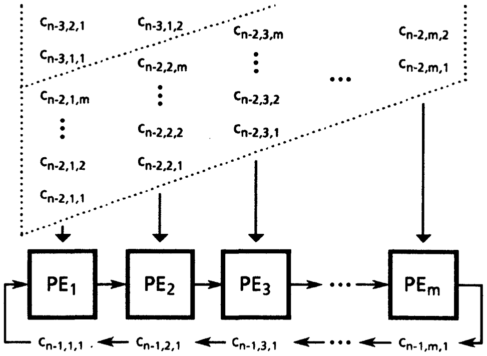

*figure 2.* VLSI array for serial dynamic programming

This parallel architecture requires $m$ processors. The first must be able to store values which can be as large as $(n-1)C$, the others as large as $(n-2)C$. Hence, each processor requires area $O(\log n)$, so the area of the entire array is $O(m\log n)$.

The time for the array to complete the computation is determined by that of the first processor, since it performs both the first and last operations. In processing the $i^{\text{th}}$ stage, it must perform $m$ additions which require time $l((n-i-1)C) + l(C)$ and $(m-1)$ comparisons which take $l((n-i)C)$. Thus, the time required is

$$\sum_{i=1}^{n-2} \left[ m[l((n-i-1)C) + l(C)] + (m-1)l((n-i)C) \right]$$

which yields a time complexity of $O(mn\log n)$.

### The Delta Transformation

We now proceed with the main result of this paper, the development of which we illustrate with the serial dynamic programming problem. The knowledge that the edge weights in the multistage graph are known to have a fixed range is powerful; it permits us to transform the standard algorithm into one which requires asymptotically less area and time under the logarithmic cost criterion.

### The Residue Reduction

We first observe that the bound on edge weights constrains the maximum difference between terms which appear in a minimization.

**Lemma 1:** the difference between any two terms which appear in a minimization in the standard serial dynamic programming algorithm is at most $2C$. That is,

$$\max_{i,j,k_1,k_2} \left[ (r_{i+1,k_1} + c_{i,j,k_1}) - (r_{i+1,k_2} + c_{i,j,k_2}) \right] \le 2C$$

(for proofs of this and following lemmas and theorems, see [4]).

This fact can be exploited to make determining the minimum simpler. In particular, it is only necessary to examine low order bits.

**Lemma 2:** given three non-negative integers $x_1$, $x_2$, and $\delta$ such that

$$x_1 - \delta \le x_2 \le x_1 + \delta$$

choose any $\Delta$ greater than or equal to $2\delta+1$ and let $y_1 = x_1 \mathrm{mod}\Delta$ and $y_2 = x_2 \mathrm{mod}\Delta$. If we define

$$min_\delta^\Delta[y_1, y_2] = \begin{cases} min[y_1, y_2] & if\, max[y_1, y_2] - min[y_1, y_2] \le \delta \\ max[y_1, y_2] & otherwise \end{cases}$$

then

$$min_\delta^\Delta[y_1, y_2] = min[x_1, x_2] mod\Delta$$

Now we replace the standard dynamic programming recurrence with the following

$$r_{n-1,j}^\Delta = c_{n-1,j,1} \qquad 1 \le j \le \sigma_{n-1}$$

and

$$r_{i,j}^\Delta = \underset{i,j,k}{min_{2C}^\Delta} \left[ r_{i+1,k}^\Delta +_\Delta c_{i,j,k} \right] \qquad \begin{matrix} 1 \le i \le n-2, 1 \le j \le \sigma_i, \\ 1 \le k \le \sigma_{i+1} \end{matrix}$$

(where $+_\Delta$ is addition modulo $\Delta$) for any $\Delta$ greater than or equal to $4C+1$. Whence we arrive at the main result of this section.

**Theorem 1:** for $r^\Delta{}_{i,j}$ defined above

$$r_{i,j}^\Delta = r_{i,j} mod\Delta \qquad 1 \le i \le n, 1 \le j \le \sigma_i$$

That is, the new recurrence performs precisely the same computation as the old, only using values modulo $\Delta$. We call $r^\Delta{}_{i,j}$ so defined a *residue reduction*; it is a distillation of the original algorithm.

### The Path Augmentation

The residue-reduced algorithm does not give us the true cost of the shortest path through the graph, although it does determine its remainder modulo $\Delta$ correctly. We observe, however, that the costs for the $n-1$st stage (the initial conditions) are determined precisely as before. Consider picking an $r^\Delta{}_{n-1,j}$ as an initial sample and inductively walking a path through the residue values to determine the true cost, $r_{1,1}$. To this end, we state

**Lemma 3:** the difference between the costs of the shortest paths from vertices in any two consecutive stages is at most $C$. More specifically,

$$r_{i,j} - C \le r_{i+1,k} \le r_{i,j} + C$$

Now we make a second general observation; it concerns determining the true value of a non-negative integer given only the remainder of that integer modulo some value and the full value of another integer which is known to be close in magnitude.

**Lemma 4:** given three non-negative integers $x_1$, $x_2$, and $\delta$ such that

$$x_1 - \delta \le x_2 \le x_1 + \delta$$

choose any $\Delta$ greater than or equal to $2\delta+1$ and let $y_1 = x_1 \mathrm{mod}\Delta$ and $\mu = \mathrm{min}^\Delta{}_\delta[y_1, x_2\mathrm{mod}\Delta]$. If we define

$$aug_\delta^\Delta[y_1, x_2] = \begin{cases} x_2 - (x_2 mod\Delta -_\Delta y_1) & if\, \mu = y_1 \\ x_2 + (y_1 -_\Delta x_2 mod\Delta) & if\, \mu = x_2 mod\Delta \end{cases}$$

then

$$aug_\delta^\Delta[y_1, x_2] = x_1$$

By Lemma 3 we can augment the reduced recurrence along any path from the last stage to the first. If we want to retain the general interconnection scheme of the original matrix-vector multiplication array, we should make the augmenting values available in an end processor. A logical choice is the path along the top of the recurrence, corresponding to $r_{1,j}$, as these values are always available in the first processing element.

Now, to the residue recurrence given earlier we add

$$a_{n-1} = r_{n-1,1}^\Delta$$

and

$$a_i = aug_{2C}^\Delta[r_{i,1}^\Delta, a_{i+1}] \qquad 1 \le i \le n-2$$

We then assert

**Theorem 2:** for the recurrence defined above and any $\Delta$ greater than or equal to $4C+1$

$$a_i = r_{i,1} \qquad 1 \le i \le n-1$$

That is, this new recurrence correctly determines the values $a_i = r_{i,1}$ and in particular the cost of the shortest path through the graph, $a_1 = r_{1,1}$. We call the combination of a residue reduction and a path augmentation a *delta transformation.*

### Space and Time Complexity of the Delta Algorithm

The residue-reduced recurrence $r^\Delta{}_{i,j}$ requires storage of $l(\Delta)$ bits for each value. As before, the space complexity is determined by that required to compute one stage of costs. There are $m$ vertices in a stage, so the space complexity is $O(m\log\Delta)$ which is $O(m)$ since $\Delta$ is a constant. For the augmentation path, we observe that a value at the $i^{\text{th}}$ stage can be as large as $(n-i)C$. Since only two augmentation values need be retained at any one time, the storage required is at most $l((n-1)C)+l((n-2)C)$ bits. Thus, the space complexity of the entire delta-transformed algorithm is $O(m+\log n)$. This is asymptotically less than the $O(m\log n)$ required by the standard dynamic programming algorithm.

The time required for a $\min^{\Delta_\delta}$ at any stage of the computation is $O(\log(\Delta))$, which is to say constant. Hence, the complexity contributed by the reduced recurrence is $O(m^2n)$. The time required for an $\text{aug}^{\Delta_\delta}$ at the $i^{\text{th}}$ stage is proportional to $l((n-i)C)$, hence the augmentation path contributes $O(n\log n)$ to the time complexity. Thus, the complexity for the entire algorithm is $O(m^2n+n\log n)$, which is asymptotically faster than the $O(m^2n\log n)$ required by the original.

### Mapping the Delta Algorithm into Silicon

We can again use Li and Wah's matrix multiplication scheme, with a slight addition. Recall that the value $r_{i,1}$ is available at $\text{PE}_1$ after the $i^{\text{th}}$ stage has been processed; on odd numbered iterations it is the stationary value, on even numbered iterations it is the first value to shift in. Hence, we add a processor external to the array on the left side, as depicted in figure 3. This processor is initialized with the value $c_{n-1,1,1}$. Then, every $m$ clock cycles, it alternates between sampling $\text{PE}_1$'s stored value and the first value of the next pass to shift in.

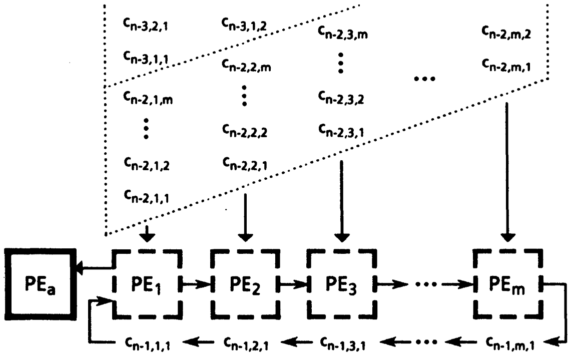

*figure 3.* VLSI array for the delta-transformed algorithm

This scheme requires a total of $m+1$ processors. Each of the $m$ computing the residue recurrence store values which can be at most $\Delta$; hence each requires area $O(\log\Delta)$, which is a constant, so their combined area is $O(m)$. The augmenting processor must manipulate values as large as $(n-1)C$, hence it requires area $O(\log n)$. Thus, the area of the entire array is $O(m+\log n)$ as opposed to the $O(m\log n)$ that the original required.

The reduced processors perform inner product steps on data values of constant size, which require constant time. Since each processor handles $O(mn)$ of these steps, their time complexity is $O(mn)$. In the same time that these processors compute an entire stage, the augmenting processor must perform operations which require time at most $O(\log n)$. Since there are $O(n)$ stages, the augmenting processor requires a total time $O(n\log n)$. Hence the time complexity of the entire array is $O(n\max[m, \log n])$ as opposed to the $O(mn\log n)$ the original array required.

### Conclusions

We have demonstrated a technique to simplify VLSI processor arrays for a general case of serial dynamic programming. Extensions to other dynamic programming algorithms, both serial and nonserial, are straightforward; the necessary and sufficient condition for application of a delta transformation is that all values to be minimized (or maximized) are close in magnitude. Unfortunately, the transformations as presented here will not yield space/time savings for every problem [4]. They can be applied, however, in many important instances, including approximate string matching, two-dimensional image comparison, and dynamic time warping of speech. For example, we have designed and fabricated a linear systolic array for comparing DNA sequences (essentially strings over a small alphabet) [5]. Using a delta transformation, we were able to place 30 processors on a single nMOS chip which runs at six megahertz, whereas if we had implemented the unmodified algorithm, we would have been fortunate to fit four processors running at a much lower speed.

This paper is a condensed version of [4].

# Parallel External Merging

by

Eliezer Dekel and Istvan Ozsvath

University of Texas at Dallas

## Abstract

The problem of merging two large ordered sets A, and B is considered. An efficient parallel algorithm is developed. The shared memory model of computation is used.

Key words: Parallel algorithm, SIMD, parallel merge, external sorting.

## 1. Introduction

The merging and sorting problems have received considerable attention in the literature [1] - [5], [7] - [18]. While the merge operation serves as a basic operation in many algorithms [10] it is usually treated in the context of sorting. With the growing use of databases, the problem of merging becomes more important. Much effort has been devoted to solving this problem on parallel processors [9], [12], [13], [17]. In this paper we present an optimal parallel algorithm for merging two sets of records.

Classically the merge becomes external when the sets are too large to be contained in the memory of the processor. In parallel models input is considered to be external if it cannot fit in the internal memory of the PEs. For this particular problem, the two sets can be stored on a disk. Disks with multiple read/write heads can be regarded as a EREW P-RAMs. We associate with each read/write head a PE and consider the disk medium as the shared memory. The PEs can communicate with each other in 0(1) time by leaving messages in predetermined memory locations.

## 2. Parallel External Merge Algorithm.

Two sorted files A and B with m and n records respectively are to be merged. The result of the merge is a third sorted file C, with n+m records. The serial merge of the two input files, (given correct buffering and overlapped I/O and computation) can be performed in O(m + n) time. In this paper we present a solution to the external merge problem when a fixed number, p, of PEs are available.

Ideally with p PE's, where p < m+n, the files can be merged in O((n+m)/p) time. Our algorithm performs the merge within this optimal time. Conceptually the algorithm has three stages. In the first stage we identify pairs of subfiles from files A and B that could be independently merged. In the second stage, we merge all these subfiles in parallel. Each of these pairs is merged serially by one of the p available PE's. In the last stage, the results of the individual merges are concatenated to produce the result file C.

Let the key of record q in file X be $K_q^X$. Record i in file A has insertion point j in file B if $K_j^B \le K_i^A \le K_{j+1}^B$. If $K_j^A \le K_1^B$ (the key of the first record in B) then it has insertion point 0. If $K_n^B \le K_i^A$ then record i has insertion point n+1 (n is the index of the last record in B).

We first partition each of our input files into p subfiles: subfile $A_i$ with at most $\lceil m/p \rceil$, $1 \le i \le p$ and subfile $B_j$ with at most $\lceil n/p \rceil$, $1 \le j \le p$ records. Define the partition records to be the records with indexes: 1, $\lceil m/p \rceil$, $2*\lceil m/p \rceil$, ... ,$(p-1)*\lceil m/p \rceil$, m in A and, $\lceil n/p \rceil$, $2*\lceil n/p \rceil$, ... , $(p-1)*\lceil n/p \rceil$, n in file B. Next for each of the 2p+2 partition records, we read into memory its key and mark whether it came from file A or file B. Observe that the p+1 keys from each file are sorted. We now merge the two sets of keys, using a bitonic merge [11] to form a sorted sequence. Let the sorted sequence be $S = \{K_h^X, 1 \le h \le 2p+2\}$, where X can be either A or B. Let $J_h$, $1 \le h \le 2p+2$ be the original index of $K_h^X$ in file X. Having created this sequence, it is easy to see that there is no need to search the whole file in order to find an insertion point for some record i. Let $K_h^A$ be a key for partition record i in A, i. e. $J_h = i$. Let $K_f^B$ be the last key from file B in S such that $K_f^B \leq K_h^A$. Also let $K_r^B$ be the first key from file B in S such that $K_h^A \leq K_r^B$. Clearly, when looking for the insertion point of record i of A in file B we can limit our search in file B to records between the records indexes $J_f$ to $J_r$.

By performing the bitonic merge on the keys of the partition records we reduced both the number of disk accesses and also the number of read conflicts. When looking for an insertion point for record i (j) of A (B) in B (A) we have to search a subfile with at most $\lceil n/p \rceil$ ($\lceil m/p \rceil$) records. Since the search range is clearly partitioned, no record has to be accessed more then once. Clearly the number of disk accesses is reduced. Although we did not eliminate read conflicts, we definitely reduced the probability of one occurring.

Although we showed how to find insertion points in file B corresponding to the records in A, the same method can be used to find insertion points in file A corresponding to the records in file B. To identify the partition records in A that are candidates for creating read conflicts, we mark all instances in S where there are j > 1 keys from file A in between two given keys from B. Let us consider one instance of j > 1 keys from A falling in between two consecutive keys of partition records in B. More formally we look at the following subsequence of S: $K_h^B$, $K_{h+1}^A, \ldots, K_{h+j}^A$, $K_{h+j+1}^B$. As explained earlier, this translates to a search for insertion points in B for records $J_{h+1}$, $J_{h+2}$, ..., $J_{h+j}$ of file A. The search for the j points has to be conducted on records $J_h$ to $J_{h+j+1}$ in file B. Since in the search step we assign one PE for each partition record in A, we can expect j PEs to be assigned to search in the interval $J_h$ to $J_{h+j+1}$ in B. These j PEs can partition the interval to j subfiles in B. Each of the new subfiles can have at most $\lceil \lceil n/p \rceil / j \rceil$ records. The new j partition points from B can next be merged with the j keys from A. Now, there are two possible cases. Either there is one j point from A between two consecutive points from B, or there are several. In the first case, the PE can conduct the search independently; namely, there is no danger of a read conflict. In the latter case the process can be repeated until a situation with one PE searching a partition is arrived at (i. e. no read conflicts occur). In the worst case the search without read conflict problem will be trivially solved when a partition with only one record is created.

The introduction of the first level of bitonic merge has a cost of O(log p) when using p PEs. The search step, still with read conflicts, can be performed in O(log (n/p)) time on file B. On file A the search step takes O(log (m/p)). To eliminate read conflict we continue to partition intervals and perform bitonic merges until we can ensure searches without read conflicts. This process can be done in $O((\log p)*(\log_p (n/p)))$ for file B and in $O((\log p)*(\log_p (m/p)))$for file A. The complexity of the partition stage of our new algorithm is readily seen to be O(log m + log n) as before.

In order to simplify the discussion above we assumed that a PE "knows" whether it is the only one to be searching the interval. To perform the Bitonic merge effectively each PE should also have the boundaries of the search interval and the number of PEs sharing that interval. This information can be obtained in O(log p) time. A detailed discussion of this step is given in Dekel and Ozsvath [7].

## 3. Conclusions.

In this paper we describe a parallel merge algorithm. We show how to eliminate the possibility of read conflicts without changing the complexity of the algorithm. We chose to develop an algorithm for an important operation, file merging. The need for algorithms like our merge algorithm will increase dramatically as more parallel computers are in use. Indeed, such computers are likely to become quite common in the near future. These computers will come with a fixed number of processors and will be expected to perform operations on varied sizes of data.

# Parallel Algorithms for Bucket Sorting and the Data Dependent Prefix Problem

*Robert A. Wagner*
*Yijie Han*

Department of Computer Science
Duke University
Durham, NC 27706

## Abstract

The data dependent prefix problem is to compute all the $n$ initial products $x_1 \bigcirc x_2 \bigcirc \cdots \bigcirc x_k$, $1 \le k \le n$, where the order is specified by a linked list. A parallel algorithm for the data dependent prefix problem is presented. This algorithm has time complexity $O(\frac{n}{p}+\log n \log\frac{n}{p})$ using $p$ processors on the exclusive-read exclusive-write computation model. A bucket sorting algorithm is also developed to be used as a component of the prefix algorithm. This bucket sorting algorithm sorts $n$ numbers in the range $\{1,2,...,m\}$ using $p$ processors in $O(\lceil \frac{\log m}{\log(\frac{n}{p}+\log p)} \rceil (\frac{n}{p}+\log p))$ time.

Index words -- Prefix, bucket sorting, parallel algorithms, graph algorithms, optimal algorithms.

## 1. Introduction

Parallel algorithms have been studied in many different areas. Some serial algorithms are easily parallelized while some other serial algorithms seem difficult to parallelize. The study of parallel algorithms reveals many properties of the problems which were previously unknown. In the serial case, time complexity is usually the most important complexity measure for algorithms. In the parallel case, the processor complexity also comes into play. To measure how much parallelism of the problem has been exploited by an algorithm the parameter of *speedup* is defined as $\frac{T_1}{T_p}$, where $T_i$ is the time complexity of the algorithm using $i$ processors and $T_1$ is the time complexity of the fastest known sequential algorithm for the same problem. It is not difficult to see $\frac{T_1}{T_p} \le p$. When $T_p = \Theta(\frac{T_1}{p})$ we say the parallel algorithm achieves linear speedup with $p$ processors. In the parallel environment algorithms with maximum speedup and algorithms with optimal performance (linear speedup) are both sought. As the number of processors grows the utilization of the processors tends to decrease and linear speedup algorithms become difficult to obtain. The contribution of the research presented in this paper is a new parallel algorithm for the data dependent prefix computation. This algorithm achieves linear speedup allowing asymptotically more processors than previously known algorithms. The time complexity of our algorithm improves the best previous result. A bucket sorting algorithm used as a component of the prefix algorithm is also presented. This sorting algorithm shows better performance than known algorithms.

The shared memory computation model is assumed in this paper. In a shared memory model both memory cells and processors are linearly ordered and each memory cell can be addressed by any processor. Three shared memory models are distinguished according to the ways they resolve read or write conflicts[10]. The Concurrent-Read Concurrent-Write model(CRCW), which is the strongest model among these three, allows simultaneous read and write of one memory cell by several processors. The content resulting after a cell is written by more than one processor can be determined in a variety of ways. In the Concurrent-Read Exclusive-Write(CREW) model several processors can simultaneously read one memory cell, but simultaneous write is prohibited. The weakest model among three, the Exclusive-Read Exclusive-Write(EREW) model, prohibits both simultaneous read and write. Our algorithms are EREW and CREW algorithms.

Let $\bigcirc$ denote an associative operation. Given $x_1, x_2, \cdots, x_n$, the (data independent) prefix problem is to compute $x_1 \bigcirc x_2 \bigcirc \cdots \bigcirc x_k$, $1 \le k \le n$. The data dependent prefix problem is to compute $x_1 \bigcirc x_2 \bigcirc \cdots \bigcirc x_k$, $1 \le k \le n$, for a given linked list containing $x_1, x_2, ..., x_n$, with $x_i$ following $x_{i-1}$. For both cases, the product computation problem is to compute $x_1 \bigcirc x_2 \bigcirc \cdots \bigcirc x_n$.

The prefix problem is a fundamental problem in parallel computation. It finds applications in many problems such as processor allocation and reallocation, data alignment, data compaction, sorting and polynomial evaluation. The data dependent prefix problem is especially important since linked lists have been used widely as a data structure in many algorithms and prefix computation is probably the most basic and fundamental computation for linked list manipulation. One example is to use the prefix algorithm to number the data items in a linked list so that each item knows how far it is from the first element of the linked list (compute list rank for each element). This numbering operation is extremely useful when one intends to apply certain parallel operations to the linked list.

Studies have been conducted on the parallel prefix problem[2][5][7][8][9]. These studies assume that the input data is data independent in the sense $x_i$ is in memory cell $i$. For the data dependent case, where input data forms a

0190-3918/86/0000/0924 $01.00 © 1986 IEEE

linked list and a map specifies which element follows which, optimal algorithms are also pursued. The best previous result is due to Kruskal, Rudolph and Snir[6] which achieves time complexity $O(\frac{\log n}{\log(2n/p)}\frac{n}{p})$* using $p$ processors on the EREW model. In this paper we show that time complexity $O(\frac{n}{p}+\log n \log\frac{n}{p})$** can be obtained on the EREW model. Our result achieves linear speedup whenever $p=O(\frac{n}{\log n \log\log n})$. This shows improvement over the best previous result[6] which achieves linear speedup only when $p<n^{\epsilon}$, $0\leq\epsilon<1$. When our algorithm uses the maximum number of processors for which it can achieve linear speedup its time complexity becomes $O(\log n \log\log n)$, a polynomial in $\log n$. In contrast the best previous algorithm[6] can achieve a time complexity of $O(n^{1-\epsilon})$ using the maximum number of processors for which the algorithm obtains linear speedup. Our algorithm is the first result which shows that linear speedup can be achieved for the data dependent prefix problem with polylogarithmic time complexity.

Parallel sorting problem has been studied extensively. See [1] for a survey of this area. For our purpose, a sorting algorithm is required for sorting $n$ numbers in the range $\{1,2,...,\log n\}$ with $p$ processors in time $O(\frac{n}{p}+\log p)$. Parallel sorting algorithms mentioned in [1] do not meet our requirement. Parallel comparison sorting algorithms are not useful here because they will take at least $\Omega(\frac{n\log n}{p})$ time with $p$ processors. Hirschberg's bucket sorting algorithm [1][4] also implies a time bound of $O(\frac{n\log n}{p})$. Kruskal, Rudolph and Snir claimed a sorting algorithm which sorts $n$ numbers in the range $\{1,2,...,n\}$. The time complexity of their algorithm is $O(\frac{\log n}{\log(2n/p)}(\frac{n}{p}+\log p))$ with $p$ processors. Application of their sorting algorithm to our problem would imply a time bound of $O(\frac{\log n}{\log(2n/p)}(\frac{n}{p}+\log p))$ which is also too slow. We have developed our own bucket sorting algorithm. Our algorithm sorts $n$ numbers in the range $\{1,2,...,m\}$ with $p$ processors. The time complexity of our sorting algorithm is $O(\lceil\frac{\log m}{\log(\frac{n}{p}+\log p)}\rceil(\frac{n}{p}+\log p))$. Compared to the results of Hirschberg and Kruskal et. al., our result is more flexible in the sense that it adjusts itself better to the range of the numbers and the number of processors used.

## 2. Basic Fact and Definition

Product circuits, which are directed acyclic graphs, are also widely used as a parallel computation model. Some results may be obtained relatively easily using this model. We allow indegree of any node in the graph to be no more than 2. A node with indegree 2 represents a product of its two inputs. The nodes with indegree 0 are the input nodes. The depth of a circuit is the longest directed path in the graph. Fig. 1 shows two circuits for product computation. For the prefix computation the following fact is important to us.

**Fact:**

> Any circuit for product computation with the property that every node of the circuit represents a product of $\bigcirc_{k=i}^{j} x_k, 1\leq i\leq j\leq n$, can be used to construct a circuit for the prefix problem, and the depth of the prefix circuit is within a constant factor of the depth of the original product circuit.

For the product computation, the circuits can be viewed as trees, which we will call product trees, with sons pointing to fathers. For the class of product trees satisfying the condition stated in the above fact we can define, for each non-input node, its left son as the node which feeds $\bigcirc_{k=i}^{m} x_k$ to it and right son which feeds $\bigcirc_{k=m+1}^{j} x_k$ to it.

The fact comes from the following observation. To compute the prefix, each node representing $\bigcirc_{k=1}^{j} x_k, 1<j\leq n$, passes its product to its father. Each of these fathers then passes the product received to its right son. Each interior node getting a product from its father will transfer it to its left son and then compute a new product by combining the product passed from its father with the product accumulated by its left son during the process of computing the product. This new product will be passed to the interior node's right son. Fig. 2 shows this process.

This fact essentially shows that, for the serial and parallel (data independent) case, the prefix problem is no harder than the product problem. This fact is noted by Schwartz[9] and many other researchers and is used to construct parallel (data independent) prefix algorithms. This fact also applies to the data dependent prefix problem as it was used by Kruskal et. al. to construct their algorithm. Our algorithm also uses this fact, i.e. we are going to construct a parallel product algorithm with the product tree which the algorithm implicitly builds satisfying the condition stated in the fact. Thus our algorithm can be easily transformed to compute the prefix. This is accomplished by, when the product computation finishes, reversing the computation and popping out the product stored during the process of product computation.

Now we give definitions for some concepts related to linked list.

**Definition:**

> A linked list with $n$ elements is a data structure whose $n$ elements are associated with $n$ consecutive memory locations, where these $n$ memory locations are linked one after another by arcs. The last arc in the list points to a special symbol *nil* denoting the end of the list. An arc $(a,b)$ indicates that the element associated with location $a$ is followed by the element associated with location $b$. This arc is represented by value $b$ in location $a$. $a$ is the tail of the arc and $b$ is the head of the arc.

* Logarithms in this paper are to the base 2.

** We note here that $O(\frac{n}{p}+\log p)=O(\frac{n}{p}+\log n)$ and $O(\frac{n}{p}+\log p\log\frac{n}{p})=O(\frac{n}{p}+\log n\log\frac{n}{p})$, for $p\leq n$.

## 3. Previous Results for the Prefix Problem

It is advantageous here to mention some of the previous work on the prefix problem, since our algorithm uses some of the previous known algorithms as components and our work represents a continuation of the effort of these researchers.

The following well-known algorithm can be used to solve the prefix problem.

```
PREFIX_INDEPENDENT ($X[0..n-1]$);
   begin
      for $k:=0$ to $\lceil \log n \rceil -1$ do
         forall $i: 2^k \leq i < n$ do
            $X[i]:=X[i-2^k] \bigcirc X[i]$;
   end.
```

Algorithm PREFIX_INDEPENDENT has a corresponding version for the data dependent case, which is expressed by Wyllie[11]:

```
PREFIX_DEPENDENT($X[0..n-1]$,$NEXTX[0..n-1]$,$HEAD$);
  forall $i: 0 \leq i < n$ do
     begin
       $temp:=HEAD$;
       if $NEXTX[i] \neq nil$ then $NEXTX[NEXTX[i]]:=i$
       else $HEAD:=i$;
       $NEXTX[temp]:=nil$;
       for $k:=1$ to $\lceil \log n \rceil$ do
          if $NEXTX[i] \neq nil$ then
             begin
                $X[i]:=X[i] \bigcirc X[NEXTX[i]]$;
                $NEXTX[i]:=NEXTX[NEXTX[i]]$;
             end
     end.
```

If $n$ processors are available both algorithms will take $O(\log n)$ time. However, in no situation will they achieve linear speedup. This occurs because the total number of operations $N$ involved in these algorithms is $O(n \log n)$. With $p$ processors the best one can hope for is $O(\frac{n \log n}{p})$.

Kruskal et. al. [6] discussed an improved version of PREFIX_INDEPENDENT which achieves linear speedup. The elements are partitioned into $p$ blocks where block $i$ is $X[i \cdot \frac{n}{p} .. (i+1)\cdot\frac{n}{p}-1]$, $0 \leq i < p$. Processor $P_i$ is assigned to block $i$ to calculate the prefix (and therefore the product $p_i$) of block $i$. Then PREFIX_INDEPENDENT can be used to obtain the prefix $p_i^*$ for the $p$ products. Finally $p_i^*$ is added to each element of block $i+1$ by processor $P_i$.

However, no technique similar to the one mentioned above is known for algorithm PREFIX_DEPENDENT. A handy improvement can be made to achieve $O(\frac{n \log p}{p})$ time with $p$ processors. Fig. 3 shows that a linked list can be transformed into a linked tree of $p$ branches, each with length no more than $\frac{n}{p}+1$. This can be done in $O(\frac{n}{p}\log p)$ time with $p$ processors by repeatedly assigning $NEXTX[i]:=NEXTX[NEXTX[i]]$. This is equivalent to executing PREFIX_DEPENDENT for $\lceil \log p \rceil$ loops. Thereafter each processor works on one branch. The timing will be $O(\frac{n \log p}{p})$.

Kruskal, Rudolph and Snir's result shows that with $p$ processors $O(\frac{\log n}{\log(2n/p)}\frac{n}{p})$ time can be achieved for the data dependent prefix computation[6]. The hard part of the problem is to process arcs, in an order that guarantees that the arcs being simultaneously processed are not chained together. By dividing the $n$ elements into $\frac{n}{p}$ blocks, they apply $p$ processors to visit the $\frac{n}{p}$ blocks one at a time. During this phase, only arcs leaving a block are processed. Since no processor will look at the head of the arcs leaving the block which the processors are visiting, it is ensured that arcs simultaneously processed are not chained together. After this all the inter-block arcs are treated so the whole problem is divided into $\frac{n}{p}$ equal size subproblems. By distributing processors evenly to all the subproblems and applying recursion all the arcs will be processed. This is one pass of the so-called Pair-Off. After pair-off each remaining element must have both of its neighbors eliminated, thus the number of remaining elements is at most $\frac{2n}{3}$. Elements are compacted and another pass of pair-off is applied. The number of elements left after each pass will form a geometric series and consequently, time complexity of $O(\frac{\log n}{\log(2n/p)}\frac{n}{p})$ is obtained.

## 4. A Parallel Bucket Sorting Algorithm

In this section a parallel bucket sorting algorithm is presented. This algorithm sorts $n$ numbers in the range $\{1,2,...,m\}$ using $p$ processors. The sorting requires time $O(\lceil \frac{\log m}{\log(\frac{n}{p}+\log p)} \rceil (\frac{n}{p}+\log p))$.

To sort $n$ elements in the range $\{1,2,...,m\}$ with $p$ processors, we divide the elements into $\lceil \frac{n}{p} \rceil$ blocks. These blocks will be visited by the $p$ processors sequentially. Suppose element $i$ valued $v_i$ is visited by processor $P_k$, the element will be dropped into the $((v_i-1)\cdot p+k)$-th bucket. After all the elements are dropped into buckets, packing the elements will yield the sorted sequence. The details of the algorithm are shown below.

```
BUCKETSORT($A[1..n]$) /* $1 \leq A[i] \leq m$, $1 \leq i \leq n$. */

  processors: $P_i$, $1 \leq i \leq p$;
  array:     $S[1..m \cdot p]$,  /* Buckets */
             $C[1..n]$,        /* Counter for each element to
                                calculate its rank.
                              */
             $G[1..m]$;        /* $G[i]$ is the total number
                                of occurrences of elements
                                valued $i$.
                              */
```

```
forall $P_i : 1 \leq i \leq p$
  begin
  /* Initialization. Takes $O(m)$ time.*/
    $S[1..m \cdot p] := 0$;

  /* Throwing elements into buckets.
     Takes $O(\frac{n}{p})$ time.
  */
    for $k := 1$ to $\lceil \frac{n}{p} \rceil$ step 1
      begin
        $C[(k-1) \cdot p + i] := S[(A[(k-1) \cdot p + i] - 1) \cdot p + i]$;
        $S[(A[(k-1) \cdot p + i] - 1) \cdot p + i] :=$
           $S[(A[(k-1) \cdot p + i] - 1) \cdot p + i] + 1$;
      end

  /* $G[i]$ is going to be returned to the calling
     procedure. Takes $O(m + \log p)$ time.
  */
    forall $k : 1 \leq k \leq m$ do $G[k] := \sum_{i=(k-1) \cdot p+1}^{k \cdot p} S[i]$;

  /* Packing. Takes $O(\frac{n}{p} + m + \log p)$ time. */
    PREFIX_INDEPENDENT($S[1..m \cdot p]$);
    for $k := 1$ to $\lceil \frac{n}{p} \rceil$ step 1
      begin
        $C[(k-1) \cdot p + i] := C[(k-1) \cdot p + i]$
           $+ S[(A[(k-1) \cdot p + i] - 1) \cdot p + i - 1]$;
      end
 end
```

For $n$ elements ranging from 1 to $m$, BUCKETSORT takes $O(\frac{n}{p} + m + \log p)$ time units with $p$ processors. When $m > \frac{n}{p} + \log p$, we can use the idea of radix sorting. The $\log m$ bits representing the numbers are divided into $\lceil \frac{\log m}{\log(\frac{n}{p} + \log p)} \rceil$ blocks. Starting from the least significant block of bits, BUCKETSORT can be applied. After applying BUCKETSORT $\lceil \frac{\log m}{\log(\frac{n}{p} + \log p)} \rceil$ times, once for each block of bits, the sorting is accomplished. The total time will be $O(\lceil \frac{\log m}{\log(\frac{n}{p} + \log p)} \rceil (\frac{n}{p} + \log p))$ since the $m$ in the BUCKETSORT is $\frac{n}{p} + \log p$ now.

We note here that this sorting algorithm can also be used to pack data. Assigning 1 to each marked element and 2 to each unmarked element, execution of this sorting algorithm will pack the marked elements to the beginning of the array and unmarked elements to the end of the array.

## 5. The Main Algorithm

Our algorithm for the data dependent prefix problem is presented in this section. This algorithm uses the observation stated before, i.e. an appropriate product computation algorithm can be used to construct an algorithm for prefix computation. Thus we are focusing on constructing a suitable algorithm for product computation. The idea of Kruskal et. al. that appropriate pairs of elements are combined such that one pass of combining (or 'pair-off') will reduce the number of elements by at least one third is followed here. However, instead of using $p$ processors to cut $n$ elements into $\frac{n}{p}$ blocks we observed that the $n$ arcs in the linked list can be divided into $O(\log n)$ groups and all the arcs in one group can be eliminated simultaneously by one 'pair-off' pass. The details of this idea are expressed below.

We divide arcs into groups by the following rule: arc $(a, b)$ is in group $2k - a_k$ where

$k = \min \{ i \mid \text{the } i\text{-th bit of } a \ XOR \ b \text{ is } 1 \}$,

*XOR* is the exclusive-or operation, bits are counted from the least significant bit starting at 1, $a_k$ is the $k$-th bit of $a$. We prove the following lemma.

**Lemma:**

a) Each arc belongs to one and only one group.

b) For any group $G$, if two different arcs $(a, b) \epsilon G$ and $(c, d) \epsilon G$, then $a, b, c, d$ are all distinct.

**Proof:**

Part a) is obvious from the way we form groups. Now we prove part b).

Assume $G$ is an arc group indexed by $2i - a_i$. $a \neq c$ since no two arcs can originate from one element, and $b \neq d$ since no two arcs can have the same target. Since both arcs are in $G$, $a_i = c_i$. Now by the definition of grouping, $b_i = d_i = (a_i \ XOR \ 1)$. Hence $a$, $b$, $c$, $d$ are all distinct.

Q.E.D.

By the above lemma, we know pairs of elements connected by arcs in a group can be combined simultaneously without interfering with each other. Since at most $\lfloor \log n \rfloor + 1$ bits are used to represent the elements in the linked list, at most $2 \lfloor \log n \rfloor + 2$ groups are needed. To determine, for arc $(a, b)$, which group it belongs to, we compute

$c := a \ XOR \ b$;
$c := (((c-1) \ XOR \ c) + 1)/2$;

This will set all the bits of $c$ to zeros except the lowest bit valued 1. Now we use value $c$ to index into a table $T$ to determine which bit of $c$ is 1. Table $T$ can be built by the following simple procedure.

```
TABLE($n, p$)
  begin
    for $j := 0$ to $\log n$ step 1
      $T[2^j] := j + 1$;
  end.
```

It is possible that several processors attempt to read the same entry of the above table simultaneously. We can use this table on the CREW model anyway. The time for table building will not dominate the overall time complexity.

The procedure for determine the arcs' group membership is as follows.

```
MEMBER($X[1..n]$, $NEXTX[1..n]$)
  forall $P_i : 1 \leq i \leq p$
    begin
      for $k := 1$ to $\frac{n}{p}$ step 1
        begin
          $M[i] := X[(i-1)\frac{n}{p}+k]$ XOR $NEXTX[(i-1)\frac{n}{p}+k]$;
          $M[i] := (((M[i]-1)$ XOR $M[i])+1)/2$;
          $A[(i-1)\frac{n}{p}+k] := 2 \cdot T[M[i]]$;
          if ($M[i]$ AND $X[(i-1)\frac{n}{p}+k]) > 0$ then
              $A[(i-1)\frac{n}{p}+k] := A[(i-1)\frac{n}{p}+k]-1$;
        end
    end.
```

After the group of each arc is calculated, the bucket sorting algorithm is used to move arcs so that arcs in the same group are gathered together. Now, one group at a time, all the arcs are visited. This will take no more than $O(\sum_{i=1}^{2\log n+2} \lceil \frac{|G(i)|}{p} \rceil) = O(\frac{n}{p}+\log n)$ time, where $|G(i)|$ is the number of arcs in group $i$. Specifically, when the head of an arc visited by a processor is already deleted due to the previous processing of that arc's predecessor then the processor does nothing, otherwise it combines the head and the tail of the arc, marks the tail deleted, and updates the arc to point to the successor of its successor. After one pass of this 'pair-off', any remaining element must have both its predecessor and successor marked deleted. So at most $\frac{2n}{3}$ elements can survive. The remaining elements are packed and after $O(\log\frac{n}{p})$ passes, there are no more than $p$ elements left. Finally the remaining elements are combined by algorithm PREFIX_DEPENDENT. The following gives the details of our algorithm for the CREW model.

```
PRODUCT_PREFIX($X[1..n]$, $NEXTX[1..n]$, $HEAD$)
  begin
    TABLE($n$, $p$);
    COMBINE($X[1..n]$, $NEXTX[1..n]$, $HEAD$);
  end

COMBINE($X[1..n]$, $NEXTX[1..n]$, $HEAD$);
  forall $P_i : 1 \leq i \leq p$
    begin
      $DELETED[1..n] := false$;
      if $n \leq p$ then
  PREFIX_DEPENDENT($X[1..n]$, $NEXTX[1..n]$, $HEAD$);
      else
        begin
          /* Calculating group membership. */
          MEMBER($X[1..n]$, $NEXTX[1..n]$);

          /* Bring elements of the same group together.*/
          /* BUCKETSORT returns each element's rank
            in array $C$.
          */
          BUCKETSORT($A[1..n]$);
          for $k := 1$ to $\frac{n}{p}$ step 1
            $B[C[(i-1)\frac{n}{p}+k]] := (i-1) \cdot \frac{n}{p}+k$;

          /* Visiting arcs one group at a time. */
          /* Array $G$ is returned by BUCKETSORT.
            $G[k]$ is the total number of elements
            in group $k$.
          */
          $j := 1$;
          for $k := 1$ to $2\log n+2$ step 1
            begin
              while $G[k] \geq p$ do
                begin
                  PAIR-OFF($B[j..j+p]$);
                  $j := j+p$;
                  $G[k] := G[k]-p$;
                end
              if $G[k] \neq 0$ then PAIR-OFF($B[j..j+G[k]]$);
              $j := j+G[k]$;
            end

        /* Now pack. PACK is a simplified version
          of BUCKETSORT. PACK returns the size
          of the packed array.
        */
        $n' := $PACK($A[1..n]$);
        COMBINE($X[1..n']$, $NEXTX[1..n']$, $HEAD$);
  end

PAIR-OFF($B[a..b]$)
  begin
    if $b-a < p$ then Disable $P_i : i > b-a+1$;
    if NOT $DELETED[B[a+i-1]]$ then
      begin
        $X[B[a+i-1]] := X[B[a+i-1]] \bigcirc$
                    $X[NEXTX[B[a+i-1]]]$;
        $DELETED[NEXTX[B[a+i-1]]] := true$;
        $NEXTX[B[a+i-1]] :=$
                $NEXTX[NEXTX[B[a+i-1]]]$;
      end
    Enable $P_i : 1 \leq i \leq p$;
  end
```

Each execution of procedure MEMBER takes $O(\frac{n}{p})$ time and each execution of procedure BUCKETSORT takes $O(\frac{n}{p}+\log n)$ time, for the $n$ numbers range from 1 to $2\log n+2$. As mentioned before, visiting groups of arcs takes $O(\frac{n}{p}+\log n)$ time, and packing can be easily verified to take $O(\frac{n}{p}+\log p)$ time. Thus one pass of the combining process, i.e. an execution of procedure COMBINE, takes $O(\frac{n}{p}+\log n)$ time. After executing COMBINE no more than $\frac{2n}{3}$ elements are left, and hence the following recursive formula for time complexity $T_p$ can be established.

$$T_p(n)=O(\frac{n}{p}+\log n)+T_p(\frac{2n}{3}).$$

Since $O(\log\frac{n}{p})$ passes of COMBINE are used and the remaining less than $p$ elements can be combined in $O(\log p)$ time units, we have $T_p(n)=O(\frac{n}{p}+\log n\log\frac{n}{p})$. All the operations in the algorithm except the ones for calculating the group membership of the arcs are EREW operations.

For the EREW model, one way to determine the group membership for an arc $(a,b)$ is to continuously bisect the bits of $a$ $XOR$ $b$ and ask if the lower half of the bits are 0's. In this binary splitting fashion, we can calculate the group membership for all the arcs in time $O(\frac{n}{p}\log\log n)$. The $\log\log n$ factor can be eliminated by using $p$ copies of table $T$, one copy for each processor. This table $TE$, which is of size $n \cdot p$, has only $(\log n+1)\cdot p$ entries which could possibly be indexed into. These entries are $TE[i][j]$, $1 \leq i \leq p$, $j=2^k$, $0 \leq k \leq \log n$. Table $TE[1..p][1..n]$ can be built by copying relevant entries of table $T$. Distribute processors such that $P_i$, $(k-1)\cdot\frac{p}{\log n+1}+1 \leq i \leq k\cdot\frac{p}{\log n+1}$, $1 \leq k \leq \log n+1$, are assigned to entries $TE[1..p][2^{k-1}]$. These processors will make $p$ copies of the $T[2^{k-1}]$ and put them in $TE[1..p][2^{k-1}]$. The total copying operation will take $O(\log n)$ time. The procedure for determine arcs' group membership is obtained by merely replacing the statement

$$A[(i-1)\frac{n}{p}+k]:=2\cdot T[M[i]]$$

in procedure MEMBER by

$$A[(i-1)\frac{n}{p}+k]:=2\cdot TE[i][M[i]].$$

The table storage technique due to Fredman, Komlós and Szemerédi[3] can be used here to reduce the size of the index table to $O(p\cdot\log n)$ while retaining constant time for table lookup, i.e. $O(\log n)$ space is enough for one copy of the index table. Although the sequential time complexity of the algorithm[3] for building a single copy of the index table is $O(\log^4 n)$, $O(\frac{n}{p}+\log n\log\frac{n}{p})$ time is more than enough when $p$ processors are employed to build a single copy of the index table. Thus, we can first create a single copy of the index table with the help of $p$ processors, then duplicate the table to $p$ copies. The time complexity of $O(\frac{n}{p}+\log n\log\frac{n}{p})$ still holds. The algorithm just obtained is an EREW algorithm.

As mentioned before, for the prefix computation we execute our algorithm first and then reverse the computation and pop out products stored at each node of the product tree.

## 6. Conclusion

Parallel algorithms allowing a maximum number of processors to achieve linear speedup for the data independent prefix problem have already been obtained, even on weaker models such as ultracomputers[9]. This is not the case in the data dependent case. We conclude this paper by raising the question: is $O(n/p+\log n)$ time bound achievable for the data dependent prefix problem on the EREW model?

*ABSTRACT*

The problem of range search arises in many applications in areas such as information retrieval, database, robotics and computational geometry. There are a good number of sequential algorithms for this problem based on data structures such as k-d tree, quad tree, range tree, d-fold tree, super B-tree, overlapping k-ranges, non-overlapping k-ranges, etc. In this paper we present a parallel algorithm for a Single Instruction Multiple Data (SIMD) computing system with $p$ processing elements. We make use of the linearized multiple attribute tree as the underlying data structure. Our algorithm has the complexity of $O(kN/p)$, $p \leq N$ where $k$ is the dimensionality and $N$ is the number of points of the data space.

## 0. INTRODUCTION

The problem of range search arises in many application areas such as information retrieval, database, robotics, and computational geometry. There have been many sequential algorithms for range search problem using the data structures such as k-d tree, quad tree,- range tree, overlapping k-ranges, nonoverlapping k-ranges, d-fold tree, super B-tree, k-fold tree, and multiple attribute tree [1,3,5-7].

In this paper, we present a parallel algorithm for the range search problem. We make use of the Multiple Attribute Tree (MAT) as the underlying data structure. Our model of computation is a *Single Instruction Multiple Data* (SIMD) computing system, consisting of $p$ processing elements. The system has a single shared memory that supports simultaneous reads. The time complexity of our algorithm is given by $O(kN/p)$, $p \leq N$.

The organization of this paper is as follows: In Section 1, we discuss the MAT data structure and the corresponding directory. In Section 2 the basic range search algorithm is discussed, and its complexity is estimated. Firstly an $O(k)$ algorithm is obtained using a processor array of size $N$ in a straight forward manner. Then, an $O(kN/p)$, $p \leq N$ algorithm using a processor array of size $p$ and an augmented directory.

## 1. THE MULTIPLE ATTRIBUTE TREE

The MAT data structure was first introduced and analyzed by Kashyap et al [2]. The MAT is shown to outperform the inverted file structure for partial match and complete match queries in the cases when the directory resides on the main and secondary memories in [4]. An exhaustive treatment on various structural aspects of MAT can be found in [5].

The k-dimensional MAT on $k$ attributes $A_2,A_3,...,A_k$ for a set of records is defined as a tree of depth $k$, with the following properties [4]:

i) it has a root at level 0,

ii) each child of the root is a (k-1)-dimensional MAT, on (k-1) attributes, $A_1,A_2,...,A_k$, for the subset of the records that have the same $A_1$ value. This value is the value of the root of the corresponding (k-1)-dimensional MAT, and

iii) the child nodes of the root are in the ascending order of their values. This set of child nodes is called the *filial-set.* □

From the above definition we note that there is a root node at level 0, and it does not have any value. Every node of level $i$,$i$=1,2,...,$k$, corresponds to a value of the attribute $A_i$. Fig 1(b) shows the MAT data structure for the sorted set of records of Fig.1(a). The attributes $A_1,A_2,...,A_k$ form the hierarchy of of levels 1 through $k$. The nodes of every filial-set are ordered according to their values. Another important property is that each record or point is represented by a unique path from the root to the corresponding terminal node. The total number of nodes in the MAT is at most $kN$ for a given data set containing $N$ records or points.

The MAT is *linearized* and stored as a directory. We make use of the *breadth-first* linearization in which the nodes are stored in the order they are encountered when MAT is traversed in a breadth-first manner. The directory is an array of $M$ ($\leq kN$) directory elements and each directory element has the following fields:

```
directory-element =   record
             value:   1..M;
       first-child:   1..M;
        last-child:   1..M;
                      end;
```

where the fields corresponding to a node $T$, at level $j$, and numbered $n$ are defined as follows:

value: the value of the node $T$;
first-child: node number of the first child of the child set of $T$;
last-child: node number of the last child of the child set of $T$;

The idea of breadth-first linearization is illustrated in Fig.2 and the corresponding directory is shown in Fig.3. In the first-child field of leaf nodes contain the pointers to the corresponding records. The time complexity of constructing this directory using a uniprocessor system is $O(N \; logN)$

(including the time required to sort the records on all the attributes) [5]. Here, we are concerned only with answering the range query, assuming that the directory is available in memory. This directory is utilized in the design of parallel range search algorithms in the next section.

## 2. PARALLEL RANGE SEARCH ALGORITHM

A range query is given by $Q = \bigcap_{i=1}^{k} q_i$, where $q_i$ specifies the range $[l_i, h_i]$ at the level $i$. In geometric terms a range query specifies a *rectilinearly oriented hyper rectangle* in $k$ dimensional space. Answering a range query calls for the retrieval of the points enclosed by the specified hyper rectangle, and these points form a 'sub' MAT, called the *query* MAT (QMAT), on the original MAT. These nodes of the QMAT are called the *qualified* nodes of MAT for the query $Q$. Answering a range query involves identifying the nodes of the QMAT on the MAT. Let $R$ be the number of records contained in the hyper rectangle. The number of the nodes of the QMAT is no more than $kR$.

An algorithm for range query proceeds by descending down the MAT level by level, starting from the first level. At each level $i$, the child sets of qualified nodes of previous level are searched for the containment in the range $[l_i, h_i]$. The algorithms is as follows:

```
algorithm RANGE-SEARCH(level,qnodes);
begin
    tempset:= $\phi$;
    for each $n \in$ qnodes do
        add to tempset all the child nodes of $n$ that lie in
        the range $[l_{level}, h_{level}]$;
    if level < $k$
    then RANGE-SEARCH(level+1,tempset)
    else return the pointers given by the elements of tempset;
end
```

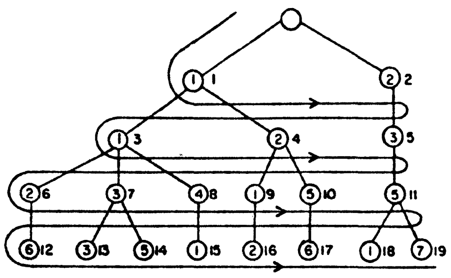

FIG. 2 Breadth - first linearization

In the algorithm RANGE-SEARCH, at a level $i$, all the nodes that satisfy the partial query $\bigcap_{j=1}^{i} q_j$ are collected as tempset. In the next level $i$+1, the child nodes of these nodes are tested for inclusion in the range $[l_{i+1}, h_{i+1}]$. At the final level, the pointers to the information about the records that satisfy the given query are retrieved.

The MAT data structure has some builtin parallelism with respect to answering a range query. The searching for the qualified nodes can be simultaneously carried out on the sub MATs of the same level. However, there seems to be a stringent sequentiality in the way the attributes are processed one after the other. Again, speaking in geometric terms, processing of each attribute reduces the dimensionality of the search space by one. From the above discussion, we conclude that $O(k)$ is lower bound on the steps involved in answering a range query on the MAT-based approach.

The model of computation is in the form of an array of processor elements $PE_j$, $j$=1,2,...$p$, and operates in *Single Instruction and Multiple Data* (SIMD) mode. More specifically, each processor element executes the same algorithm in synchronism with all the other processor elements. We use single shared memory in which the breadth-first MAT directory and other variables are stored. As will be shown later there will be no conflicts in writing into the memory. But, simultaneous read operations are supported. The range query is represented by low-limit[$i$] and high-limit[$i$], $i$=1,2,...,$k$, which give the lower and upper limits of the range for the attribute $A_i$.

Firstly, consider the processor array $PE_i$, $i$=1,2,...$N$ where $N$ is the number of records in input set. The array base[$i$], $i$=1,2,...,($k$+1) is stored in the memory, where any node of level $i$ lies in between the entries indexed by base[$i$], and base[$i$+1]-1 in the directory. We use the array enable[$i$], $i$=1,2,...$N$ to selectively enable and disable the processor elements of the processor array. The algorithm consists of $k$ steps and in step $i$, $i$=1,2,...,$k$ the level $i$ is processed to obtain the qualified nodes of the level $i$. Each enabled processing element acts on a child node of a qualified node at previous level, and checks if the child node satisfies the range constraint of the current level. The processor elements corresponding to the qualified nodes of current level are enabled in the next step. For the final level, the points that satisfy the range query are obtained. The algorithm executed by the processor element $PE_j$, $j$=1,2,...$N$ for the step $i$, $i$=1,2,...$k$ is as follows:

```
algorithm $PE_j$;
begin
1.   if enable[$j$]
2.   then
     begin
3.       enable[$j$] = false;
4.       $n$ = base[$i$] + $j$;
5.       if low-limit[$i$] ≤ value[$k$] ≤ high-limit[$i$]
6.       then
         begin
7.           for $l$ = first-child[$n$] to last-child[$n$] do
8.               enable[$l$ - base[$i$]] = true;
         end;
     end;
end;
```

In the above algorithm the qualified records have to be returned in the final level by suitably modifying the lines 7 and 8. This parallel algorithm implements the algorithm RANGE-QUERY and it is very easily seen that this correctly answers the range query. Since the algorithm is executed in $k$ synchronous steps, it is evident that the time complexity of this algorithm is $O(k)$.

In applications involving large amounts of data, the value of $N$ could be very large and the assumption of the array of $N$ processors is not very pragmatic. We now present an algorithm that utilizes an array $PE_i$, $i=1,2,...,p$, $p \leq N$ processor elements. The basic idea of 'processing the MAT nodes level by level' is still followed; at any level the processor array is invoked required number of times along breadth of the MAT. In this case the directory is augmented with two more fields - enable and level. The former is used to selectively enable and disable the processor elements and latter field gives the level of the node. The global variable current-level gives the level-number that is currently being processed, and it is incremented after each level is processed. The array index[$i$], $i=1,2,...,p$ gives the current index (into the directory) to be used by the processor element $PE_i$. Initially, the enable field is made true for all the nodes of level 1 and also the entries of the array index corresponding to the first level nodes are filled up. For the final level, the qualified records are retrieved. The algorithm executed by the processor element $PE_j$, $j=1,2,...,p$ is as follows:

```
algorithm $PE_j$;
  begin
1.    $l$ = index[$j$];
2.    if ((current-level = level[$l$]) and (enable[$l$]))
3.    then
      begin
4.        if (low-limit[current-level] ≤ value[$l$]
                             ≤ high-limit[current-level])
5.        then
          begin
6.            for $m$ = first-child[$l$] to last-child[$l$] do
7.                enable[$m$] = true;
          end
8.        index[$j$] = $l$+$p$;
9.        enable[$l$] = false;
      end;
  end;
```

The if statement in line 2 makes sure that all processors of the SIMD array process the nodes of the current level. After the first $p$ nodes of a level are processed, the next $p$ nodes are processed by the use of the array index as in line 8. The lines 6 and 7 are to be modified to retrieve the qualified records in the final level. It is straight forward to see that the range query is processed correctly.

**THEOREM**: The time complexity of the parallel range search algorithm, on an SIMD system of $p$ processors is $O(kN/p)$.

**PROOF:** For the execution of the algorithm, at any level $i$, the maximum number of times the processor array is invoked is given by:

$$\lceil \text{(number of nodes of level } i/p \rceil$$

The total number of times the processor array is invoked is

$$\sum_{i=1}^{k} (\lceil \text{(number of nodes of level } i\text{)}/p \rceil)$$

$$= (\sum_{i=1}^{k} \lceil \text{ (number of nodes of level } i \rceil)/p = O(kN/p+k)$$

Hence, the time complexity of this algorithm is $O(kN/p)$. □

We note that for the case $p=N$ this algorithm has the same complexity as the earlier one. But, earlier is superior as it uses less memory space. We also note that the maximum number of times the processor array is invoked is given by $k(N/p+1)$. This upperbound corresponds to the wosrt-case structure of the MAT. In an average-case the number of times that the processor array is invoked will be less than this bound. The authors are presently working on this aspect.

## 3. CONCLUSIONS

We have developed an $O(kN/p)$ algorithm for range search problem using the linearized MAT data structure and SIMD computing system. Since the attributes are processed one after the other, the MAT based parallel algorithm has a lower bound complexity of $\Omega(k)$ on the processor array containig no more than $N$ processor elements.

**Abstract.** A fundamental measure of processing power in a database management system is the performance of the sort utility it provides. When sorting a large data file on a serial computer, performance is limited by factors involving processor speed, memory capacity, and I/O bandwidth. In this paper, we investigate the feasibility and efficiency of a parallel sort-merge algorithm through implementation on the *JASMIN* prototype, a backend multiprocessor built around a fast packet bus. We describe the design and implementation of a parallel sort utility. We then present and analyze the results of measurements corresponding to a range of file sizes and processor configurations. Our results show that using current, off-the shelf technology coupled with a streamlined distributed operating system, three and five microprocessor configurations provide a very cost-effective sort of large files. The three processor configuration sorts a 100 megabyte file in one hour, which compares well with commercial sort packages available on high-performance mainframes.

## 1. Introduction

Sorting of large data files is one of the most important and frequently performed operations in database management. Output files generated by a report are usually sorted with respect to an attribute or a combination of attributes that are of interest to the users of the report. In mass-storage devices, files are often maintained sorted with respect to a key attribute in order to facilitate subsequent searching and processing. Database management systems also pre-sort files in order to eliminate duplicate records [5, 14] or to process complex join and aggregate queries [14]. Thus, one of the fundamental measures of processing power in a transaction management system is the performance of the sort utility it provides [1].

In most systems, sort performance is not satisfactory. For large files, a sort may require hours of processing time during which it saturates the CPU and I/O devices. As a consequence, even in high-performance transaction management systems, a large sort will often be deferred to after-hours processing in order not to interfere with the execution of short interactive transactions.

What limits the performance of a file sorting operation, and how can this performance be enhanced? A theoretical machine with a 100 megabyte memory and a 50 nanosecond Compare instruction could sort one million 100 byte records in 1.5 minutes, including 30 seconds to read the file from a disk with a 3 million-byte per second transfer rate and 30 seconds to write it back to the same disk[a] [1]. In practice, file sizes exceed main memory capacity by several orders of magnitude, comparisons and record moves are slower, and the effective I/O bandwidth is well below the maximum bandwidth of the disk channel. In addition, general purpose operating systems impose processor overhead and limit the utilization of other resources. The designer of a sort utility must strive to minimize record moves in memory, overlap I/O latency with computation, and reduce disk seek times. Even then, the efficiency of file sorting on a serial computer with conventional mass-storage remains severely limited. Parallel computation combined with high I/O transfer rates is a natural approach to overcoming these limits. Indeed, a number of recent database machine designs use parallel sorting as a fundamental building block for query processing [8, 9, 15, 16].

In this paper, we investigate the feasibility of parallel file sorting on a backend multiprocessor machine. We describe the design of a sort utility that exploits parallel computation and high I/O bandwidth, and its implementation on the *JASMIN* multiprocessor. We consider two schemes which differ in the starting location of the unsorted data (Figure 1), and may lead to significant differences in performance. The first scheme corresponds to a *Backend Sort*, where a file initially located on the host is downloaded to a backend multiprocessor for sorting. The file is distributed to the backend processors, which sort it and then return the sorted file to the host. The second scheme, a *Distributed Sort*, assumes that the source file is initially distributed across a number of disks attached to backend processors. The processors sort the file in parallel, then send it to the host or write it to a backend disk. Basically, the parallel sorting algorithm used in both schemes is the same, but the design goal of overlaping computation with the distribution of the data in one case (*Backend Sort*), is replaced with overlapping computation with disk access in the other (*Distributed Sort*).

The remainder of this paper is organized as follows. In Section 2, we describe the hardware and software architecture of the *JASMIN* system. In Section 3, we describe the parallel external sort algorithm, and the implementation choices that we have made – in particular the process structure and the buffering scheme. In Section 4, we present the performance of our algorithm as implemented on *JASMIN*. We analyze the execution time, processor utilization, and network traffic as functions of the file size and the multiprocessor configuration. Finally, Section 5 contains our conclusions.

Support for this work was provided by the National Science Foundation, under grant DCR-8410889, a Hewlett-Packard faculty development fellowship, and Bell Communications Research.

[a] With an efficient algorithm, sorting $n$ records in main memory requires $O(nlogn)$ record comparisons and exchanges. For $n$ = 1,000,000, a typical proportionality of 1.5 and 20 instructions for a comparison and an exchange, this amounts to 600M instructions.

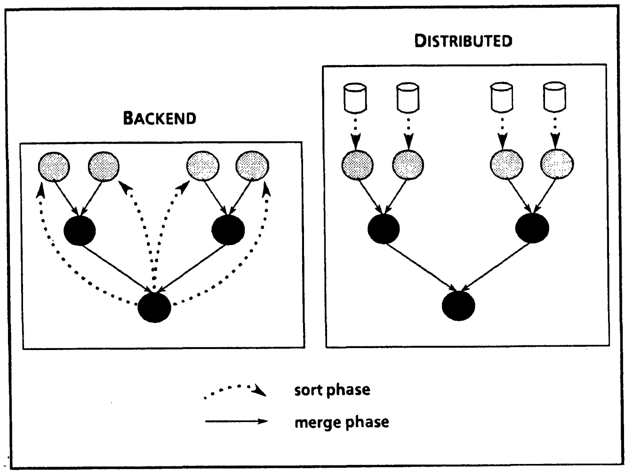

Figure 1: Backend and Distributed Sorting

## 2. A Backend Multiprocessor

Our parallel external sort algorithm was implemented on a prototype AT&T Bell Laboratories multiprocessor [2]. This multiprocessor may be configured with up to 12 microcomputers communicating through a fast packet bus. It also has an umbilical connection to a DEC VAX host running UNIX[b] System V. The backend processors run the *JASMIN* distributed operating system kernel, which is under development at Bell Communications Research. *JASMIN* is designed to efficiently support distributed applications. In this section, we briefly describe the hardware characteristics of the multiprocessor and process management and communication in *JASMIN*. The reader is referred to [12] for a complete description of the operating system and to [7] for a description of a distributed database management system which runs on *JASMIN*.

### 2.1. The S/Net

The multiprocessor used in *JASMIN* is built around the S/Net, a fast (80 Mbit/s) packet bus developed at AT&T Bell Laboratories. The multiprocessor consists of a set of Multibus-based microcomputers, each with an S/Net Processor Interface Board. The S/Net itself consists of a set of Buffer Interface Boards, tied together on a single backplane, each connected to a Processor Interface Board. A designated Buffer Interface Board is connected to the VAX host. The VAX downloads the microcomputers via the S/Net and provides some support, such as file access and debug output, for the execution environment. The microcomputers consist of a 10 MHz Motorola 68000 CPU and 1 Megabyte of main memory. Some of the microcomputers also have an SMD disk controller and a Fujitsu Eagle local disk.

While the total bandwidth of the S/Net is 80 Mbit/s, no single processor can achieve that speed. The maximum kernel level data transfer rate that a single processor can attain on the S/Net is approximately 300 Kbyte/sec, or 3% of the network's total capacity. Operating system overhead further reduces the effective data transfer rate between processes to 100 Kbyte/sec.

### 2.2. The *JASMIN* Operating System

The *JASMIN* distributed operating system is modeled after DEMOS [3]. The basic object implemented by the system is an interprocess communication capability called a *path*, over which small, fixed length messages can be sent. Holding a path enables a process to send a message to the creator of the path. Additionally, bulk data transfers between processes may be accomplished by attaching a buffer to a path in the creator's address space and using kernel primitives to move data into or out of the buffer. The system allows any process to create paths and to pass them to other processes via messages.

A set of processes which share text and data address space, but have separate execution stacks, are said to form a *load module*. Since memory is shared by these processes, a load module cannot span processors. While processes in the same load module share text and data space, their execution stacks inhabit different memory segments, they hold different sets of paths, and they receive messages from separate queues. In other words, paths and messages are exchanged between processes, not load modules. The load module notion is a convenience to permit cooperating processes to share memory.

*JASMIN* process scheduling is particularly simple. When created, each process is assigned a static priority level. Within each priority level, scheduling is strictly non-preemptive. A running process will execute until it performs a blocking system call, or until a higher priority process becomes ready-to-run. This guarantees mutual exclusion among a set of processes operating on shared data structures within a load module, as long as these processes are run at the same priority level.

## 3. A Parallel File Sorting Algorithm

Large files cannot usually be sorted in main memory, and so file sorting requires an *external sort algorithm*. Most external sort algorithms are based on iterative merging. They partition the file into subfiles that separately fit in memory, internally sort the individual subfiles, and then iteratively merge them into a single sorted file. During each iteration, every record is read and written once to mass-storage. These serial algorithms can be parallelized in a number of ways [4, 6, 10].

### 3.1. The Algorithm

We have implemented a parallel N-way merge-sort algorithm adapted from [4]. The algorithm assumes a logical tree connection between the processors (Figure 2). Each of the leaf processors has a disk attached to it, and thus can perform an external sort, independently of the host and the other processors in the backend. The parallel algorithm has two phases. We will refer to the first phase as the *sort phase*, and to the second as the *merge phase*. During the *sort phase*, each leaf processor creates fixed-length sorted subfiles from its partition of the file; during the *merge phase*, these subfiles are merged in parallel. Parallelism in merging is exploited both through pipelining merge steps between levels of the tree, and through concurrent merging performed by processors on the same level of the tree. The two phases of the algorithm are described in more detail below.

During the sort phase, fixed-length sorted subfiles are created by the leaves as in a serial sort. Partitions of the file are sorted in memory using Quicksort, and then written to disk. Available memory is divided between a subfile and an array of pointers to records in that subfile. During Quicksort, data records are not moved in memory, only pointers are

[b] UNIX is a trademark of AT&T Bell Laboratories.

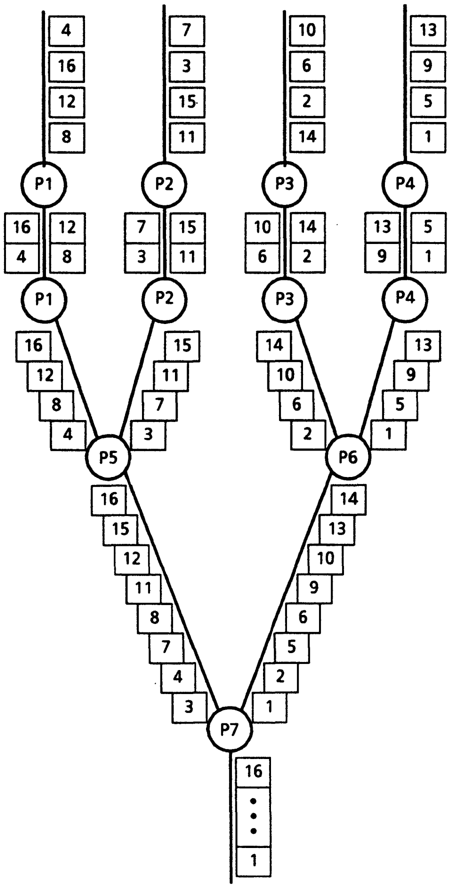

**Figure 2: A Parallel Merge-Sort**

changed.

After the sort phase completes, each leaf merges its subfiles, producing a single sorted partition of the file. As it is produced, the partition is transferred to the leafs parent in the merge tree. The parent processor merges the partitions it receives from its children and sends the result one level up in the tree. The complete sorted file is produced at the root of the merge tree. In our implementation, merge streams are transferred in blocks containing many records. While pipelining of successive merge phases *could* be at the record granularity, communication overhead makes such a design prohibitively inefficient.

It is interesting to note that, given a fixed topology for the merge tree, most of the steps in our sort algorithm are linear in terms of the number of comparisons performed. The partitioning of $n$ records into $n/b$ fixed-size sorted blocks of $b$ records each takes $O(nlog(b))$ comparisons. Similarly, merging $d$ sorted streams of $n/d$ records takes $O(nlog(d))$ comparisons. Thus, at non-leaf nodes, where the degree of the merge is fixed by the topology of the tree, the merge is linear. At the leaves, the degree of the merge is equal to the number of temporary files, which is in turn proportional to the size of input. The merge phase at the leaves is thus the only point where the number of comparisons is non-linear. Because comparisons are a small portion of the total work done in sorting a large file, even the uniprocessor configuration of our sort only shows significant non-linear behavior in file sizes over 25 megabytes (see Section 4.2).

### 3.2. Implementation on *JASMIN*

In order to concentrate on designing the parallel part of the sort utility, and have a good baseline for evaluating our implementation, we chose to start with a robust serial sort program. We considered the *Linderman Sort*, a program recently developed at Bell Laboratories [13]. The program has been extensively tuned, and achieves very good performance on UNIX. The algorithm implemented in Linderman's program is a polymerge sort [11], where initial runs are generated with Quicksort. Each sorted run is stored as a temporary file. Then the files are merged in one or more $N-way$ merge passes. We started with adapting this code for sorting the subfiles in the sort phase of our parallel algorithm, and for merging subfiles on one processor. Then, we turned our attention to design issues that are critical to the performance of the parallel sort program:

(1) the process configuration and synchronization protocol

(2) the memory configuration (including buffer allocation),

(3) the layout of files on the local disks.

**3.2.1. Process Configuration** On each backend processor, processes were configured so that delays due to data transfer and processor synchronization would be minimized. In particular, data transfers (processor-to-disk, or processor-to-processor) had to be overlapped with computation whenever possible. To avoid copying data within a processor, we adopted a structure consisting of a single *JASMIN* load module per processor. Multiple processes within each load module share access to a single buffer pool, but communicate and synchronize using messages.

Data transfers are organized as *streams* of record blocks. Each stream consists of a series of fixed size blocks containing a number of records. There are three types of streams, each with its own block size. *Input streams* carry unsorted record blocks from the root to the leaves. *Disk streams* carry sorted temporary files between a leaf and its disk. *Merge streams* carry sorted record blocks between processors in the merge tree.

During the sort phase, the records to be sorted are sent as input streams from the root to the leaf processors. In order to overlap communication latency, leaf processors interact with multiple communications processes in the root. In the leaf processors, an *input spooler* process reads the *input stream* from the the root, and builds *sort buffers*, which consist of data records and an array of pointers to these records (Figure 3).

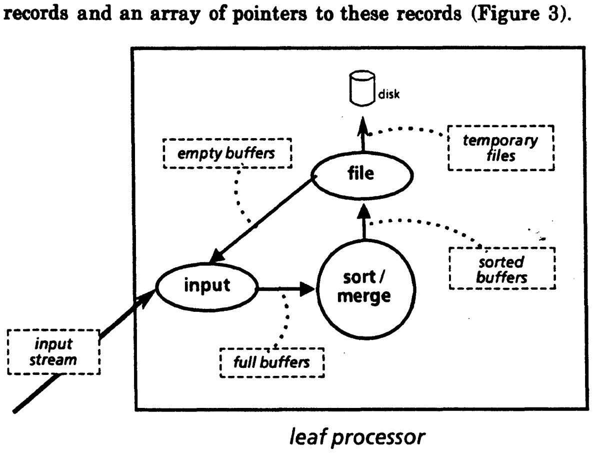

**Figure 3: Sort Phase Leaf Process Structure**

Once a sort buffer is built, it is passed to the main *sort/merge process.* This process performs a Quicksort on the pointer array, and passes the buffer to the *file spooler* process. The file spooler moves records for the first time from the input blocks, in which they were received, to disk blocks which are then written to disk. Each sorted buffer forms one *temporary file* on the disk. The use of two sort buffers per processor ensures a high degree of overlap between input, sorting and writing to disk.

During the merge phase, the sort buffers are unused and so are returned to free memory for use as disk or merge block buffers. The sort/merge process is central to the merge phase on both leaf and non-leaf processors (Figure 4). In the leaves, it merges sorted disk streams from the temporary files, one stream per file. In a non-leaf node, merge streams from the node's children in the tree are merged. In the former case, disk streams are read through the file spooler, which performs double buffering (disk read-ahead). In the latter case, a special *network spooler* process synchronizes data transfer from child processes and implements double buffering of merge streams. On all non-root processors, the output spooler process implements double buffering of merge streams being sent to the parent in the merge tree.

**3.2.2. Memory Configuration** Having only one megabyte of main memory attached to each processor restricts the maximum size of data buffers. After loading the operating system, utility tasks, the text segment for the sorting program, a stack segment for each sorting process, and miscellaneous sort program variables, about 576K remains for buffers. This led us to a configuration of two 256K sort buffers, resulting in temporary files somewhat smaller than that (the buffer must hold not only the records, but also an array of pointers to them). In contrast, a mainframe sort routine will typically use a 1 megabyte sort buffer.

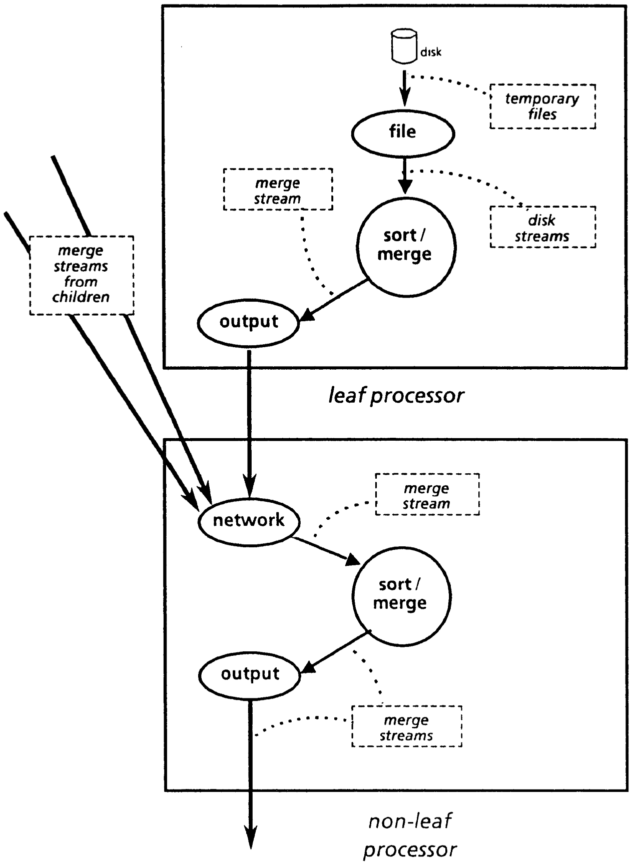

**Figure 4: Merge Phase Process Structure**

During the merge phase, each leaf processor must read a potentially large number of disk streams, and merge them to produce a single merge stream. Each stream is double buffered so the total memory used when merging $n$ files will be

$$M = 2nB_{disk} + 2B_{merge}$$

where the $B_x$ are block sizes. Now, the memory used as sort buffers during the sort phase can be reused as disk and merge blocks during the merge phase. Thus, all 576K are available for allocation. If we are to sort a 100M file using two leaf nodes, then each leaf must handle 50M, or 200 temporary files. Rearranging our equation, we see that

$$B_{disk} = (M - 2B_{merge})/2n \le (576K/400) \approx 1.4K$$

So, choosing $B_{disk} = 1K$, we get $B_{merge} \le 88K$.

The constraint on the size of a merge block does not arise at the leaves, but at non-leaf nodes. If a non-leaf node merges $m$ merge streams to form a single sorted merge stream, then it requires $2m + 2$ merge blocks for buffering. Since non-leaf nodes use no memory for disk blocks, if we want to handle values of $m$ up to 8, we get

$$B_{merge} = M/(2m + 2) \le 576K/18 \approx 32K$$

Thus, the demands of the problem we posed – sorting a 100Mbyte file in configurations ranging from two to eight leaf processors using varying tree structures – leads to a rather narrow choice of buffer sizes. We used the closest powers of two:

$$(B_{disk}, B_{merge}) = (1K, 32K)$$

**3.2.3 Disk File Layout** The layout of files on disk is central to minimizing access time. We experimented with two approaches: contiguous files and interleaved files. In contiguous file layout, the logical disk blocks of a file lie in consecutive physical disk addresses. This means they will be physically contiguous unless they cross a cylinder boundary. In interleaved file layout, the first logical block of all files lie in one consecutive set of disk addresses, followed by the second block of all files, etc. (Figure 5).

Contiguous file layout minimizes seeking when reading or writing an entire sequential file. It maximizes seeking when multiple sequential files are to be accessed concurrently.

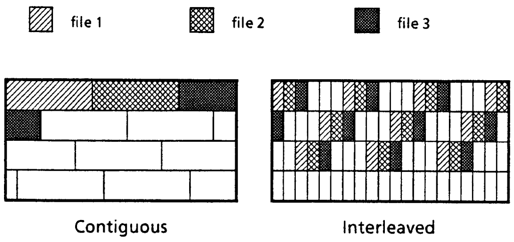

**Figure 5: Contiguous vs Interleaved File Layout**

Interleaved layout achieves the opposite: maximal seeking when accessing a single file sequentially; minimal seeking when accessing many files concurrently. Intermediate schemes which interleave files in segments larger than one logical block are possible, but we did not implement any. In our sort algorithm, temporary files are written one at a time during the sort phase, and then all are read concurrently during the merge phase. Thus, contiguous layout performs best during the sort phase, while interleaved layout wins in the merge phase.

### 3.3 Choosing Parameter Values

We experimented with various ways to partition the 576K of memory that were available for buffer configuration in each processor. The parameter to which the sort time was most sensitive was merge block size. Larger merge blocks decreased the overhead during the merge phase, and reduced the number of interprocessor synchronization points. With double buffering, the maximum size of a merge block that we could choose was 32K (see Section 3.2). To a lesser extent, increasing the input block size also increased sort speed and we settled on an input block size of 8K. Larger input blocks caused wasteful fragmentation of sort buffers.

The large amount of idle time in the leaves during the merge phase suggests that double buffering of disk blocks may not be advantageous. It may be better to consolidate the two buffers into one large buffer to reduce the number of disk accesses. Additional enhancement could also come from improving the scheduling of network data transfers. In the current implementation, the network spooler in a parent node transfers merge blocks from the node's children in the order in which they are requested. However, at the same time, double buffering may cause network traffic that blocks the transfer of data which is needed for merging to proceed. Children are serviced in approximately round-robin order, giving no priority to a transfer which is holding up the merge.

We compared the performance of our sort with the two alternative file layouts: *contiguous* and *interleaved*. Using the interleaved scheme provided an overall improvement of 5% in elapsed time.

## 4. Measurements

In this section, we present and analyze our measurements for a range of backend configurations and file sizes. In order to establish a performance baseline, we start with our uniprocessor sort (*JS1*) on *JASMIN*, and compare it to the Linderman Sort on a fast UNIX machine (Section 4.2). We then analyze in detail the performance of the parallel *Backend Sort*, for different multiprocessor configurations (Section 4.3). Finally, we estimate elapsed times for the *Distributed Sort* (Section 4.4).

### 4.1. Parameters Varied

In our experiments, we varied the following parameters:

(1) Number of processors in the backend:

We configured the backend as a single processor, as a two-level tree with 3 and 5 processors (2 and 4 leaves), and as a three-level binary tree with 7 processors (4 leaves, 2 internal nodes). In subsequent tables, these configurations are labeled as *JS1, JS3, JS5,* and *JS7*, respectively. In all the tree configurations, each leaf processor had a local disk.

(2) Structure and size of the data file:

We varied the size of our data file from 1 to 100 megabytes. The data was randomly generated as a stream of 100 byte records, with a 10-byte ascii-numeric sort key. The record format included a header consisting of a 2-byte record-length field and a 2-byte key-length field, which were interpreted by the sort program. Thus, our implementation can also sort variable length records. In addition to the data records, we used two types of control records, *end of block* and *end of file*, in order to form streams of records. These control records are four bytes long.

We also varied the memory configuration and the file layout scheme. However, all the measurements presented below correspond to experiments with double buffering and interleaved file layout, since these appeared to be more efficient.

### 4.2. Uniprocessor Efficiency

In order to establish a baseline performance measure for our implementation, we compared a single-processor configuration to the UNIX sort [13] on a faster machine. Figure 6 shows the times recorded for sorting files of 1 to 50 megabytes on a *JASMIN* 68000-based microcomputer and on a CCI Power-6 computer running UNIX 4.2 BSD. In both cases the disk was a Fujitsu Eagle. The *JASMIN* figures constitute a baseline that we will use to evaluate the parallel speedup achievable in multiprocessor configurations. We will use the UNIX-CCI numbers as a baseline for comparing the performance of a fast, general-purpose serial machine with that of a backend multiprocessor.

The 68000-based microcomputer is rated at 0.6 MIPS, while the CCI processor is rated at 5 to 6 MIPS. Considering the difference in processor capabilities, the comparison greatly favors the *JASMIN* sort. The UNIX-CCI sort is 1.6 times faster for small files, but only 1.2 times faster for large files. From Figure 6, we observe that, up to 35M, the rate of the *JASMIN* sort is almost constant at 18 Kbyte/sec. On the other hand, the rate of the CCI-UNIX sort degrades rapidly for file sizes above 20M. This degradation is at least partly due to the limit of 20 on the number of open files in a UNIX process, which necessitates multiple N-way merge passes in the merge phase. The comparison illustrates the limits imposed by a general-purpose operating system (UNIX) compared to *JASMIN*. The *JASMIN* kernel essentially gives an application the full power of the underlying computer. In this application, we observed a processor utilization rate of 90%.

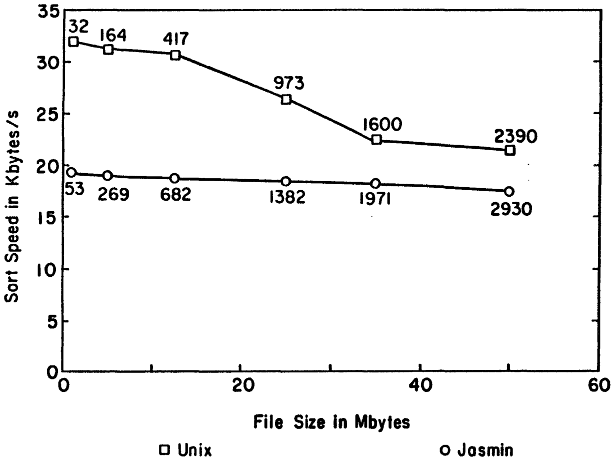

**Figure 6: Serial Sort Times in Seconds on *JASMIN* and UNIX**

### 4.3. Backend Sort

In Table 1, we show the total execution time of the Backend Sort for 4 processor configurations, and for file sizes of 5, 12.5, 25, 50 and 100 megabytes. The times shown correspond to the root's elapsed time, which was only slightly higher than the leaves' or internal nodes'. Figure 7 compares the sorting speed achieved in these experiments to the UNIX-CCI sort.

The most striking observation from this table is how fast the 100M sort is, for both JS3 and JS5. The backend multiprocessor sorts 100M in 1 hour with 3 processors, and in 52 minutes with 5 processors. This performance is comparable to that of highly-tuned commercial sort packages such as the IBM SYNC-SORT on a high-performance mainframe (e.g. an IBM 3081, rated at approximately 7 MIPS). It is thus clear that our parallel Backend Sort provides a very cost-effective alternative to main-frame, serial sorting of large files.

Further analysis of the data in Table 1 leads us to the following observations on parallel speedup:

(1) The 3 processor configuration is faster than the 1 processor configuration by a factor of 1.5 for small files to 1.6 for a 50M file.

(2) Using two additional leaves (i.e. the 5 processor configuration) further improved the sort time by up to 16%.

(3) Using a two-level merge tree with 7 processors does not improve performance. In fact JS7 shows slightly higher overall times than JS5.

| File Size | JS1 | JS3 | JS5 | JS7 |
|---|---|---|---|---|
| 5M | 269 | 178 | 178 | 173 |
| 12.5M | 682 | 439 | 419 | 427 |
| 25M | 1384 | 884 | 836 | 869 |
| 50M | 2930 | 1782 | 1584 | 1682 |
| 100M | —[c] | 3625 | 3131 | 3305 |

**Table 1: Total Sort Times In Seconds 1, 3, 5 and 7 Processor Configurations**

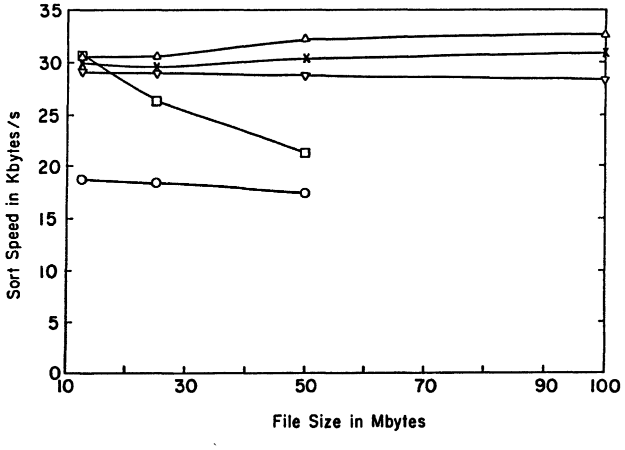

**Figure 7: Parallel and Uniprocessor Sort Speeds**

The added processing power and I/O bandwidth in JS3, with 3 processors and 2 disks, proved very effective in reducing up the elapsed time of the sort. However, as more processors and disks were added, the additional performance enhancement was limited. These observations suggest that the parallel sort is limited by network data transfer rather than by computation or disk activity. We tested this hypothesis by instrumenting the sort program to record idle and elapsed times for both the sort and merge phases. Table 2 shows these measurements for a 25 megabyte sort with 3 processors, and a 50 megabyte sort with 5 processors.

The times in Table 2 are for the root, and one of the leaves. (Since all leaves had similar elapsed and idle times, we only present our measurements for one.) Discrepancies between the elapsed times shown in Table 1 and Table 2 for the same configurations are due to distortions introduced by measuring idle time. The additional data in Table 2 supports our hypothesis in the following ways:

(1) The sort phase of the 50M sort lasts almost twice as long as the sort phase of the 25M sort, although the leaves do exactly the same work in both. The additional time shows up as idle time at the leaves, while they wait for data from the root. In both configurations, the root shows little idle time during the sort phase. I/O delays (shown as *Disk Busy* time) are almost null during the sort phase.

(2) The merge phase of the 50M sort lasts almost exactly twice as long as that of the 25M sort, and substantial idle time accumulates at both the leaves and the root. Unlike the sort phase, where the root processor is saturated, both root and leaves appear to be waiting on the network. Disk waiting during the merge phase accounted for less than 10% of the idle time, in both configurations. Furthermore, it did not decrease with the use of two additional disks (JS5 versus JS3).

(3) The non-idle time at the leaves during the sort and merge phases, is approximately the same on both configurations: sort phase 320 seconds, merge phase 340 seconds. The non-idle time at the root varied linearly with the amount of data in both phases. The sort phase might be speeded up by starting with a distributed file (see Section 4.4), or increasing the power of the root processor. However, it is clear that a higher network transfer rate is necessary in order to speed up the merge phase.

| | | JS3-25M | | JS5-50M | |
|---|---|---|---|---|---|
| | | leaf | root | leaf | root |
| **Sort Phase** | elapsed time | 638 | 639 | 1004 | 1005 |
| | disk busy | 2 | 0 | 0 | 0 |
| | idle time | 320 | 162 | 680 | 26 |
| **Merge Phase** | elapsed time | 937 | 938 | 1871 | 1873 |
| | disk busy | 53 | – | 55 | – |
| | idle time | 598 | 629 | 1534 | 1274 |
| **Total**<br>(Both Phases) | elapsed time | 1575 | 1577 | 2875 | 2878 |
| | disk busy | 55 | – | 55 | – |
| | idle time | 918 | 791 | 2217 | 1300 |

**Table 2: Sort, Merge and Idle Time In Seconds 3 and 5 Processor Backend Sort**

[c] This number is unavailable due to processor memory limitations.

We conclude that for the Backend Sort, the limitation of a low network transfer rate means that the use of more than 4 processors as leaves can speed the sort phase only marginally, and the extra processor power is not used efficiently. Similarly, use of additional processors as interior merge nodes in the 7 processor configuration only reduces non-idle time at the root, which does not improve the overall merge speed. A network which delivered data at the faster rate would be able to increase the utilization of the leaves and root during the merge phase, and so could effectively utilize more processors.

### 4.4. Distributed Sort

The above discussion of Table 2 indicates that the distribution of the file from the root to the leaf processors created a bottleneck. In a *Distributed Sort*, where the file is initially distributed across the local disks at the leaves, the sort phase would be much faster. In fact, since, during this phase, the computation is fully partitioned and every leaf processor has its own disk, the sort phase time at the leaves is simply the uniprocessor sort phase time for one partition. Thus, a good estimate of the sort phase time in the Distributed case is the sort phase time of one partition in the JS1 configuration. Merge phase time in the Distributed Sort is identical to that in the Backend case. By combining these estimates of the sort and merge phase times, we obtained the total times for the Distributed Sort. The results obtained are shown in Table 3.

| | | Sort | Merge | Total |
|---|---|---|---|---|
| **JS3** | 10M | 147 | 158 | 305 |
| | 50M | 738 | 828 | 1566 |
| **JS5** | 10M | 74 | 157 | 231 |
| | 50M | 370 | 696 | 1066 |

**Table 3: Distributed Sort Estimate**
**Sort, Merge and Total Times in Seconds**

While in the Backend Sort, the bottleneck at the root made the use of more than 3 processors inefficient, we now observe a substantial speedup with 5 processors. For a file of 50 megabytes, the elapsed time is 1566 seconds for a distributed 3 processor sort and 1066 seconds for a 5 processor sort. This is a speedup of 1.5 compared to 1.1 for the Backend Sort.

## 5. Conclusions

We have described our experience with developing and evaluating a parallel sort utility. Our goal was to explore the feasibility of fast file sorting algorithms under limited parallelism, limited inter-processor communication bandwidth and the constraints of conventional I/O devices. Our testbed was a multiprocessor that can be configured with up to 12 microprocessors, communicating through a fast packet-switched bus and running a distributed operating system kernel. Multiple disk drives, each attached to one microprocessor, provided high I/O bandwidth.

We implemented a parallel external merge-sort algorithm, and measured its performance for a range of file sizes and processor configurations. After detailed analysis of our measurements, and scaling of our results, we reach a number of conclusions:

(1) Using current off-the-shelf technology, 3 and 5 processor configurations provide a very cost-effective solution to sorting a large file. The 3 processor configuration sorts a 100 megabyte file in 3625 seconds (1 hour), which compares well with commercial sort packages available on high-performance mainframes. The 5 processor sort is 16% faster for large files. This level of performance, at a low hardware cost, results from a design which makes effective use of a streamlined, distributed operating system to exploit a limited amount of parallelism in computation and I/O.

(2) Latency in network data transfer prevents the effective use of higher levels of parallelism in the backend sort model, where the data file is not distributed. Interestingly, the 10 Mbyte/sec physical bandwidth of our network was not the limiting factor: Only 300 Kbyte/sec of that is available to any one processor, and operating system overhead reduces that to approximately 100 Kbyte/sec for the actual process-to-process data transfer rate. At this rate, network latency allows even a microprocessor (rated at 0.6 MIPS) to sort and merge data as quickly as it can be moved between machines. Adding processors to the backend configuration simply increased idle time.

(3) We observed that distributed storage of files provides a substantial benefit in sorting. For instance, with the 5-processor configuration, a 50-megabyte distributed file could be sorted in 17 minutes, compared to 26 minutes needed for a non-distributed file. Our distributed sort model makes efficient use of additional leaf processors to accelerate the sort phase, which the backend model is unable to do.

This study demonstrates that, with current microprocessor and communication technology, parallel sorting of large files is a viable, cost-effective alternative to highly tuned sort utilities on mainframes. Our analysis indicates that its efficiency can be expected to increase dramatically due to improvements in local area network technology in the next few years.

## 6. Acknowledgements

We would like to acknowledge the early work of Bill Burnette and Susan Fontaine at AT&T-Bell Laboratories in developing the JASMIN operating system (then called MAX). U. Premkumar was responsible for developing the network interface which distributes JASMIN across processors. His work with the JASMIN and S/Net software and hardware made this project possible. Hikyu Lee also made significant contributions to the JASMIN S/Net implementation. We thank Ming-Yee Lai for graciously allowing us to disrupt his use of the S/Net, and for helping us with an early draft of this paper.

We are grateful to two managers who have been especially supportive of our work. Dan Fishman saw JASMIN through its early days at Bell Laboratories, and, although now at HP Labs, he continues to encourage our efforts. Mike Lesk, of Bell Communications Research, has generously supported the collaboration with Cornell University which has made this research possible. Finally, we thank Jim Gray from TANDEM Computers for his helpful comments and suggestions.

# A DISTRIBUTED IMPLEMENTATION SCHEME FOR COMMUNICATING PROCESSES

A. A. Aaby and K. T. Narayana

Department of Computer Science
The Pennsylvania State University
University Park, Pa 16802

*Abstract*: We present an efficient time stamp based distributed scheme for synchronization of communicating sequential processes. In the communication model assumed, processes name ports in their communication commands and both the input and output commands can appear in the guards of an alternative command, a general framework than that allowed by Hoare's CSP. We further assume synchronized communication between processes. An implementation of the scheme is described. The scheme can become part of the kernel for a programming language for distributed computation. We provide a discussion on fault tolerance of the algorithm against node failures. We prove the correctness of the scheme by establishing that the scheme is deadlock free and further that if two processes are willing to communicate and don't synchronize with any other, they do synchronize with each other. A specification in interval logic of the scheme and the verification of it, including strong fairness, is given elsewhere.

## 1. Introduction

A distributed system is an interconnection of a network of computing elements with each of the elements having its own local store. The local storage of one computing element is not shared by any other. A distributed program consists of a system of processes with each of the processes executing on some computing element of the distributed system. The processes of a distributed program cooperate so as to achieve a common purpose. Because of the absence of shared storage, the processes achieve cooperation by the exchange of messages. Thus, interprocess communication using message passing constitutes a basic paradigm for the computations evoked by a distributed program.

A model of distributed computation known as Communicating Sequential Processes(CSP) has been proposed by Hoare[8]. A programming notation for the expression of distributed algorithms, constituting a distributed program, has also been suggested in the same work. The model consists of a set of sequential processes, without nesting, with each of the processes confining access to its own data and effecting cooperation between one another by the use of input and output commands for message passing. Processes are explicitly named in the input and output command. Communication between the processes occurs when the output command of a process matches the input command of another process. Such a communication model is termed as synchronous or unbuffered. An alternative command based on Dijkstra's guarded command construct [6] permits an arbitrary selection of a command, for execution, from out of the commands whose guards have been successful. A guard in the command can be a boolean expression or a boolean expression followed by an input command or an input command itself. A boolean guard is said to be successful if it evaluates to true. An input command is successful if a matching output command from the process named in the input command can be found. A guarded input command is said to be successful if the boolean guard preceding the input command evaluates to true and the input command is successful. In an implementation scheme, an arbitrary selection of a command from out of those guards that are successful at the earliest may be made. This strategy assures that a process may synchronize, while in an alternative command, with any of the processes named by it and are ready to synchronize.

However, the introduction of output commands in the guards of an alternative command can simplify the specification of distributed algorithms using the CSP notation[7, 8]. Buckley and Silberschatz[4] suggest a distributed implementation scheme based on assignment of static priorities between processes. They offer four distinct criteria to be met by any implementation scheme. They are as follows:

1) The number of system processes involved in establishing a handshake must be minimal so as to reduce processor interrupts.
2) The amount of system information that each of the processes needs in order to make a decision about synchronization must be minimal.
3) There must be a bound on the number of messages exchanged so as to guarantee that two processes willing to communicate do so within a certain finite time.
4) The number of control signals exchanged between processes must be minimal.

The implementations suggested in [3, 7, 14, 15] violate one or more of these four criteria.

Time stamps have been used for the termination detection of CSP programs[2]. The algorithm given in this paper is based on the use of time stamps and is superior to that given in [12] both in its simplicity and its performance.

The paper is organized as follows. In section 2, a communication model is presented. In section 3, the time stamp based distributed implementation scheme (ANa scheme) is presented. In section 4, an implementation of the algorithm in a programming notation is given. In section 5, various properties of liveness, deadlock freedom, weak fairness and the performance parameters of the scheme are established. In section 6, a discussion is provided on a) the degree of

0190-3918/86/0000/0942 $01.00 © 1986 IEEE

concurrency, b) the comparative performance of the algorithm and c) the resilence of the algorithm against node failures. Section 7 concludes the paper with closing remarks.

## 2. The Communication Model

We assume a port directed communication model. In this model, each process is associated with a finite collection of input ports and output ports through which the messages are sent and received. A process can use an output port only to send messages and an input port only to receive messages. The input port of one process may be connected to the output port of another process. Such interconnection of ports using channels may be specified separately. We require that each port of a process must be connected to one and only one other port and the communication between processes is synchronous. Each process, while in an alternative command, names a collection of ports on which it is willing to communicate. The port based communication paradigm is in contrast to explicit naming of processes in CSP.

To facilitate communication between processes, each process is associated with a port manager. The process, upon entering an alternative command with communication commands in the guards, transmits to its associated port manager the set of ports (called the candidate communicant set) on which it is willing to communicate. The details of transmission of arguments are ignored for reasons of brevity and to concentrate on the implementation scheme establishing synchronization.

## 3. The Algorithm (ANa Scheme)

Whenever a process enters an alternative command, the process requests its port manager to provide the alternative command service by transmitting to the port manager the set of ports named in the alternative command of the process, i.e., the candidate communicant set. If an input command (output command) appears as a statement in the process, then the process utilizes the alternative command service made available by its port manager to achieve a matching output command (input command) on the designated port. Once a process triggers the alternative command service of its port manager, the process waits until the port manager establishes the handshake. Each of the port managers runs the same distributed synchronization algorithm with which it obtains a synchronization partner. Since we assumed a fully distributed system without shared memory, the port managers have to find a synchronization partner by exchanging control signals with other port managers of the ports linked to the candidate communicant set. We now describe, informally, the distributed scheme given in figure 1.

A port manager uses a variable Turn for each of the ports to mark the port to indicate whether it is its own turn to initiate communication on that port or if it is the turn of the port manager of the port linked to that port to initiate communication. Initially, when the distributed program is set up, the port manager of each of the processes marks for each port the variable Turn as MyTurn, meaning that it is MyTurn to contact a partner on that port. A port manager uses a variable Committed for each of the ports to mark the port to indicate that a Commit signal has been received on that port and that a reply has not been sent. A port manager acquires a time stamp for each of the alternative commands it services (the generated time stamps are monotonically increasing).

Assume now that some of the processes in the distributed program have requested the initiation of the alternative command service by their respective port managers. Consider a process P executing an alternative command. The port manager of P picks arbitrarily one of the candidate communicant ports, p, whose state is MyTurn and sends the control signal Commit(p,Tid), where Tid is the time stamp acquired for this alternative command service by the port manager. The port manager then waits for a response. During this period of waiting for a response, two things can happen. A response may arrive on the port p and has to be dealt with. In addition, during the waiting period, some other port manager(s) may send Commit signal(s) in the hope of finding a synchronizing partner in P.

If the response to the Commit signal sent has been a Commit signal, then the port manager regards that as a willingness of another port manager to synchronize and treats that a synchronization partner has been found. It synchronizes and then sets Committed(p) to false and Turn(p) to MyTurn.

If the response to the Commit signal sent has been a No signal, then the port manager regards that the port manager of the correspondent of the port p is at the moment unwilling to synchronize and marks that fact in the variable Turn(p) as ItsTurn, denoting that it is the turn of the correspondent's port manager to seek synchronization on that port.

Suppose that during the period of waiting for a response to a Commit signal sent on the port p, Commit signals arrive on other ports. Then what should the port manager do?

If the port on which a Commit signal has been received is not in the communicant set, then, naturally, the port manager of p cannot synchronize on that port, because it is not a suitable partner. And hence the port manager sends the control signal No as a response and sets Turn(p) to MyTurn.

If the port on which a Commit signal has been received is in the communicant set, then the port manager knows that, if he were not waiting for a response, he could have synchronized with that port manager. It may withhold sending a response.

However, the port manager cannot hold back a response to all of the Commit signals it has received on its candidate communicant set during its waiting period until it itself has received a response to its Commit signal. This is because there is a potential for the creation of a cycle of port managers each of which is waiting for a response, but each of which delays sending a response to every other Commit signal received on the candidate communicant set in that period. Thus there will be deadlock. We seek to break this deadlock by requiring that each port manager send the time stamp that it has acquired along with the Commit signal. Thus, during the period of waiting for a response to a transmitted Commit signal, the port manager of p sends a No signal on those candidate communicant ports on which a Commit signal with a time stamp less than that of its own time stamp is received. In addition, the port state variable Turn is set to MyTurn, denoting that the port manager of p must attempt communication on that port at any future instant. On the other hand, if the time stamp received on the Commit signal is larger than its own time stamp, then the port manager of p delays a response to that Commit signal and marks the variable Committed for that port as true and the port state variable Turn as MyTurn.

If a port manager has failed to synchronize on the chosen port p, then it seeks to send a Commit signal on a port, arbitrarily selected, on which the sending of a response to a Commit signal is pending. Synchronization then occurs on that port, Committed is set to false. The port manager sends the control Signal No on the rest of the ports on which response is delayed, marks the variable Turn for that port as MyTurn and Committed for that port to false, so that future invocations of the alternative command may use that information.

If there are no ports on which a response to a Commit signal is delayed, then the port manager selects a port q other than p and sends a Commit(q,Tid) signal. The port manager waits for a response and takes actions during the period of waiting in the same way as described above.

If it happens that the port manager receives a response of No on each of its candidate communicant ports to a transmitted Commit signal, then the port manager waits. It synchronizes with any port in its candidate communicant set on which it receives a Commit signal the earliest thereafter. If more than one Commit signal is received, then it selects one of them to synchronize and sends a No signal as a response to the others.

If the port manager is not servicing an alternative command, then the port manager sends a No signal as a response to every Commit signal received on any port and marks the Turn of that port as ItsTurn for future use of that information.

## 4. The Implementation of the Algorithm

An informal programming notation has been employed for the description of the implementation scheme. An explanation of some relevant notations is given below.

; denotes the sequential composition of statements.
***[S]** denotes that the statement S is repeated forever.
**S1||S2** denotes a parallel composition of the statements S1 and S2.
**Committed(p)** denotes that a Commit signal has been received on port p and a reply has not been sent.
**CP** denotes the set of candidate communicant ports.
**receive(...)** denotes that the event of the reception of a message has occurred on some port and the reception is asynchronous.
**Select(p)** denotes the procedure of the port manager which selects a port for a communication attempt.
**Selected(p)** denotes that a Commit signal has been sent on port p and either a reply has not yet been received or the transport of the message has not yet occurred.
**send(...)** is the primitive employed by the port manager to transmit a signal on some port and the transmission is asynchronous.
**synchronized** denotes that the port manager has achieved the transport of the message.
**Tid** denotes the current transaction identifier.
**Time** is the clock function of the port manager
**TM(p)** denotes the activity relevant to the transfer of the message datum.
**Turn(p)** denotes which of the predicates, MyTurn or ItsTurn is satisfied on the port p.
**wait(p)** is a command providing for the suspension of the task until the predicate p is true.

The algorithm consists of two loops and is given in figure 1.

The first loop waits for the reception of a Commit signal and upon the reception of a Commit signal certain actions are taken. If the port on which the signal was received is not a port in CP, then the offer to communicate is rejected with a No signal and Turn is set to MyTurn for that port. The case where the port is in CP is more complicated. We require the port manager which sends a Commit signal to wait for a response. This requirement could allow cycle of waiting port managers to form therefore, we prevent the formation of a cycle by a requirement that a port manager while awaiting a response must reject some offers to communicate that are received during the waiting time. The rejection of some offers is dependent on the time stamp received with the offer and the current state of the port manager. If the time stamp received with the signal is less than the time stamp obtained by the port manager in the current alternative command and the port manager is awaiting a response to a Commit signal of its own then a No signal is sent in response. Otherwise Committed is set to true for that port.

```
$\forall p$ Turn(p) := MyTurn;
$\forall p$ Committed(p) := false;
$\forall p$ Selected(p) := false;
CP := $\phi$ ;
BEGIN
  $\forall p$
  *[ wait( receive( Commit(p,u) ));
     Turn(p) := MyTurn
     If $p \notin CP$ then
        send( No(p,Time));
     else if $u > Tid \lor \forall r \in CP \neg Selected(r)$ then
        Committed(p) := true endif
     else if $u < Tid \land \exists\, r \in CP\ Selected(r) \land r \neq p$ then
        send( No(p,Tid)) endif
     endif ]
|| *[ wait( $CP \neq \phi$ );
     Tid := Time;
     synchronized := false;
     repeat
        select(p);
        Selected(p) := true;
        send( Commit(p,Tid));
        if Committed(p) then
           TM(p); synchronized := true;
           Committed(p) := false;
           Turn(p) := MyTurn
        else
           wait( receive( No(p,u)) or
                  receive( Commit(p,u)));
           if receive( Commit(p,u)) then
              TM(p); synchronized := true;
              Turn(p) := MyTurn;
              Committed(p) := false
           else Turn(p) := ItsTurn
           endif
        endif
        Selected(p) := false;
     until synchronized;
     $\forall p \in CP$
     If Committed(p) then
        send( No(p,Tid));
         Committed(p) := false;
         Turn(p) := MyTurn
     endif;
     CP := $\phi$ ]
END
```

Fig 1: Algorithm executed by a port manager.

The second loop executes only when a process is in an alternative command. Upon entering an alternative command Tid is set to a unique value obtained from a local clock which is maintained in loose synchronization with the local clocks of the other port managers in the system[10]. The selection of ports on which to attempt synchronization consists of two phases. The first phase involves active attempts by a port manager to synchronize with a candidate communicant via any port on which it is the port manager's turn to initiate communication (Turn = MyTurn) or on any port on which it has received an invitation to synchronize (Committed(p) = true). Selection of a port for a communication attempt is accomplished in the procedure select(p). (It is intended that priority be given to the port on which a Commit signal was least recently sent and on which Turn = MyTurn.) Next, the signal Commit(p,Tid) is transmitted on the port p and a period of waiting for a response (wait(receive(No(p,u)) or receive(Commit(p,u)))) follows. If the predicate Committed is satisfied on the port p which was selected, then no response is required therefore the transport of the message (TM(p)) occurs. Otherwise, if the response is Commit(p,u), then the transport of the message occurs and if the response is No(p,u), then some other port will be selected for another communication attempt. The second phase is entered when for each candidate communicant port it is the turn of some other port manager to initiate communication (Turn(p)=ItsTurn). the port manager awaits an invitation to synchronize and will synchronize with the first invitation and reject all other invitations received during this phase. In the second phase, the select operation must wait for the reception of a Commit signal on a port in CP.

## 5. Some Properties of the ANa Scheme

The specification and verification of the scheme in [1] establishes the results formally using interval based temporal logic[13].

*Theorem 1:*

*If the predicate function ItsTurn is true on all of the candidate communicant ports of a process which is in an alternative command, then, upon the reception of a Commit signal on a candidate communicant port, the port manager of the process will exit the alternative command eventually.*

*Proof:* The hypothesis corresponds to case 5 of the scheme. Since case 5 leads to case 4, and case 4 is specific to the port manager servicing the alternative command, the port manager will exit the alternative command service eventually.

*Theorem 2: Deadlock freedom of the implementation.*

*If a port manager is committed on some port p, then, eventually, it makes progress on that commitment.*

*Proof:*

*case 1:* Assume that there does not exist a cycle of commitments between port managers. Then, a port manager receives as a response either a Commit signal or a No signal to a Commit(p,id) signal transmitted by it on some candidate communicant port p. The two cases are dictated by case 2a and case 2b of the scheme. Thus the port manager makes progress on its commitment in these two cases.
*case 2:* Assume that there exists a cycle of port managers $P_1,P_2,...P_n$ with transaction identifiers $t_1,t_2,...t_n$ such that, for $1 \leq i \leq n$, $P_i$ has sent a commit signal to $P_{i+1 \bmod n}$ and is awaiting a response. Since the transaction identifiers obtained by each of the port managers in the cycle are totally ordered and responses to Commit signals may be delayed to processes with greater transaction identifiers, there exists a port manager, say $P_k$, with the minimum transaction identifier in the cycle which has sent a commit signal to a port manager $P_{k+1 \bmod n}$. Thus it may be assumed that the transaction identifiers are ordered as follows: $t_1 > t_2 > \cdots > t_k < t_{k+1} > \cdots t_n$ and $t_n > t_1$. The response in $P_{k+1 \bmod n}$ is dictated by case 3c of the scheme. Hence, a No signal is transmitted on a port to $P_k$ and the cycle is broken. Thereafter, progress in commitment is achieved as in case 1.

*Theorem 3:*

*If an alternative command names M ports as candidate communicants, then the signal Commit(p,*$\mathrm{id}_1$*) need be sent on some candidate communicant port p at most once, by the port manager, prior to synchronization with any one of the candidate communicants.*

*Proof:* By step 1 of the scheme a Commit signal may only be transmitted on a candidate communicant port p satisfying the predicate Turn(p) = MyTurn. If on such a port a Commit signal is transmitted and as in case 1 of the scheme and a Commit signal is received on the port p as a response to the Commit signal, then synchronization occurs and the theorem is satisfied. If, however, a No signal is received as a response to the Commit signal then case 2b of the scheme specifies that Turn(p) = ItsTurn is satisfied on that port and the scheme requires that no further signals be transmitted on p until Turn(p) = MyTurn is satisfied. The predicate Turn(p) = MyTurn is satisfied on p under the condition of the reception of a Commit signal on p as in case 2a, case 3a, case 3c or case 6 of the scheme. If on p a Commit signal is received, then, after a possible delay, either synchronization occurs following the transmission of a Commit signal on p as in case 4a or case 5 of the scheme or, if synchronization occurs on some other candidate communicant port then case 4b specifies that a No signal is transmitted on that port. In all of the cases, only one Commit signal is sent and the theorem is satisfied.

*Lemma 1:*

*If* $\mathrm{Cl}_i$ *and* $\mathrm{Cl}_j$ *are, respectively, the communicant lists of two processes* $P_i$ *and* $P_j$*, both of which are in alternative commands with transaction identifiers* $\mathrm{id}_i$ *and* $\mathrm{id}_j$*, respectively, and neither of which has synchronized, and further, the ports* $p_i$ *and* $p_j$ *are linked, where the port* $p_i \in \mathrm{Cl}_i$ *and the port* $p_j \in \mathrm{Cl}_j$*, then ItsTurn(*$p_i$*)→MyTurn(*$p_j$*)*$\wedge$ $\mathrm{id}_j < \mathrm{id}_i$.

*Proof:* By case 2b of the scheme the candidate communicant port $p_i$ satisfies Turn($p_i$) = ItsTurn iff the port manager of the process $P_i$ has received a No signal as a response to a Commit signal on port $p_i$. If the port $p_i$ is linked to the port $p_j$ and the port $p_j$ is a candidate communicant port of the process $P_j$, then the port manager of the process $P_j$, by case 2a, must satisfy Turn($p_j$) = MyTurn on the port $p_j$. Thus the lemma is established.

*Theorem 4: Synchronization Condition*

*If two processes* $P_i$ *and* $P_j$*, each of which is in an alternative command, each name some pairs of ports,* $p_i$ *and* $p_j$*, linking* $P_i$ *and* $P_j$ *as candidate communicants, and further if neither of them synchronizes with any other candidate communicant, then they synchronize with each other on any pair of the named pairs of linked ports* $p_i$ *and* $p_j$.

*Proof:* From Lemma 1, the linked pairs of ports $p_i$ and $p_j$ of the processes $P_i$ and $P_j$ satisfy, ItsTurn($p_i$)→MyTurn($p_j$)$\wedge \mathrm{id}_j < \mathrm{id}_i$, and since it is assumed that there is only a finite number of candidate communicant ports and since, by Theorem 2, the implementation is deadlock free, the port manager of at least one of the processes $P_i$ or $P_j$, say process $P_i$, by case 1, must eventually transmit a Commit signal on one of the linked ports, say $p_i$, to which the port manager of the process $P_j$, by case 4a, must respond with the transmission of a Commit signal on the linked port $p_j$. Thus the theorem is established.

*Theorem 5:*

*When a process is in an alternative command with M number of candidate communicant ports, the port manager of the process need send at most M Commit signals on the candidate communicant ports in order to synchronize.*

*Proof:* From Theorem 3, a Commit signal need be sent at most once on a candidate communicant port prior to synchronization. Since there are M candidate communicant ports, at most M Commit signal need be sent.

*Theorem 6:*

*When a process is in an alternative command with M number of candidate communicant ports, the port manager of the process need send no more than* 2M–1 *Commit or No signals on the candidate communicant ports.*

*Proof:* If, by case 1, the port manager of the process $P_i$, with M number of candidate communicant ports, has sent a Commit signal, on some candidate communicant port $p_i$, and is awaiting a reply to the Commit signal, it may, while awaiting the reply, receive at most M - 1 Commit signals on the other candidate communicant ports $p_j$. The port manager of the process $P_i$ must, by case 2b, send at most M - 1 No signals on the ports $p_j$ on which it received the Commit signals. (If after having sent the No signals the port manager continues to await the reply to the Commit signal sent on the port $p_i$, and receives a second Commit signal on any of the other candidate communicant ports $p_j$, then the port manager will delay response to that Commit signal since by Theorem 3 the second Commit signal received on the port $p_j$ represents a new alternative command transaction and contains a transaction id greater than the transaction obtained by the port manager of the process $P_i$.) If, thereafter, the port manager of the process $P_i$ receives a No signal on the candidate communicant port $p_i$, it may, by case 1 or case 4a of the scheme, send Commit signals, in turn, on each of the M - 1 candidate communicant ports $p_j$ on which No signals have been sent. For each of the Commit signals transmitted by the port manager of the process $P_i$, a No signal may received as a response. In this eventuality case 5 is applicable. That is Commit signals may be received on each of the M candidate communicant ports of the process $P_i$. The port manager then transmits a Commit signal on one of the candidate communicant ports of the process $P_i$. Upon synchronization, and prior to the termination of the alternative command, case 4b requires a No signal be sent, by the port manager of the process $P_i$, on those candidate communicant ports on which a Commit signal is pending. Since there can be at most M - 1 such ports, at most M - 1 No signals are sent after synchronization. Thus, when a process is in an alternative command with M number of candidate communicant ports, no more than 2M - 2 No signals and 1 Commit signal are transmitted by the port manager of that process.

*Theorem 7:*

*When a process is in an alternative command with M number of candidate communicant ports, the port manager of the process need expect no more than 6M - 2 signals on the M candidate communicant ports.*

*Proof:* From the theorems 5 and 6, the port manager need send at most 2M - 1 + M signals. Each of the signals sent is either in response to a Commit signal received or is a Commit signal soliciting a communication. Thus the total number of signal that a port manager need expect on the candidate communicant ports is no more than 6M - 2.

## 6. Discussion

a) Degree of concurrency obtained by the algorithm:

The degree of concurrency achieved by the algorithm is something hard to quantify. However, a comparison of the level of concurrency achieved by the implementation scheme with respect to that achieved by the implementations suggested in the literature can be made by identifying relevant computational steps in each of the algorithms. For such purposes of comparison, the implementation scheme suggested by Buckley and Silberschatz[4], hence forth referred to as BSi scheme, is considered. For purposes of comparison, the BSi scheme is mapped onto the communication model of this paper. The port manager of the process in the ANa (BSi) scheme awaits a response for a Commit (QUERY) signal transmitted by it. If during the period of waiting, the port manager receives a Commit (QUERY) signal on another candidate communicant port, it either delays a response or transmits a No (BUSY) signal, (If a Commit(QUERY) signal is received on a noncommunicant port then a No(NO) signal is sent). Thus each of the schemes are bound to achieve the same degree of concurrency or loss of concurrency there of in their abilities to synchronize. Unlike the ANa scheme, the port manager of a process, in the BSi scheme, transmits a RES signal on all its candidate communicant ports on which it has transmitted a BUSY signal in response to QUERY signals received by it. After the transmission of the RES signal, the port manager awaits RETRY signals on those ports. Of all the RETRY signals received by the port manager, the port manager selects one to synchronize with, by sending a COMMIT signal, and rejects all others by sending a NO signal. In the ANa scheme, on the other hand, if the port manager of a process has received a No signal in response to a Commit signal on any of its candidate communicant ports, then the port manager expects a Commit signal to arrive on that port. When on all of the ports the port manager has received No signals in response to Commit signal sent, the port manager awaits Commit signals on those ports. Then, of all Commit signals received by the port manager, the port manager selects one to synchronize with, by sending a Commit signal, and rejects all others by sending a No signal. Thus the degree of Concurrency in the selection of a port on which to synchronize is the same in both of the schemes.

b) Comparative Performance of the Algorithm

The performance of the algorithm is measured in terms of the number of signals which must be exchanged to achieve synchronization. In the BSi scheme, a process sends out at most 2M unsolicited signals per each execution of an alternative command where M is the number of candidate communicant ports. The unsolicited signals in the BSi scheme correspond to the Commit signals in the ANa scheme. In the ANa scheme the number of unsolicited signals needed is halved. Theorem 5 shows that in the ANa scheme at most M Commit signals need be sent out. Natarajan distinguishes between input ports and output ports. On the assumption that input and output ports are equally likely to occur in an alternative command, Natarajan's scheme is also able to halve the number of unsolicited signals required to achieve synchronization. Natarajan's scheme requires the port manager to initiate communication on output ports while on input ports the scheme requires the port manager to have received a signal prior to attempting synchronization. Thus, Natarajan's scheme sends at most N unsolicited signals on output ports, where N is the number of output ports. If there are N input ports and on those ports a Ready signal had been received and a Reject signal sent and a Not Ready signal has not yet been received, then the port manager may send the equivalent of an unsolicited signal on those ports, thus achieving the M number of unsolicited signals, where M = 2N. In the ANa scheme the total number of signals generated in the system due to the initiation of an alternative command by a process is 3M, where M is the number of candidate communicant ports. In the BSi scheme the total is 3M + Q, where Q is the number of candidate communicants with priority number less then that of the process.

c) Resilence against node failures:

In a distributed system nodes tend to fail. For the distributed program to achieve its goals in spite of node failures, the ANa scheme has to recover from node failures. A simple scheme for effecting such a recovery in the presence of node failures can be imposed on the ANa scheme. It is assumed that, at each node of the distributed system, there exists mechanisms for the detection of the failure and the restart of the node. In addition, it is assumed that when a node fails, the states of the port managers at that node are lost. The communication system is assumed to be reliable and that the messages and signals sent are delivered in the order of transmission and, further, when a message is transmitted, it is either delivered to the destination port or an exception is signaled to indicate the failure of the destination node.

Whenever the node kernel is restarted after the failure of the node, the kernel signals the restart to each of the port managers at that node. Upon the receipt of a restart signal from the node kernel, the port manager at the previously failed node transmits a Restart signal on all of its ports. The port manager then waits for responses to its Restart signal in order to reset it local clock. A port manager which receives a Restart signal on a port satisfies the predicate function MyTurn on that port and transmits on that port the signal, Time(p,t), containing the time, t, indicated on its local clock. The port manager receiving the signal Time(p,t), sets its local clock to the maximum of the Time signals received.

If the communication system detects a failure of the destination node, of a signal or a message, then the port manager which transmitted the signal or message receives from the communication system a failure signal on the port on which the message or signal was sent. The port manager then satisfies the predicate function ItsTurn on that port.

## 7. Conclusions

We have presented a simple and efficient time stamp based synchronization scheme for communicating processes, utilizing output commands as guards in the alternative command. The scheme was developed out of an interest in the utility of temporal interval logic for the specification and synthesis of parallel algorithms. A temporal interval logic based specification of the scheme is presented in [1]. The scheme is port based, utilizes the exchange of control signals to select a suitable communication partner and relies on time stamps to introduce the asymmetry required to avoid deadlock. The selection of a communication partner requires a process to send at least one and at most M signals indicating its willingness to establish communication, where M is the number of ports on which the process is willing to communicate. During the time that a process is attempting to find a communication partner, and prior to the determination of its communication partner, at most M - 1 signals will be sent rejecting pending offers to establish communication. These signals are required to prevent deadlock in the implementation. After the selection of a communication partner and prior to the termination of the alternative command, at most M - 1 signals are required to reject pending offers to establish communication. These are required to insure the progress of other processes in their own selection algorithm. The various properties of deadlock freedom of the implementation and performance of the scheme have been established. A critique of the scheme has been presented in the light of some other schemes appearing in the literature. It has been shown that the scheme is efficient in the number of signals transmitted for achieving synchronization. The degree of concurrency achieved by the scheme is also comparable to that achieved by that of other schemes. The time stamps may be implemented through the use of logical clocks in each process which are kept in loose synchronization using the algorithm due to Lamport[10]. The storage requirements of the scheme are small, a local clock and for each port two bits to indicate the state of the port.

It is hoped that the implementation scheme be imbedded in the runtime system of a compiler which extends OCCAM[9] to include output commands in the guards. Propositional temporal logic has been shown to be suitable for the synthesis of synchronization skeletons for communicating processes[5, 11] and we are exploring the suitability of temporal interval logic for the specification and synthesis of parallel algorithms.

*ABSTRACT:* Concern for performance of concurrency control protocols, in distributed database systems, raises an important question 'does performance improve by permitting intra-transaction concurrency'. This paper answers this question for protocols which use abortion of transactions to preserve consistency. Variants of the protocol proposed by Reed [REE78] are simulated and used as a representative of those protocols which abort transactions. The results strongly points out that as the workload increases the intra-transaction concurrency leads to poorer performance. Further, it suggests that all entities should be assigned an order and, whenever access set of a transaction is known a priori, the transaction should access entities in this assigned order with possible skips.

## 1. Introduction.

To improve performance of distributed database systems, we may like to execute each transaction concurrently at multiple sites. Further, if such Intra-transaction concurrency at multiple sites does improve the performance then we would like to increase this improvement by increasing the number of sites: we could stretch this to the extreme by having each entity as a site (i.e. by associating a processor with each entity.) In this paper we look in to the efficacy of permitting Intra-transaction concurrency, particularly in systems which abort transactions to preserve consistency. Some of the protocols which use transaction aborts for preserving consistency are, Optimistic protocol [KUN81], Reed's protocol [REE78], Two-phase locking protocol[1*] [ESW76], the protocol presented in [BAY80], etc. An increase in the workload[2*] will lead to increase in the transaction aborts for each of these protocols which in turn will increase the workload. For sustained workloads higher than a certain level (which is different for each protocol) this cyclic process will lead to a non-linear drop in performance. Effect of different system parameters on such drop is not well understood. The extent and the rate of this drop will vary, but for each protocol, the performance will be unacceptable for workloads higher than a certain workload level. We investigate the effect of intra-transaction concurrency on this level by conducting simulation studies. We note that, it is desirable to have this workload level as high as possible even if it results in a poorer performance for the lower workloads, since poor performance is more affordable at lower workloads than at higher workloads. For the purpose of this study we chose variants of the protocol proposed by Reed [REE78] which permit varying degrees of intra-transaction concurrency.

We found that as the workload increases the performance (in terms of the response time and the throughput) deteriorates at a faster rate for higher levels of Intra-transaction concurrency. In section 2 we summarize the variants of the Reed's protocol. In section 3 we briefly describe the simulated System Model. In section 4 we analyze the results and in section 6 we summarize the conclusions.

## 2. A summary of the Reeds protocol.

First we briefly describe a variant of Reed's [REE78] Protocol to be termed as RP. Then we shall explain how we can incorporate different levels of intra-transaction concurrency in RP.

Multiple versions and tokens are maintained at each entity and are logically ordered in the order of the logical precedence among their creator transactions. A token is a possible version written by a transaction which is still executing. A token may be either converted to a version or deleted, depending upon whether the creator transaction completes or aborts. Each version and token has four fields: first, value of the version; second, the 'start' field, which is the timestamp of the transaction which created the version or the token; third, the 'end' field, which is the timestamp of the transaction which last read the version (in the case of tokens, this is same as the start field); fourth, a boolean 'commit' which is 'true' for a version and 'false' for a token. In addition each token has a pointer to a record of the status of its creator transaction called possibility of the creator transaction.

When a transaction T is initiated, the initiating site assigns it a globally unique timestamp TS and creates its possibility P. Transactions logically execute in the order of their timestamps. P indicates whether T is active, or it has successfully completed or aborted. When T is active then associated with P is a list of messages which are replied when T either completes or aborts; so that the tokens created by T may be either converted to versions or deleted and the transactions waiting to read these tokens may be activated. When all the tokens created by T have been notified about completion or abortion of T then P is deleted.

When T wants to read an entity, it must select a version or a token with start field of the highest value less than TS. If a version is selected, then T reads the version and the value of the end field of the version is set to TS if it is less than TS. However, if a token is selected, then a message is associated with the token to activate T when either the token is converted to a version or is deleted and T waits.[3*] When a message is received indicating that the creator of a token has completed then token becomes a version and any waiting transaction is activated to reads it and to update the end field if required. When a message is received indicating that the creator of a token has aborted then the token is deleted and each waiting transaction is activated to restart the read operation.

When T wants to write an entity, it first selects a version (or token) just as for a read operation. The new token to be written will be placed after this selected version (token). End field of such selected version is then compared with TS. If it is not less than TS then T aborts,[4*] and the associated tokens and P are deleted. Otherwise, the new token can be written without violating consistency. If T wants to read the entity before writing then it does a read operation on the selected version or token. If reading of such token fails then T restarts the write operation otherwise the write operation continues as follows. A new token is created with TS as the start field and is appropriately placed among other versions and tokens of the entity. A message is placed in the list associated with P to notify the site of this entity whenever T completes or aborts.

When T has accessed all the required entities then a message is sent to T's initiation site. When this message is received, messages are sent to entities at which T created any version and T is committed. Old versions are deleted as soon as it is established that no transaction will need to read them in order to maintain

* This work was partially supported by National Science Foundation under Grant MCS-9214613.

** This work was done while the Author was at U.T.Austin.

[1*] In context of Two-phase locking protocol, we use the term 'abort' to mean releasing of the locks granted to a transaction during the locking phase, when a deadlock is detected.

[2*] In this paper we do not define workload quantitatively and refer to a change in the workload in terms of a change in the parameter values. Typical reasons for an increase in the workload are, a reduction is inter-arrival time between transactions, an increase in the average number of entities accessed by transactions, an increase in the extent of data sharing etc.

[3*] In [REE78], the proposed procedure is a little different.

[4*] A transaction with timestamp higher than TS has read the selected version after which the new token will be placed.

0190-3918/86/0000/0950 $01.00 © 1986 IEEE

consistency. This simulates a system with the least number of versions, without resulting in abortion of read transactions. This procedure is different, and deletes old versions sooner, then the procedure proposed in [REE78].

[REE78] does not require or suggest any particular order in which a transaction may access entities. We considered three options RP1, RP2, and RP3, as shown n Figure-1. These options permit different levels of intra-transaction concurrency. In RP1, a transaction executes sequentially (i.e. no intra-transaction concurrency) and it accesses entities in an order pre-assigned to all entities.[5*] This option requires that each transaction be able to incrementally declare its access subsets from the successive parts of the pre-ordered entities. In RP2, at each site, transactions access entities just as in option 1, and they may concurrently execute at all the sites to be accessed. This option permits partial intra-transaction concurrency, and requires that each transaction be able to incrementally declare its access subsets from the successive parts of the pre-ordered entities on each site . In RP3, a transaction concurrently attempts to access all the required entities. This option permits the highest possible intra-transaction concurrency.

Nature of a transaction may impose some constraints on the order in which entities should be accessed. A transaction may not be able to determine whether to read/write an entity $e_x$, or may not be able to determine the value to be written until it reads some entity $e_y$ after $e_x$ in the pre-assigned order. In all simulated options such writes are done after $e_y$ has been read. However, whenever possible such reads are done in anticipation (i.e. before reading $e_y$.)

## 3. The System Model.

In the process of describing the system model we shall define parameters and give, in parentheses, the values assigned to the parameter in the simulation runs. The simulated system has S (10) sites. There are a total of M (1000) entities in the database system, and each site has M/S (100) number of entities. There is no data replication. We presume a network topology in which the communication delays between any two sites have the same mean and the same distribution. Communication delay between any two sites either is zero or follows an exponential distribution with a mean DEL (100 time units) over the entire range of communication traffic generated in the system. The communication network of the system never fails. Transactions are of two types: read transactions and write transactions. Read transactions only read. Write transactions write all of the entities to be accessed; and, before writing an entity, they read it. A write operation may have a constraint such that before writing $e_x$ the $N^{th}$ ($5^{th}$) entity to be accessed after $e_x$ must be read. Each write transaction may have L (1) such constraints. R/W (3, 15) is the ratio of the number of read and write transactions entering the system. Inter-arrival time between transactions follows an exponential distribution with a mean of ARRL (1, 10, 20, 100 time units). Each transaction accesses SN (3) number of sites and an equal number of entities at each site. Transaction size, or number of entities accessed by a transaction, follows a geometric distribution with mean transaction size TZ (3, 6, 15, 100). Each read, write or a comparison takes 1 time unit.

When a new transaction is initiated, it is assigned a transaction type and an initiation site. Then sites to be accessed by the transaction are selected. First site is selected with uniform probability from the $1^{st}$ through the $(S-SN)^{th}$ sites. Let $k^{th}$ site be the last selected site when SM sites have been selected. The next site is chosen from $(k+1)^{th}$ to $(S-SN-SM)^{th}$ sites, such that the distance between two consecutively selected sites[6*] follows a geometric distribution with mean Dis-s (5.0, 1.66, 1.0). This process is repeated until all SN sites to be accessed have been selected or until n sites are yet to be selected and only n more sites remain to choose from, in which case all the remaining n sites are selected. Process for selection of entities is similar to the process for selection of sites except that the mean distance between two consecutively selected entities is Dis-e (5.0, 1.66, 1.0).

## 4. Results and the analysis.

The simulator was validated by validating various events and the results for extreme cases. The results were collected for 2000 (in few cases 1000) completed transactions. The data was collected after completion of 500 transactions. Since RP3 is a special case of RP2 (in which each entity is a different site) we planned to run simulations for RP3 only if RP2 performed better than RP1 for an interesting range of parameter values. As the results will show we did not have to run simulations for RP3. The average response times reported here refer to the response times of completed transactions. Hence, under heavy workloads (when many transactions have not completed), the reported average response times are less than the actual average response times. Each such occurrence has been marked with an asterisk (*) alongside the average response times.

[AHU84] reports results for a wide range of parameters and concludes that it is sufficient to study results for two extremes of dispersal of accessed sites and entities, which are termed high and low. A combination of Dis-s=5.0 and Dis-e=5.0 represents a high dispersal and combined effect of Dis-s=1.0 and Dis-e=1.0 represents low dispersal. Comparison of the performance of RP1 and RP2 based on the results reported in [AHU84] can be typically summarized by the selected results presented in Table-1. These results correspond to DEL=100, TZ=15, SN=3, R/W=3, for low and high dispersal.

We observe that at low workloads (i.e. for ARRL=100), the average response times are lower for RP2 compared to RP1. With respect to other parameters also, RP2 performs marginally better than RP1. The primary reason for this is the lower communication delay for RP2 during execution of a transaction.

As the workload increases, however, the response time of transactions and the rate of abortion of write transactions increase (as shown by an increase in the number of times a write transaction had to be submitted.) The aborted transactions result in the abortion of other transactions, and the abortion rate increases in a cyclic process. We are interested in finding out if this process occurs at substantially different workload levels for RP1 and RP2. In the following discussion, we shall cite a reduction in ARRL as the reason for an increase in the workload. However, the observations made here are true for an increase in the workload due to other reasons (e.g., an increase in TZ or dispersal.)

We observe that for high ARRL (e.g., 100) the abortion rate of transactions is marginally lower for RP2 than for RP1. With a reduction in ARRL, however, the abortion rate increases much more sharply for RP2 than for RP1 and for RP2 it quickly becomes extremely high. In Figure-2 we have plotted the average number of times a write transaction had to be submitted for both RP1 and RP2 against ARRL, for low and high dispersals. These plots support the above observations and they show the magnitude by which the abortion rate and the rate of its increase are higher for RP2 compared to RP1. The reason for this behavior is that above a certain workload level, when a transaction aborts, the increase in the probability of aborting other transactions is higher for RP2 than for RP1. At first it is due to the higher average number of entities accessed by aborted transactions[7*] and at yet higher workloads it is due to higher abortion rate in RP2.

[5*] An alternative to RP1 which does not permit any intra-transaction concurrency could be that each transaction executes sequentially and accesses entities in a random order. Few simulation runs strongly confirmed that this option does not perform as well as RP1 (due to a transaction visiting a site more than once and due to higher abortion rate, both due to transactions accessing entities in a random order.) So we eliminated this option from further detailed study.

[6*] Distance between two neighboring sites (entities) in the order of sites (entities) is considered to be one.

[7*] At low workloads, on average an aborted transaction will have accessed more number entities in RP2 than in RP1. For RP1, when a transaction is aborted it will have read entities before (but not after) the entity at which it could not write. For RP2, however, when a transaction is aborted it might have accessed the entities both before and after the entity which it could not write.

At low workloads, higher number of entities accessed by aborted transactions in RP2 leads to higher abortion rate, due to the following reason. The value of the end field of the version read by an aborted transaction $T_i$ will be equal to (or more than) the timestamp of $T_i$. This may lead to abortion of another transaction with a timestamp lower than the timestamp of $T_i$ (while logically, $T_i$ did not read the version, since it was aborted). Hence, for RP2 the cyclic process leading to higher abortion rates occurs at lower workloads and at a faster rate. For example, let us consider an increase in the dispersal of accessed sites and entities from low to high, for ARRL=10. For RP2 the abortion rate increased 7.8 times (from 22.28 to 179.0) as compared to a corresponding increase of 2.7 times (from 4.47 to 12.04) for RP1.

As the workload increases, the cyclic process leads to more frequent abortion of transactions in the earlier stages of execution: and this happens at higher rate for RP2. At high workloads this abortion of transactions at earlier stages can be confirmed for RP2 by the results in Tables-1. Consider the example of an increase in the dispersal of accessed sites and entities from low to high for ARRL=10. The average number of entities accessed by an aborted transaction reduced by approximately a factor of 1.95.[8*]

We conclude that at low workloads average number of entities accessed by an aborted transaction is higher for RP2 compared to RP1. This leads to the cyclic increase in the abortion rate at much lower workloads for RP2. This conclusion can be extrapolated to compare RP1 with RP3. If a transaction accesses TS entities, then RP3 can be viewed as RP2 with SN=TS. For SN=TS the analyses given above for comparing RP1 and RP2 are likely to be all the more valid. Hence, it is advisable to choose RP1 compared to RP2 and RP3, and it is advisable to not permit intra-transaction concurrency. This leads to chosing a marginally higher cost at lower workloads (when the higher cost is affordable) in favor of the savings at higher workloads. It is a wiser choice, since the need for a well performing protocol is more critical at higher workloads. Just as in RP, in other protocols which permit transaction aborts, an increase in the workload increases the abortion rate. Also the factors which increased this rate for RP when intra-transaction concurrency is permitted also occur in these protocols. Hence by the same reasoning, for these protocols also it is advisable to not permit intra-transaction concurrency.

## 5. Conclusions.

We conclude that permitting intra-transaction concurrency is not an effective way to improve performance, if transactions are aborted to preserve consistency. Also whenever possible transactions should access entities in some pre-assigned order. This improves the overall system performance at high workloads. If such ordering cannot be implemented over the entire database then it may be done over a part.

# TASK ALLOCATION PROBLEMS IN DISTRIBUTED COMPUTER SYSTEMS

Pauline Markenscoff and Weikuo Liaw

Department of Electrical Engineering
University of Houston - University Park
Houston, Texas 77004

**ABSTRACT** -- Task allocation problems for a class of distributed systems are studied. The subtasks comprising the computational task should satisfy certain precedence constraints and the minimization of the system response time is the criterion used to determine the optimal allocation strategy. This task allocation problem is NP-complete. An optimal branch and bound algorithm as well as two approximate algorithms based on the greedy and local search approaches are developed for its solution. Finally, a comparison of the algorithms is presented.

## INTRODUCTION

An important design problem of distributed systems is the allocation of the subtasks comprising the computational task to the individual processors. Task allocation for distributed systems has been studied in [1-6]. These studies employed the maximization of the system throughput or the minimization of the interprocessor communication cost as the criterion to determine the optimal task allocation.

The requirement of fast real-time response, however, necessitates the use of a different performance criterion. The optimal task allocation must now be determined by minimizing the system response time. This criterion was used by Stone [7] to study the allocation problem for a task with no parallelism and a nonhomogeneous system of processors.

The allocation problem for a task that exhibits parallelism is considered in this study. This task is modeled as a directed acyclic graph (DAG), whose nodes denote the subtasks and whose arcs indicate precedence constraints that must be satisfied during the execution of the subtasks. The optimization problem considered corresponds to the partitioning of the nodes of the graph in such a way as to minimize the system response time.

If the execution of two subtasks must satisfy a precedence constraint and these subtasks are allocated on different processors, the constraint can be satisfied via interprocessor communication. However, communication between processors may incur significant overhead. In that case, a system not allowing for interprocessor communication may provide faster response times despite the fact that it introduces the need for redundancy of subtask executions. The system without interprocessor communication is also interesting for another reason. Communication links between processors may be among the least reliable parts of the system and communications between processors may collapse due to hardware or software faults or to externally inflicted damage. Therefore, in many real-time applications with high reliability requirements (e.g. critical control and navigation computers), the multiple processor system should be able to operate in an optimal way without interprocessor communication links.

Optimal and approximate algorithms are developed for the solution of the task allocation problem without interprocessor communication and their performance is evaluated.

## PROBLEM DEFINITION

The computational task considered consists of subtasks whose execution must satisfy certain precedence constraints. Such a task can be modeled as a directed acyclic graph (DAG) (see Fig. 1). The nodes of this DAG correspond to the subtasks and the arcs indicate precedence relationships for the execution of the subtasks. Arcs emanating from node i and ending at nodes j1, j2, ...., jk, for example, indicate that subtask i must wait for data from the execution of all subtasks j1, j2, ...., jk before it can be processed.

The problem is now to schedule the subtasks on m identical processors subject to the precedence constraints indicated by the DAG. It is assumed that there is no interprocessor communication and consequently there is no data flow between subtasks allocated on different processors.

Since no interprocessor communication is allowed, if a node is allocated to a processor then all of its immediate descendants should also be allocated to the same processor. For the example of

0190-3918/86/0000/0953 $01.00 © 1986 IEEE

Fig. 1, if node 5 is allocated to the i-th processor, then nodes 4, 2, and 3 must also be allocated to the i-th processor because node 5 requires data from nodes 2, 3, and 4. A root of a DAG corresponds to an independent process which includes all nodes that can be reached from that root. All the nodes of an independent process must be allocated to the same processor.

Clearly, the problem of task allocation corresponds to the allocation of independent processes derived from a DAG. For example, the DAG shown in Fig. 1 has three independent processes each corresponding to a root and defined by a subgraph of the DAG (or subdag) as follows.

**Process 1** ($p_1$) : Subdag 1 containing nodes 8, 6, 4 and 1.

**Process 2** ($p_2$) : Subdag 2 containing nodes 9, 6, 4 and 1.

**Process 3** ($p_3$) : Subdag 3 containing nodes 10, 7, 6, 5, 4, 3, 2 and 1.

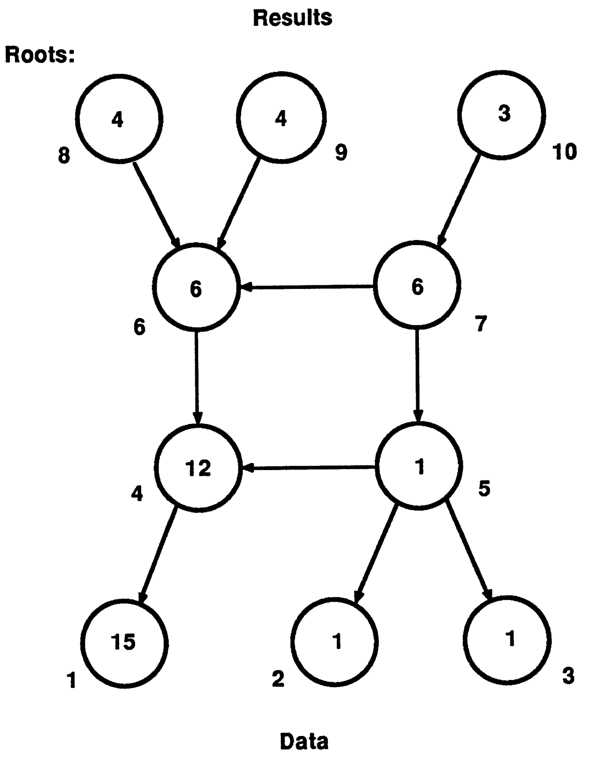

Figure 1: DAG of a computational task. The numbers inside the nodes represent the weights (execution times) associated with each subtask.

The combinatorial problem is now introduced when the number of independent processes in a DAG is greater than the number of processors. Consider the DAG of Fig. 1 and a two-processor system. There exist three possible root partitionings of the DAG of Fig. 1 leading in general to six possible allocations of the independent processes to the two processors. If the processors are identical, it is obvious that, for example, the allocation ($p_1$, $p_2$) to processor 1 and $p_3$ to processor 2 is equivalent to the allocation $p_3$ to processor 1 and ($p_2$, $p_3$) to processor 2. Thus, the number of possible allocations is reduced to three and these allocations are shown in Table 1.

A specific weight equal to the execution time $E_i$ of the subtask is associated with each node. Each independent process associated with a root partitioning has a total weight that is equal to the sum of the weights of the nodes it contains. Obviously, the process with the maximum weight determines the system response time.

In order to optimize the system response time, the following optimization problem must be solved: **"Minimize the system response time over all possible process allocations"**.

Table 1 shows all the possible allocations and the corresponding system response times for the example of Fig. 1. Note that while a subdag is allocated to only one processor, a subtask may be allocated to more than one processor if it belongs to more than one subdag. Thus redundancy is introduced whose amount can be significantly affected by the choice of process allocation. In our example, nodes 1, 4 and 6 are executed twice.

An investigation [8] of the computational complexity of the task allocation problem described above has shown that it is NP-complete [9].

**TABLE 1**

**Independent Processes and System Response Times for a two processor system.**

Three independent processes derived from Fig. 1
$p_1$ has nodes 8, 6, 4 and 1

## ALGORITHM DESIGN AND ANALYSIS

Three types of algorithms have been developed for the solution of our task allocation problem : an optimal Branch-and-Bound algorithm and suboptimal algorithms based on the Greedy and Local Search approaches. The notation used in the presentation of algorithms is defined in Table 2.

### Optimal Algorithm

This algorithm is implemented using the branch-and-bound method. It finds the optimal solution for an instance but its run-time cannot be bounded by a polynomial of the input size of the instance. However, it finds the optimal solution in a tolerable time for instances of small input size.

The solution space is represented by a tree and a feasible point is represented by a node in the tree. Here and in the following discussion, **the term node applies to the tree of the solution space and not to a DAG.** For each node in the tree, a child is generated for every possible allocation of the next subdag. Thus, the number of branches from a node is equal to the number of possible allocations of the next subdag. A node in the tree is called a **solution node** if all subdags have been allocated. Otherwise, it is called a **branch node.**

The following procedure is used to "kill" nodes (i.e. not to generate children of this node) and thus reduce the computation time required for the search. An initial upper bound UB of the optimal solution is chosen arbitrarily. As the algorithm progresses, it is updated to the finish time of a solution node. A lower bound LB(X) of the optimal solution is computed for every node X and compared to the upper bound. If either one of the following two conditions holds

(a) LB(X) > UB, or

(b) LB(X) = UB and a solution exists

then the node is killed. If a branch node is killed, then all nodes derived from it will have lower bounds that are greater than the UB. Thus, there is no need to search for such nodes and the computation time is greatly reduced.

The lower bound LB(X) of a node is computed as follows for our problem. Let LBSPT(X) be the lower bound of the sum of processing times from node X after a task is completely allocated. LBSPT(X) is equal to the sum of the current processing times plus the sum of execution times of unallocated subtasks. Then

$$LB(X) = \max \{ \lceil LBSPT(X)/M \rceil ,\ PT_i,\ i=1,2,\ldots,M \}$$

**TABLE 2**

**Notation**

| | |
|---|---|
| N | : Number of subtasks in a task |
| M | : Number of processors |
| $N_s$ | : Number of independent subdags in a task |
| $S_i$ | : The set of subtasks of subdag i |
| $E_i$ | : Execution time of subtask i |
| T(S) | : Sum of execution times of subtasks in set S |
| $P_i$ | : Set of subtasks allocated to processor i |
| $PT_i$ | : Processing time for processor i, $T(P_i)$ |
| FT | : Finish time of task, max $PT_i$, i=1,2,....,M |

### Greedy Algorithms

When a task is completely allocated, the sum of processing times SPT is given by

$$SPT = \sum_{i=1}^{M} PT_i = \sum_{i=1}^{N} E_i + TRT \qquad (1)$$

where TRT is the total repeated execution time caused by redundancy, i.e. the allocation of some subtasks to more than one processors. The following inequality is derived for the finish time FT

$$FT \geq \lceil SPT/M \rceil \qquad (2)$$

Redundancy is minimized when TRT is made as small as possible. Also, better load balancing among the processors is achieved when FT is close to $\lceil SPT/M \rceil$. Note, however, that FT is not necessarily minimized when both TRT and ( FT - $\lceil SPT/M \rceil$ ) are at their minimum.

Three approximate algorithms (GR_1, GR_2 and GR_3) based on the greedy approach have been developed [8]. The greedy algorithms proceed stage by stage making the best decision at each stage [10]. In our case, a stage is the allocation of a subdag. GR_1 attempts to minimize the maximum processing time at each stage by balancing the computational load of processors. Algorithm GR_2 attempts both to balance the computational load of processors and to reduce the repeated execution time due to redundant execution of subtasks. Algorithm GR_3 is a refinement of GR-2 [8].

The general version of the greedy approach for our task allocation problem is shown below.

```
Greedy Approximate Algorithms

Input:  N, $N_s$, $S_i$, i=1,2,...,$N_s$, $E_j$, j=1,2,...,N, M

Output:  $P_i$, i=1,2,...,M, FT

Method:

(1) Call the function SORT(subdags) to sort the
    subdags in order of nonincreasing execution
    times.

(2) Remove the first subdag $S_\ell$ from the sorted
    sequence.

(3) j ← SELECT($P_i$, i=1,2,...,M, $S_\ell$).
    The function SELECT chooses a processor j for
    the subdag $S_\ell$ according to the rules discussed
    in this section.

(4) Allocate subdag $S_\ell$ to processor j and update
    $P_j$ to $P_j + S_\ell$.

(5) Repeat steps (2) through (4) until all subdags are
    allocated.
```

Algorithms GR_1, GR_2 and GR_3 employ different SELECT functions. Only the SELECT function for algorithm GR_1 is presented below and detailed descriptions of the corresponding SELECT functions for GR_2 and GR_3 may be found in [8].

```
SELECT_1:

Input:  $P_i$, i = 1, 2, ..., M, $S_\ell$

Output:  j

Method:

(1) Compute $T(P_i + S_\ell)$ for all used processors and
    one unused processor.

(2) Select processor j whose $T(P_i + S_\ell)$ is the
    minimum among those computed in step (1).

(3) Return.
```

## Local Search Algorithms

Local search is based on a trial and error optimization method [11]. Starting from some feasible solution x, a neighborhood NBH(x) of x is searched for a better solution. This neighborhood NBH(x) consists of points that are "close" in some sense to the point x. The general local search algorithm is shown below.

```
LOCAL SEARCH ALGORITHM

Input:  The starting solution t.

Output:  The local optimal solution x.

Method:

(1) x ← t.

(2) Repeat IMPROVE(x) until IMPROVE(x) is false.

(3) Output x since "no further improvement is
    possible".
```

IMPROVE(x) searches for a better solution in a neighborhood of x and is defined by:

$$\text{IMPROVE}(x) = \begin{cases} \text{TRUE and } x \leftarrow y, \text{ if there exists} \\ \text{a } y \text{ in NBH}(x) \text{ with } c(y) < c(x). \\ \\ \text{FALSE and a better solution} \\ \text{does not exist in NBH}(x). \end{cases}$$

The function c(x) above is the cost function for the optimization problem. If an improved solution exists, we adopt it and repeat the neighborhood search from the new solution. The search stops when a local optimum is reached.

This approach is now applied to our particular task allocation problem whose cost function is the finish time FT. IMPROVE(x) searches a neighborhood of x for a solution yielding smaller FT than that of x. Two schemes are used to reduce the finish time of a task and they are similar to those discussed in the previous section.

(1) Balance the computational load of processors by exchanging subdags among them. This yields processing times that are close to one another, thus reducing the finish time FT.

(2) Reduce the repeated execution time of shared subtasks by combining subdags that have repeated subtasks.

These exchange and combination schemes are applied to a pair of processors P1 and P2 at a time and a skeleton code of the functions that implement them follows.

```
EXCHANGE1 (P1, P2, TEST): BOOLEAN

(1) Try exchanging one subdag of processor P1 with
    one subdag of processor P2 or moving one
    subdag from processor P1 to processor P2.

(2) If the resulting FT is less than TEST, then return
    TRUE.

(3) If no further exchange is possible, then return
    FALSE. Else go back to step (1).
```

```
EXCHANGE2 (P1, P2, TEST): BOOLEAN

(1) Exchange two subdags of processor P1 with one
    subdag of processor P2 or one subdag of
    processor P1 with two subdags of processor P2.

(2) If the resulting FT is less than TEST, then
    return TRUE.

(3) If no further exchange is possible, then return
    FALSE. Else go back to step (1).
```

```
COMBINE (P1, P2, TEST): BOOLEAN

(1) Find all subtasks shared by P1 and P2.

(2) If there are no shared subtasks, then return
    FALSE.

(3) For a shared subtask, move all subdags
    containing it from P1 to P2. All subdags of P2
    that do not contain the shared subtask are
    considered for allocation to either P1 or P2
    according to a GR_2 scheme.

(4) If the resulting FT is less than TEST, then return
    TRUE.

(5) If there are no more shared subtasks, then return
    FALSE. Else go back to step (3).
```

These three functions form the basis for the two local search algorithms developed. The first algorithm LS_1 starts with the initial guess t and attempts to find a better solution according to the following procedure.

(1) Select the processor with the longest processing time and name it P1.
(2) Find the processor with the shortest processing time and name it P2.
(3) Try to exchange subdags between P1 and P2 in order to obtain a shorter finish time FT.
(4) If this search (performed by EXCHANGE1) is not successful, pick the processor with the next shortest processing time, name it P2 and repeat step (3) for P1 and the new P2. Repeat this process by always selecting as P2 the processor with the shortest processing time among those that have not been tested yet.
(5) If such an exchange of subdags leads to a shorter finish time, a new solution has been found and an attempt to further improve this solution is made by repeating steps (1) through (5).
(6) If all processors have been tested without improving the solution, a local optimum has been reached.

At this point the algorithm repeats steps (1) through (6) above in an attempt to improve the local optimal solution by combining the subdags containing shared subtasks. The search is now performed by calls to the COMBINE subroutine described above and is carried out if (a) this is the first pass or (b) a previous search using EXCHANGE1 was successful in improving the solution. If the new search using COMBINE is successful, the algorithm attempts still another search using EXCHANGE1 and the entire procedure is repeated until no further improvement of the solution is possible.

The second local search algorithm LS_2 enlarges the neighborhood of a point searched for a better solution by using the subroutine EXCHANGE2 instead of EXCHANGE1. LS_2 is likely to obtain a better solution at the expense of longer run-times.

## COMPARISON OF ALGORITHMS

The greedy and local search algorithms presented in the previous section were evaluated and compared. Problem instances (i.e. dags representing tasks) were randomly generated [8]. For a given problem instance, the error ERR(A) of algorithm A was defined as:

$$ERR(A) = [SOL(A) - EXACT] / EXACT$$

where SOL(A) is the solution of an instance by algorithm A and EXACT is the exact solution obtained by the branch and bound algorithm. Computation times necessary for computing the exact solution were tolerable for small instances. Thus, average results obtained via the approximate algorithms could be compared to the exact solution for small randomly generated instances.

### Greedy Algorithms

Table 3 presents the average error, maximum error and average computation time for the algorithms GR_1, GR_2 and GR_3. The results presented are for 50 randomly generated instances of 10 subtasks and varying number of processors (M = 2, 3 and 4). Table 4 presents again the average and maximum errors as well as the average computation time for the greedy and the branch-and-bound algorithms. A fixed number of processors (M = 2) was used for these runs while the number of subtasks varied (N = 10, 20 and 30).

The average and maximum errors decrease as we go from the GR_1 to the GR_3 algorithms while the computation time increases. This small increase in computation time is expected because the greedy algorithms become more complex as we go from GR_1 to GR_3.

TABLE 3

## Local Search Algorithms

Randomly generated starting solutions for the local search algorithms were tested first. In addition, solutions generated from the greedy algorithms were used to start the local search.

Table 5 presents the results for one randomly generated instance and 20 randomly generated starting solutions. Two processors were considered and the number of subtasks varied (N = 10, 20 and 30 ) for these experiments.

The results show that when the optimal solutions were not obtained, the maximum errors were very small. As expected, LS_2 has a higher probability to provide a better solution, but it requires considerably more computation time. In some instances, LS_2 may run even more slowly than the branch and bound algorithm.

TABLE 5

Results for Algorithms LS_1 and LS_2

| ALGORITHM | N=10 | N=20 | N=30 |
|---|---|---|---|
| LS_1<br>Number of optimal solutions found<br>Minimum error<br>Maximum error<br>Average run-time | <br>3<br>0.000<br>0.033<br>20 | <br>15<br>0.000<br>0.004<br>78 | <br>5<br>0.000<br>0.023<br>291 |
| LS_2<br>Number of optimal solutions found<br>Minimum error<br>Maximum error<br>Average run-time | <br>20<br>0.000<br>0.000<br>58 | <br>19<br>0.000<br>0.002<br>357 | <br>9<br>0.000<br>0.020<br>2358 |
| Branch-and-Bound<br>Optimal Solution<br>Run-time | <br>271<br>50 | <br>530<br>610 | <br>738<br>1700 |

Table 6 shows the results obtained with LS_1 and LS_2 for 50 randomly generated instances and one randomly generated starting solution. Two processors and N = 10, 20 and 30 subtasks were considered.

The starting solution was also generated by using one of the greedy approximate algorithms GR_1, GR_2 or GR_3. A local search algorithm, LS_1 or LS_2 , was then applied to improve the starting solution. The average and maximum errors for the results obtained by these combinations are presented in Tables 7 through 9 together with the average computation times. At the same time the results for these combinations are compared to those obtained from the greedy algorithms alone.

The presented results show that by applying local search to a solution obtained by the greedy approach algorithms a significant reduction in the average error can be achieved. A fixed number of procesſsors (M = 2) and a variable number of subtasks (N = 10, 20 and 30) were used for these runs.

**TABLE 6**

**Results for Algorithms LS_1 and LS_2**

| | AVERAGE ERROR | | |
|---|---|---|---|
| ALGORITHM | N=10 | N=20 | N=30 |
| LS__1<br>LS__2 | 0.0016<br>0.0002 | 0.0005<br>0.0000 | 0.0021<br>0.0012 |
| | MAXIMUM ERROR | | |
| ALGORITHM | N=10 | N=20 | N=30 |
| LS__1<br>LS__2 | 0.0246<br>0.0052 | 0.0036<br>0.0000 | 0.0179<br>0.0199 |
| | AVERAGE RUN-TIME | | |
| ALGORITHM | N=10 | N=20 | N=30 |
| LS__1<br>LS__2 | 14.6<br>43.4 | 47.0<br>363.6 | 153.4<br>1047.2 |
| | MAXIMUM RUN-TIME | | |
| ALGORITHM | N=10 | N=20 | N=30 |
| LS__1<br>LS__2 | 30.0<br>120.0 | 80.0<br>620.0 | 270.0<br>2700.0 |

**TABLE 7**

**Average Error for GR_1, GR_2, GR_3 and for LS_1 and LS_2 with Starting Solution Obtained from GR_1, GR_2 and GR_3**

| ALGORITHM | N=10 | N=20 | N=30 |
|---|---|---|---|
| GR__1<br>LS__1 (GR__1)<br>LS__2 (GR__1) | 0.0423<br>0.0020<br>0.0012 | 0.0128<br>0.0004<br>0.0001 | 0.0444<br>0.0029<br>0.0025 |
| GR__2<br>LS__1 (GR__2)<br>LS__2 (GR__2) | 0.0276<br>0.0023<br>0.0010 | 0.0093<br>0.0017<br>0.0004 | 0.0299<br>0.0038<br>0.0020 |
| GR__3<br>LS__1 (GR__3)<br>LS__2 (GR__3) | 0.0120<br>0.0023<br>0.0009 | 0.0073<br>0.0014<br>0.0003 | 0.0280<br>0.0028<br>0.0018 |

Table 9 shows that the time required for the branch and bound method shows a large standard deviation. Finally, a comparison of Table 6 to Tables 7 through 9 shows that the choice of the starting solution does not greatly affect the results of the local search algorithms. The use of the solution obtained from a greedy algorithm as an initial guess for the local search does not lead to significant or even consistent improvement over the case of randomly generated initial guess.

**TABLE 8**

## CONCLUSIONS

An optimal branch and bound algorithm was developed first for solving the task allocation problem. Its computation time in the worst case, however, increases faster than

$$O ( M^{N_s} / M! )$$

as shown in [8]. Approximate algorithms were then developed in order to obtain solutions close to the optimal one in polynomial time. The greedy algorithms require

$$O ( M N^2 )$$

computational time and can reach a solution with average error below 5%. GR_3 is the best among them.

The local search algorithms can reach a solution with average error below 0.5% at the expense of longer computational times. Algorithm LS_2 needs on the average much more computation time than LS_1, sometimes even more than the branch and bound algorithm. Taking into account the computation time needed for LS_2, LS_1 is obviously a much better choice.

**ABSTRACT** -- *The main aim of this paper is to study allocation of processors to parallel programs executing on a multiprocessor system, and the resulting speedups. We first consider a general program represented as a sequence of steps consisting of parallel operations, then one represented as a task graph whose nodes are do across loops and whose edges represent precedence constraints, and finally a single do across loop. General bounds on program speedup are discussed and measurements of code parallelism for the LINPACK numerical package are presented.*

## 1. INTRODUCTION

Recently there has been an almost unanimous agreement in the computing community that the near future supercomputers will be based on the shared memory multiprocessor architecture. But there are divided opinions when the question comes to the number of processors needed for an efficient and cost effective, yet very fast multiprocessor. A number of pessimistic and optimistic reports have come out on this topic. One side uses Amdahl's law and "intuition" to argue against large systems [13], [1]. The other side cites simulations and real examples to support the belief that highly parallel systems with large numbers of processors are practical, and could be efficiently utilized to give substantial speedups [5], [8], [11], [3], [7]. This question will probably be answered in a definite way only by experience, after many multiprocessor supercomputers with varying numbers of processors will have been built.

Presently the computing community has adopted a conservative approach to this issue, and that is reflected in the first multiprocessors (e.g., CRAY-X-MP, CRAY-2, Alliant FX/8) that have appeared on the market; each of them comes with a small number of processors. Of course, this is due mostly to our inexperience in using efficiently a large number of processors. Only recently the applications community has been systematically involved in research on parallel algorithms, languages and software.

The investment in traditional (serial) software is so enormous that it will be many years before parallel software dominates the market. It is then natural to ask: " How can we efficiently run existing software on multiprocessor systems?" The answer to this question is well-known: by using powerful restructuring compilers. One such powerful restructurer is the Parafrase compiler developed over the last fifteen years at the University of Illinois ([10], [17]). Besides restructuring Fortran programs into a form suitable for execution on a range of high performance machines, Parafrase also supplies various statistics useful for performance analysis and system design decisions. Such statistics include program speedup, efficiency, number of useful processors, serial/parallel timing estimates, etc.

In this paper we start with a parallel program that is the result of restructuring a serial program for execution on a multiprocessor. We discuss different types of parallelism that can be observed in such a program, the kinds of overhead involved in parallel execution on multiprocessor systems, and the effect of task size and scheduling overhead on the speedup. We then address the problem of allocating available processors to different parts of the program and estimating the possible speedup. Program Task Graphs have been chosen to provide concrete representations of parallel programs. These are directed graphs where a node represents a do across loop and an edge represents a precedence constraint. (A do across loop is a loop whose iterations may be partially overlapped [5].)

We have restructured LINPACK using Parafrase and computed the fraction of parallel code for all subroutines. Our results contradict the original Amdahl conjecture that most programs have at least 10% serial code, and hence can achieve a maximum speedup of at most 10. The experiments strongly support the view that there is enough inherent parallelism in real programs so that large numbers of processors can be efficiently utilized.

In Section 2, we present the basic concepts and definitions that are used throughout the paper. Section 3 discusses program restructuring, partitioning, critical task size, and gives a brief outline of the Parafrase compiler used for our measurements. Section 4 presents general bounds on program speedup and the measurements of parallelism in LINPACK subroutines. Section 5 presents three models of program execution on multiprocessor machines and a heuristic algorithm for allocating processors to parallel programs. In Section 6, we consider analytically our general parallel loop model and derive the speedup formula for multiprocessors. Finally, Section 7 gives some conclusions.

## 2. BASIC CONCEPTS

A basic sequential machine is a single CPU computer that can carry out operations serially, taking one unit of time for each. A $p$-unit *Multiple Execution Scalar* (MES)

+ This work was supported in part by the **National Science Foundation** under Grant No. US NSF DCR84-10110, and in part by the **U. S. Department of Energy** under Grant No. US DOE DE FG02-85ER25001.

machine is composed of $p$ identical basic sequential machines, and each processor is driven by its own control unit. Because of its flexibility, we will consider only the MES machine in this paper. It is variously referred to as a multiprocessor, a parallel machine with $p$-processors, or simply a $p$-processor machine.

An assignment statement is a statement of the form $x = E$, where $x$ is a variable and $E$ an expression. A *do across* or DOACR loop [5] with *delay* $d$ has the form

$$\begin{array}{c} L : \text{DOACR } I = 1, N \\ B \\ \text{END} \end{array}$$

where $d$, $N$ are integer constants, $I$ an integer variable with the range $\{1, 2, ..., N\}$, $B$ a sequence of assignment statements and DOACR loops, and it is understood that the iterations of $L$ can be partially overlapped as long as there is a delay of at least $d$ units of time from the start of iteration $i$ to the start of iteration $i + 1$, $(i = 1, 2, ..., N - 1)$. For $L$, the index variable is $I$, the number of iterations is $N$, and the loop-body is $B$.

Consider now the two extreme cases of overlapping. If $d = 0$, there is complete overlapping, i.e. all the iterations of $L$ can be executed simultaneously. In this case the do across loop is called a *do all* loop, and we write DOALL in place of DOACR. If $d = b$, where $b$ is the execution time (assumed to be independent of $I$) of the loop-body $B$, then there is no overlapping, i.e. the iterations of $L$ must be executed serially, one after another. In this case the do across loop is a standard serial loop, and we write DOSER for DOACR. A BAS or a block of assignment statements is a special kind of serial loop, namely a loop with a single iteration. (A BAS may also be regarded as a special case of a do all loop.)

A program is a sequence of steps where each step consists of one or more operations that can be executed simultaneously. A program is *serial* if each step has exactly one operation; otherwise it is *parallel.* Two programs are semantically *equivalent* if they always generate the same output on the same input. Parallel programs are conveniently represented in terms of do across loops (Section 3).

Let $PROG_1$, $PROG_2$ be two equivalent programs and let their execution times on a $p$-processor machine be $T_p(PROG_1)$ and $T_p(PROG_2)$ respectively. Then the *speedup* obtained (on this machine) by executing $PROG_2$ instead of $PROG_1$ is denoted by $S_p(PROG_1, PROG_2)$ and is defined by

$$S_p(PROG_1, PROG_2) = \frac{T_p(PROG_1)}{T_p(PROG_2)}.$$

An immediate consequence of this definition is the following lemma.

**Lemma 2.1.** If $PROG_1, PROG_2, ..., PROG_n$ is a sequence of programs any two of which are equivalent, then

$$S_p(PROG_1, PROG_n) = \prod_{i=1}^{n-1} S_p(PROG_i, PROG_{i+1}).$$

We usually write $S_p$ for the speedup when the two programs involved are understood. Of special interest to us is the case where $PROG_1$ is a serial program and $PROG_2$ is an equivalent parallel program obtained by restructuring $PROG_1$. We assume that the execution time of a program is determined solely by the time taken to perform its operations, and that the total number of operations in a program is never affected by any restructuring. These assumptions are not very far from the truth; they help to keep the formulas simple, and yet let us derive important conclusions. If $T_1$ is the number of operations in the serial program $PROG_1$, then $T_1$ is also the execution time of $PROG_1$ on the basic sequential machine, or on any parallel machine (i.e., $T_1 = T_p(PROG_1)$). The equivalent parallel program $PROG_2$ also has $T_1$ operations, but now these operations are arranged in fewer than $T_1$ steps. We call $T_1$ the *serial execution time* of $PROG_2$ and it can be obtained simply by counting the operations in $PROG_2$. The execution time $T_p \equiv T_p(PROG_2)$ of $PROG_2$ on the $p$-processor machine will depend on the structure of the program, the magnitude of $p$, and the way the $p$ processors are allocated to different parts of $PROG_2$. To distinguish it from $T_1$, $T_p$ is referred to as the *parallel execution time* of $PROG_2$. The speedup of a program is then the ratio of its serial execution time to its parallel execution time.

For a given program, we have the *unlimited* processor case when $p$ is large enough so that we can always allocate as many processors as we please. Otherwise, we have the *limited* processor case. These two cases will be often discussed separately.

## 3. RESTRUCTURING, PROGRAM PARTITIONING AND CRITICAL TASK SIZE

In our program model we assume that parallelism is explicitly specified in the form of tasks (disjoint code segments) which are parallel loops (DOALL or DOACR). This can be done for any Fortran program written in a serial form by employing restructuring compilers. For this paper we used Parafrase, a restructuring compiler developed at the University of Illinois, to transform programs into parallel form and compute some experimental values presented in the following section. Although a detailed presentation of the capabilities of Parafrase is beyond the scope of this paper, we briefly describe its basic functions for the sake of completeness.

Parafrase transforms serial Fortran programs into a parallel form suitable for efficient execution on a variety of parallel architectures including MES. The compiler consists of a front-end which applies a series of machine independent transformations, and a back-end which is a set of machine dependent optimizations. For each compiled Fortran program, Parafrase builds a graph called the data dependence graph whose nodes represent program statements and edges represent data and control dependencies among statements [2]. Each branch of an IF or GOTO statement is assigned a *branching probability* by the user, or automatically by Parafrase [11]. We can therefore view any program as a sequence of assignment statements, where each statement has an accumulated *weight* associated with it. All loops in a program are automatically normalized, i.e., loop indexes assume values in [1, $N$] for some integer $N$. As in the case of branching statements, unknown loop upper bounds are either defined by the user, or automatically by the compiler (using a default value). During parallel execution of the restructured program, data and control dependencies must be observed to assure that program semantics is preserved. The data dependence graph of the program is used by most transformations as a guide for this reason.

One of the most important transformations in Parafrase is the recognition and marking of DOACR loops (including DOALL and DOSER loops as special cases of DOACR). If we consider a block of assignment statements (BAS) as a serial loop with a single iteration, a restructured program can be viewed as a series of outermost DOACR loops with each such loop being arbitrarily complex. This defines a "natural" partition of a restructured program into a series of code segments or tasks. Dependencies may exist between any pair of segments in the program. We can thus define the *Program Task Graph* as a directed graph $G(V, E)$, where the nodes in $V$ are the outermost loops $L_i$ in the program, and there is an edge from a node $L_i$ to a node $L_j$ iff loop $L_j$ depends on loop $L_i$. Since backward dependencies are not allowed, $G(V, E)$ is acyclic.

In a restructured program we may observe two types of parallelism: *horizontal* and *vertical.* Horizontal parallelism results by executing a DOACR loop on two or more processors, or equivalently, by simultaneously executing different iterations of the same loop. Vertical parallelism in turn, is the result of the simultaneous execution of two or more different loops (tasks). Two or more loops can execute simultaneously only if there exists no control or data dependencies between any two of the loops. In the general case the program task graph exposes both types of parallelism. When we execute such a task graph on an MES machine, we must decide how to allocate the available processors to the program tasks so that the program speedup is maximized.

A serious problem arises when while executing a restructured program on an MES machine, we attempt to minimize the overheads of communication, synchronization and scheduling. This is a non-trivial optimization problem, and attempts to minimize such overheads usually results in reducing the degree of program parallelism. Most instances of this optimization problem have been proven to be NP-Complete [6]. Most heuristic algorithms attempt to minimize the communication cost by merging nodes of the graph together to avoid the overhead involved in communicating data from one processor to another. This however often reduces the degree of available vertical parallelism.

As an example of node merging, consider two loops $L_1$ and $L_2$ in our restructured program model, with data dependencies going from $L_1$ to $L_2$. The dependencies restrict the two loops to execute in this order since data computed in $L_1$ are used by $L_2$. In this case only horizontal parallelism inside each loop can be exploited. If we do not coordinate the execution of $L_1$ and $L_2$, then data computed inside $L_1$ will have to be stored in a shared memory upon completion of $L_1$, and then fetched from that memory to the processors executing $L_2$. If on the other hand we consider the two loops as a single task, then we can bind iterations of $L_1$ and corresponding iterations of $L_2$ to specific processors. In this manner data computed by a particular iteration of $L_1$ and used by the corresponding iteration of $L_2$ need only be stored in fast registers of the processor, thus avoiding the overhead of the redundant store and fetch. For relatively small loops the savings by such "task merging" can be very significant.

Task merging can also be used to decrease scheduling overhead that is involved when we distribute different program nodes across different processors. This scheduling overhead is in addition to the synchronization overhead and may become disastrous especially for very small tasks. For the CRAY-XM-P for example, the overhead involved with scheduling two parallel tasks can be several *msecs.* This overhead imposes a minimum size on parallel tasks, below which the speedup becomes rather a slowdown (i.e., $S_p < 1$). We call this the *critical task size.*

If during the execution of a program we schedule a set of parallel tasks, the parallel execution time is augmented by $O_T$, where $O_T$ is the scheduling overhead. The maximum expected speedup therefore is given by

$$S_p = \frac{T_1}{T_1/p + O_T}.$$

In order to have a speedup of at least 1, we must have $T_1 \geq T_1 / p + O_T$, i.e., $T_1 \geq p*O_T / p-1$ which gives the critical task size as a function of the overhead and the number of processors. More generaly, the minimum program size $T_{\min}$ required to obtain a given speedup $S^*$ on $p$ processors should satisfy:

$$\frac{T_{\min}}{T_{\min} / p + O_T} \geq S^*, \quad \text{or} \quad T_{\min} \geq \frac{p*O_T*S^*}{p - S^*}.$$

Program partitioning for minimizing data communication and scheduling overheads is a complicated optimization problem [15], [16].

## 4. GENERAL BOUNDS ON SPEEDUP

In this section we consider an arbitrary parallel program, and think of it simply as a sequence of steps where each step consists of a set of operations that can execute in parallel. The total number of operations (and hence the serial execution time) is denoted by $T_1$. Let $p_0$ denote the maximum number of operations in any step.

Suppose first we are using a $p$-processor system with $p \geq p_0$. (This is the unlimited processor case). Let $\phi_i T_1$ denote the number of operations that belong to steps containing exactly $i$ operations, $(i = 1, 2,..., p_0)$. Then $\phi_i$ is the fraction of the program that can utilize exactly $i$ processors, and we have $\sum_{i=1}^{p_0} \phi_i = 1$. We call $f = \sum_{i=2}^{p_0} \phi_i$ the *parallel part* of the program or the *fraction of parallel code,* and $1 - f = \phi_1$ the *serial part* of the program or the *fraction of serial code.* (At least $p - p_0$ processors will always remain unused.)

Consider now a limited processor situation with a $p$-processor machine where $p < p_0$. The steps with more than $p$ operations have to be folded over and replaced with a larger number of steps with $p$ operations. (For simplicity, we are assuming that each new step has exactly $p$ operations, although one of them may actually have fewer than $p$). Let $f_i \equiv f_i(p)$ denote the fraction of the modified program that can utilize exactly $i$ processors, $(i = 1, 2,..., p)$. Then we have

$$f_i = \phi_i \qquad (i = 1, 2,..., p - 1), \qquad \text{and} \qquad f_p = \sum_{i=p}^{p_0} \phi_i.$$

As long as $p \geq 2$, the parallel part $f$ is given by $\sum_{i=2}^{p} f_i$ and the serial part $1 - f$ by $f_1$.

An arbitrary $p$-processor machine is assumed in the following. The first two results are well-known [3], [12].

**Theorem 4.1.** $\displaystyle \frac{1}{S_p} = \sum_{i=1}^{p} \frac{f_i}{i}.$

**Proof:** When executing on a $p$-processor machine, the fraction of the program that uses exactly $i$ processors is $f_i T_1$, $(i = 1, 2, \ldots, p)$. Hence, the number of steps where $i$ processors are active is $\dfrac{f_i T_1}{i}$. The total number of steps is then given by

$$T_p = \sum_{i=1}^{p} \frac{f_i T_1}{i} = T_1 \sum_{i=1}^{p} \frac{f_i}{i}.$$

Since $T_1$ is the serial and $T_p$ the parallel execution time of the program, we get

$$\frac{1}{S_p} = \frac{T_p}{T_1} = \sum_{i=1}^{p} \frac{f_i}{i}. \quad \square$$

**Corollary 4.2.** $1 \leq S_p \leq p$.

**Proof:** We have $f_i \geq \dfrac{f_i}{i} \geq \dfrac{f_i}{p}$ $(i = 1, 2, \ldots, p)$. Hence

$$\sum_{i=1}^{p} f_i \geq \sum_{i=1}^{p} \frac{f_i}{i} \geq \sum_{i=1}^{p} \frac{f_i}{p}$$

$$\text{or,} \quad 1 \geq \sum_{i=1}^{p} \frac{f_i}{i} \geq \frac{1}{p}$$

$$\text{so that} \quad 1 \geq \frac{1}{S_p} \geq \frac{1}{p},$$

i.e. $1 \leq S_p \leq p$. □

**Corollary 4.3.** $S_p \leq 1 / f_1$.

**Corollary 4.4.** The speedup $S_p$, the number of processors $p$ and the fraction of parallel code $f$ satisfy (for $p > 1$)

$$S_p \leq \frac{p}{f + (1 - f)p}, \tag{4.1}$$

$$f \geq \frac{S_p - 1}{S_p} * \frac{p}{p - 1}, \tag{4.2}$$

$$\text{and} \quad p \geq \frac{f S_p}{1 - (1 - f) S_p}. \tag{4.3}$$

**Proof:** These three inequalities are equivalent; from any one the other two can be derived easily. Note that

$$\sum_{i=1}^{p} \frac{f_i}{i} = f_1 + \sum_{i=2}^{p} \frac{f_i}{i} \geq f_1 + \sum_{i=2}^{p} \frac{f_i}{p} = 1 - f + \frac{f}{p},$$

since $f = \sum_{i=2}^{p} f_i$ and $f_1 = 1 - f$. Then by Theorem 4.1,

$$\frac{1}{S_p} \geq 1 - f + \frac{f}{p}, \text{ so that } S_p \leq \frac{p}{f + (1 - f)p}. \ \square$$

Table 1. Values of $f$ for LINPACK subroutines.

Now, we have a program that can use a maximum number of $p_0$ processors. If the fraction $\phi_1$ of serial code in it is very small, we can choose $p$ $(> 1)$ processors such that $f_p = \sum_{i=p}^{p_0} \phi_i \approx 1$. Then, since

$$\frac{1}{S_p} = \sum_{i=1}^{p-1} \frac{f_i}{i} + \frac{f_p}{p} \quad \text{we get}$$

$$\left| \frac{1}{S_p} - \frac{f_p}{p} \right| = \left| \sum_{i=1}^{p-1} \frac{f_i}{i} \right| \leq \sum_{i=1}^{p-1} f_i = 1 - f_p \approx 0,$$

or equivalently, $S_p \approx p / f_p \approx p$. Thus, if for some $p > 1$, $\sum_{i=p}^{p_0} \phi_i \approx 1$, then the program runs very efficiently on a $p$-processor system giving an almost linear speedup. In this case, given the coefficients $\phi_i$ for the particular program, we can always determine the maximum number of processors that would get a linear speedup.

Based on Corollary 4.3, Amdahl and some other researchers thereafter questioned the usefulness of very large MES systems, since, according to their argument, the majority of programs have an average of more than 10% serial code and therefore their speedup on any MES machine is bounded above by 10.

We conducted some experiments to measure the fraction of parallel code $f$ in LINPACK, a widely used numerical package for solving systems of linear equations. Knowing the serial execution time $T_1$, the parallel execution time $T_p$ and the number of processors $p$ that were used during the execution of a subroutine, we can easily compute a lower bound for $f$ from (4.2). All the above parameters are supplied by Parafrase. On the other hand, if the value of $f$ for a particular subroutine is known and we want to achieve a specific speedup $S_p$ for this subroutine, then (4.3) gives us a lower bound on the number of processors that we must use.

The sorted (minimum) values of $f$ are shown in Table 1. The measurements were done on LINPACK subroutines after they had been restructured by Parafrase. From Table 1 we observe that the majority of subroutines have a very high fraction of parallel code. For the first 37 subroutines (out of 49), the average fraction of parallel code was $f \geq 0.9784$. Almost 76% of the subroutines have $f > 0.9$ and only 18% have $f < 0.8$.

Considering that LINPACK is a typical numerical package not very amenable to restructuring, the results of Table 1 are very encouraging. EISPACK for example (another numerical package), should be expected to have a much higher value of $f$ than LINPACK [11]. Since most numerical packages are more amenable to restructuring than LINPACK, Amdahl's pessimism should not be taken very seriously when designing large multiprocessor systems. His claim for the non-effectiveness of systems with large numbers of processors is mostly based on programs that exhibit $f < 0.9$. As mentioned in Section 3, the real performance threat for large MES systems lies in scheduling and interprocessor communication overheads.

Secondly, we should consider all possible operating modes of a multiprocessor. There is no question that there exist numerical programs that could fully exploit hundreds or thousands of processors. For programs that utilize only a few processors, MES systems can be operated in a multiprogramming mode to keep system utilization high. The question then breaks down to whether we can have sites with enough users (workload) to keep system utilization at acceptable levels. The answer to this question is rather obvious and it is more of a managerial and planning issue.

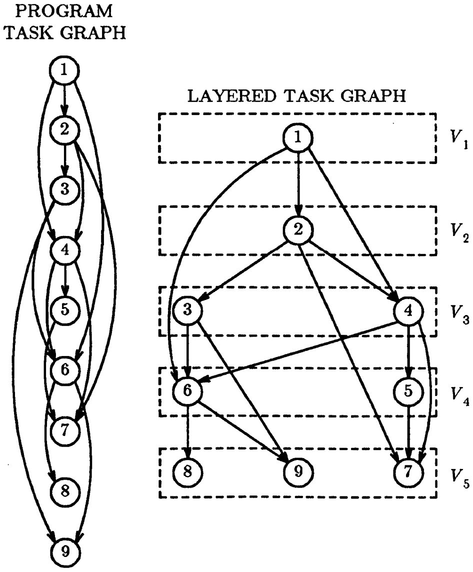

Figure 1: A example of a program task graph and its corresponding layered graph.

## 5. SPEEDUP AND PROCESSOR ALLOCATION FOR TASK GRAPHS

We consider here an arbitrary parallel program represented by a task graph $G \equiv G(V, E)$. Recall from Section 3 that this graph is defined on a restructured program with nodes representing outermost DOACR loops, and edges representing data and control dependencies among loops. Let there be $n$ nodes in $V$: $v_1, v_2, \ldots, v_n$. These nodes can be partitioned into disjoint layers $V_1, V_2, \ldots, V_k$, such that (1) all nodes in a given layer can execute in parallel, and (2) the nodes in a layer $V_{i+1}$ can start executing as soon as all the nodes in layer $V_i$ have finished, $(i = 1, 2, \ldots, k - 1)$. To construct this layered graph of $G$, we use a modified Breadth First Search scheme for labeling the nodes of the graph. Initially, the first node of the graph (corresponding to the lexically first loop of the program), is labeled 1 and queued in a FIFO queue $Q$. At each following step $v_j$, the node at the front of $Q$ is removed, and if $i$ is its label, all nodes adjacent to $v_j$ are labeled $i + 1$, and are queued in $Q$. Note that a node may be relabeled several times but its final label is the largest assigned to it. When $Q$ becomes empty, the labeling process terminates and we get the layered graph by grouping all nodes with label $i$ into layer $V_i$. An example of a program task graph and its corresponding layered task graph is shown in Figure 1. We consider below three execution models of a layered task graph on a $p$-processor MES machine. The most general and the two extreme cases are discussed.

As usual $T_1$ denotes the total number of operations in the whole program. For the node $v_j$, let $g_j T_1$ denote the number of operations in the node and $T_{pj}$ its parallel execution time, $(j = 1, 2, \ldots, n)$. Then $\sum_{j=1}^{n} g_j = 1$. The absolute speedup $S_{pj}^A$ of $v_j$ is the speedup obtained by considering the node separately as a program and is given by $S_{pj}^A = g_j T_1 / T_{pj}$.

**Case 1.** (Horizontal parallelism). Let $k = n$ and each layer $V_i$ consist of a single node $v_i$, $(i = 1, 2, \ldots, n)$. To get the maximum speedup for the whole program on $p$ processors, we need to get the maximum speedup for each node. Detailed formulas are given below.

The relative speedup $S_{pi}^R$ of $v_i$ is the speedup of the whole program when only $v_i$ is executed in parallel and all other nodes are executed serially. Thus

$$S_{pi}^R = \frac{T_1}{T_1 - g_i T_1 + T_{pi}}.$$

**Lemma 5.1.** The absolute and relative speedups of a node $v_i$ are connected by the equation

$$\frac{g_i}{S_{pi}^A} = \frac{1}{S_{pi}^R} - 1 + g_i \qquad (i = 1, 2, \ldots, n).$$

**Proof:** It follows directly from the above definitions. □

**Theorem 5.2.** The speedup $S_p$ of the whole program (when all nodes are executed in parallel) is related to the absolute and relative speedups of the individual nodes by the following equations:

$$\frac{1}{S_p} = \sum_{i=1}^{n} \frac{g_i}{S_{pi}^A} = \sum_{i=1}^{n} \frac{1}{S_{pi}^R} - n + 1.$$

**Corollary 5.3.** If all $n$ nodes give the same absolute speedup $S_p^A$, then $S_p^A = S_p$. If all $n$ nodes give the same relative speedup $S_p^R$, then

$$S_p^R \leq \frac{np}{np - p + 1} < \frac{n}{n - 1}.$$

**Proof:** The first assertion follows immediately from the above theorem, since $\sum_{i=1}^{n} g_i = 1$. For the second, we see that when the relative speedups are all equal

$$\frac{1}{S_p} = \sum_{i=1}^{n} \frac{1}{S_p^R} - n + 1 = \frac{n}{S_p^R} - n + 1.$$

Since $S_p \leq p$, this implies

$$\frac{n}{S_p^R} - n + 1 \geq \frac{1}{p} \text{ or}$$

$$S_p^R \leq \frac{np}{np - p + 1} = \frac{n}{n - 1 + \frac{1}{p}} < \frac{n}{n - 1}. \square$$

Each node of the graph can be an arbitrarily complex nested loop containing DOSER, DOALL, and DOACR loops. The problem of optimal processor allocation to such nodes has been solved optimally in [14].

**Case 2.** (Vertical parallelism). Let the task graph be *flat,* i.e. let there be a single layer $V$ consisting of $n$ nodes. This is the case when no dependencies exist between any pair of nodes. Here we may exploit vertical parallelism by executing all program nodes simultaneously. We consider the extreme case where each node requests exactly one processor. Since each node is allocated one processor, if $n \leq p$ the execution time is dominated by the largest task. In the general case bin-packing can be used to evenly distribute the $n$ nodes into $p$ bins. The Multifit heuristic algorithm, for example, can be used in this case [4]. Then, if $b_i$, $1 \leq i \leq p$ denotes the largest bin, we have the following theorem.

**Theorem 5.4.** The total speedup resulting from the parallel execution of an $n$-node flat graph on $p$ processors, where each node is allocated one processor, is given by

$$S_p = \frac{1}{\sum_{v_j \in b_i} g_j}.$$

**Proof:** The proof follows directly from the definition of speedup and the assumptions stated above. □

**Corollary 5.5.** If $n \leq p$ then

$$S_p = \frac{1}{\max(g_1, g_2, ..., g_n)}.$$

**Proof:** This follows from the previous theorem since each bin contains one node. □

**Case 3.** (Horizontal and vertical parallelism). In the most general case we have a program that exposes both types of parallelism, horizontal and vertical. In other words, the task graph consists of $k$ ($> 1$) disjoint layers $V_1, V_2, \ldots, V_k$ with at least one layer containing two or more nodes (Figure 1). If $|V_i|$ is the cardinality of the i-th layer, we assume that $|V_i| \leq p$, $(i = 1, 2, ..., k)$. (In the case of $|V_i| > p$ we fold and fuse nodes such that $|V_i| \leq p$ [15].) Our aim in this case is to exploit horizontal and vertical parallelism in the best possible way. Maximizing speedup is equivalent to minimizing parallel execution time. For each node of the task graph $v_j$ we define $r_j$ to be the maximum number of processors that the node could use. When $r_j = 1$, $(j = 1, 2, ..., n)$ our problem is reduced to the classical multiprocessor scheduling problem, which has been proved NP-Complete [6]. Our general problem can be reduced to the latter one by decomposing each node $v_j$ into $r_j$ independent sub-nodes of equal size. This trivially proves that our problem is also NP-Complete. Heuristic solutions are therefore the only acceptable approach to solving the problem suboptimally in polynomial time.

Below we present a simple linear-time heuristic algorithm for allocating processors to general task graphs. We call this *Proportional Allocation* heuristic since it allocates to each node a number of processors which is proportional to the size of the node (this term was borrowed from [16] where a similar idea was independently proposed). The idea behind proportional allocation is to allocate processors to the task graph on a layer-by-layer basis, so that the load in each layer is evenly distributed across the available processors, resulting in a suboptimal execution time. Variations of the proportional allocation heuristic and experimental results are given elsewhere [15].

For each layer $V_i$, $(i = 1, 2, ..., k)$ of $G$ we carry out the following steps. (The notation $x \leftarrow a$ used below indicates the assignment of an expression $a$ to variable $x$.)

**Step 1.** Each node $v_j \in V_i$ is allocated one processor. If $|V_i| = q_i$, then the number of remaining processors is $p_R = p - q_i$. The tasks in $V_i$ are arranged in order of decreasing size.

**Step 2.** The remaining $p_R$ processors are allocated to the nodes of $V_i$ with $r_j > 1$ so that each node receives a number of processors proportional to its size. For a node $v_j$ in $V_i$ with $r_j > 1$, the serial execution time is $t_j = g_j T_1$. Let $\tau_i = \sum_{v_j \in V_i} (g_j T_1)$ denote the total execution time of all nodes $v_j \in V_i$ with $r_j > 1$. Then, for all such nodes perform:

$$p_j = \left\lceil p_R * \frac{t_j}{\tau_i} \right\rceil \tag{5.1}$$

$$p_j \leftarrow \min(r_j - 1, p_j) \tag{5.2}$$

$$p_R \leftarrow p_R - p_j \tag{5.3}$$

where $p_j$ is the number of processors allocated to node $v_j$. Steps (5.1), (5.2), and (5.3) are repeated until all processors are allocated ($p_R = 0$), or all nodes in $V_i$ are processed. It should be noted that if at the end $p_R > 0$, then $p_j + 1 = r_j$, $(j = 1, 2, ..., q_i)$. A formal description of the proportional allocation heuristic is given in Figure 5. A simple example of the application of this algorithm to a single layer with DOALL loops, is shown in Figures 2 and 3. The number of processors allocated to each loop by our algorithm is shown in the table of Figure 2. Figure 3(a) shows the processor/time diagram when loops are executed one by one on an unlimited (in this case) number of processors, with a total execution time of 22 units. Figure 3(b) shows the processor/time diagram for the allocation performed by our algorithm. Processors were allocated so that both horizontal and vertical parallelism are utilized; 16 units is the total execution time in this case. The total program speedup on $p$ processors that results from the application of the above heuristic is given by the following theorem.

**Theorem 5.6.** The total program speedup that results from

```
 DOALL 1 I1 = 1, 7
      }1
1 END

 DOALL 2 I2 = 1, 14
      }8
2 END

 DOALL 3 I3 = 1, 5
      }5
3 END

 DOALL 4 I4 = 1, 20
      }4
4 END

 DOALL 5 I5 = 1, 24
       }6
5 END
```

| Number of processors allocated to each loop | |
|---|---|
| Loop Number | No. of Processors |
| 1 | 1 |
| 2 | 9 |
| 3 | 3 |
| 4 | 7 |
| 5 | 12 |
| Total | 32 |

Figure 2. A simple program with DOALLs and the processor allocation profile.

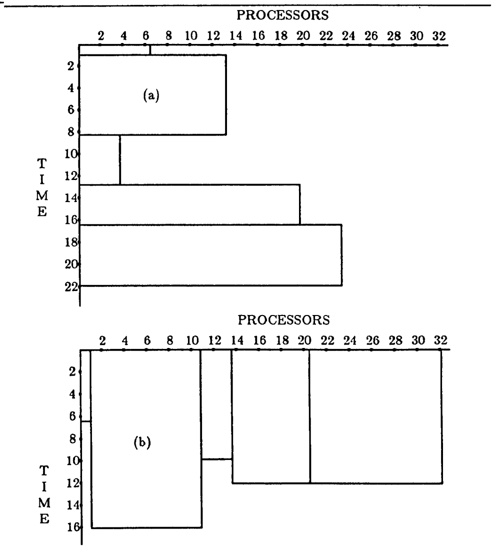

Figure 3. (a): The processor/time diagram for the program of Figure 2 (Case 1).

```
DOACR I = 1, 8    {d=4}
    }10
END
```

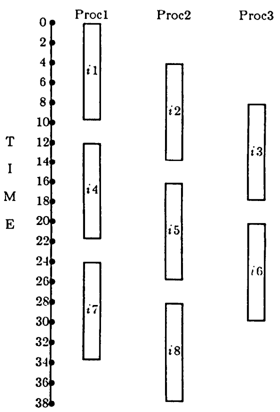

Figure 4. An example of the application of Theorem 6.1 for $p = 3$.

the parallel (vertical and horizontal) execution of a $k$-layer task graph on $p$ processors is given by

$$S_p = \frac{1}{\sum_{i=1}^{k} \lambda_i} \quad \text{where} \quad \lambda_i = \max_{v_j \in V_i} \left\{ \frac{g_j}{S^A_{p_j}} \right\} \qquad (5.4)$$

(where $S^A_{pj}$ is the absolute speedup of node $v_j$ for the number of processors $(p_j)$ allocated to it by the proportional allocation heuristic.)

Note that Theorems 5.2 and 5.4 are special cases of Theorem 5.6. If the graph is reduced to a flat graph, then $k=1$ and Corollary 5.5 holds. On the other hand, if each layer contains one node (linearized) then $q_i = 1$ in (5.4), ($i = 1, 2, ...., k$), and thus Theorem 5.2 holds true.

## 6. SPEEDUP AND PROCESSOR ALLOCATION FOR DOACR LOOPS

In this section we focus on a single node of the task flow graph representing the given program, i.e. a DOACR loop. We extended and generalized the do across model, to allow for idling processor time caused by do across delays. In [5] it is assumed that no processor may become idle unless it completes all iterations assigned to it. This is true only in certain special cases. As we shall see later by means of an example, each processor may have to idle between successive iterations. The following theorem generalizes the do across model and accounts for idle processor time.

**Theorem 6.1.** Consider a DOACR loop with $N$ iterations and delay $d$, and let $b$ denote the execution time of the loop-body. Then $p$ processors can be allocated to the iterations of the loop in such a way that the speedup is given by $S_p = Nb/T_p$, where

$$T_p = \Big( (\lceil N/p \rceil - 1) \max(\mathrm{b}, \mathrm{pd}) + d((N - 1) \bmod p) + b \Big) \qquad (6.1)$$

**Proof:** Let us number the iterations $1, 2, ..., N$ in their natural order and the processors $1, 2, ..., p$ in any order. The processors are allocated to the iterations as follows. Assume first that $N > p$. Iteration 1 goes to processor 1, iteration 2 goes to processor 2, ..., iteration $p$ goes to processor $p$. Then iteration $(p + 1)$ goes to processor 1, etc., and this scheme is repeated as many times as necessary until all the iterations are taken care of. We can now think of the iterations arranged in a $\lceil N/p \rceil$ X $p$ matrix, where the columns represent processors. If $N \leq p$, we employ the same scheme, but now we end up with a 1 X $N$ matrix instead.

Let $t_k$ denote the starting time of iteration $k$, ($k = 1, 2, ..., N$), and assume that $t_1 = 0$. (We measure time when iteration 1 starts executing). Let us find an expression for $t_N$. First, assume that $N > p$. For any iteration $j$ in the first row, the time $t_j$ is easily found:

$$t_j = (j - 1)d \qquad (j = 1, 2, ..., p)$$

Now iteration $(p + 1)$ must wait until its processor (i.e., processor 1) has finished executing iteration 1, and $d$ units of time have elapsed since $t_p$, the starting time of iteration $p$ on processor $p$. Hence

$$t_{p+1} = \max(b, t_p + d) = \max(b, pd).$$

The process is now clear. If we move right horizontally (in the matrix of iterations), each step amounts to a time delay of $d$ units. And if we move down vertically each step adds a delay of $\max(b, pd)$ units. Thus the time $t_k$ for an iteration that lies on row $i$ and column $j$ will be given by

$$t_k = (i - 1) \max(\mathrm{b}, \mathrm{pd}) + (j - 1)d.$$

For the last iteration, we have $i = \lceil N/p \rceil$ and

$$j = \begin{cases} N \bmod p & \text{if N mod p} > 0 \\ p & \text{otherwise} \end{cases}$$

Since $j - 1$ can be written as $(N - 1) \bmod p$, we get

$$t_N = \Big( \lceil N/p \rceil - 1 \Big) \max(b, pd) + d((N - 1) \bmod p).$$

Now let $N \leq p$. It is easily seen that

$$t_N = (N - 1)d$$

$$= \left(\lceil N/p \rceil - 1\right) \max(b, pd) + d((N - 1) \bmod p).$$

Finally, since the parallel execution time $T_p$ is given by $T_p = t_N + b$, the proof of the theorem is complete. □ Figure 4 shows an example of the application of Theorem 6.1. The DOACR loop of Figure 4 has 8 iterations, a delay $d = 4$, and a loop-body size of 10. The total parallel execution time on $p = 3$ processors is 38 units, as predicted by Theorem 6.1. We can maximize the speedup of an arbitrarily nested DOACR loop which executes on $p$ processors by using an optimal processor allocation algorithm described in [14].

**Corollary 6.2.** Consider a sequence of $m$ perfectly nested DOALL loops numbered 1, 2,..., $m$ from the outermost loop to the innermost. Let $S_{p_i}$ denote the speedup of the construct on a $p_i$-processor machine when only the $i$th loop executes in parallel and all other loops serially, ($i = 1, 2, \ldots, m$). Then the speedup $S_p$ on a $p$-processor machine, where $p = \prod_{i=1}^{m} p_i$ and $p_i$ processors are allocated to the $i$th loop, is given by $S_p = \prod_{i=1}^{m} S_{p_i}$.

## 7. CONCLUSIONS

We have studied the problem of allocating processors to parallel programs executing on a multiprocessor system, and measuring the speedups. Our experiments with the software packages LINPACK show that there is a high degree of parallelism available in ordinary programs, and that after proper restructuring such programs would be able to utilize fairly large multiprocessors systems. As a convenient unit of parallel program we have taken a DOACR loop which generalizes serial and DOALL loops. The speedup formula for DOACR loops has been generalized, and several other results have been derived that increase our understanding of how the speedup of a program depends on various factors. The general problem of processor allocation to programs represented as task graphs of DOACR loops being NP-Complete, we have given heuristic methods that seem to work well in practical situations and in linear time.

**ACKNOWLEDGEMENTS:** Many thanks are due to Prof. David J. Kuck for discussions, suggestions, and guidance on this work, and to Prof. David A. Padua for encouragement and discussions on the topic.

# SOFTWARE BASED MUTUAL EXCLUSION IN A MULTIPROCESSOR

Bernard T. Geary

Goodyear Aerospace Corporation
Akron, Ohio 44315

Abstract -- This paper is directed to the solution of a mutual exclusion problem involving a multiprocessor system. The multiprocessor contains six asynchronous microprocessors operating in a tightly coupled network. The system software has a master/slave organization. One processor is system executive or master while the remaining processors function as slaves and receive their tasks from the master. The task, or process, of master was previously performed on a full time basis by only one of the processors in the system. In the interests of efficiency and fault tolerance, the task of master can now float from processor to processor whenever needed. This paper presents a fast, software based method that allows only one processor at a time to assume the master task.

## Introduction

A multiprocesssor system exists called the MAPP (Modular Adaptive Parallel Processor). It was built by Goodyear Aerospace for AFWAL at Wright Patterson AFB. The MAPP contains six asynchronous microprocessors operating in a tightly coupled network. The system software has a master/slave organization. One processor is system executive or master while the remaining processors function as slaves and receive their tasks from the master. The task, or process, of master was previously performed on a full time basis by only one of the processors in the system. It was desired, in the interests of efficiency and fault tolerance, that the task of master be allowed to float from processor to processor whenever needed.

The primary problem associated with floating the master task was how to prevent two or more processors from acquiring the master task simultaneously. In accomplishing this, the following goals also had to be met:

1.) No system hardware modifications were allowed,
2.) The selected method had to be compatible with the current system software,
3.) The selected method had to be fault tolerance,
4.) The selected method had to be fast,
5.) Memory requirements had to be kept to a minimum,
6.) Future expansion of the system had to be allowed.

## Overview of the MAPP System

The MAPP is a homogeneous multiprocessor that has been primarily used for real-time signal correlation. The MAPP system architecture is shown in Figure 1. Each of the six system processors contains a general purpose 32-bit CPU. Each processor is capable of executing between 2 and 3 MIPS. Associated with each processor is a private local memory. This memory can be used for algorithm storage and data storage. The processors function asynchronously, running on independent internal clocks.

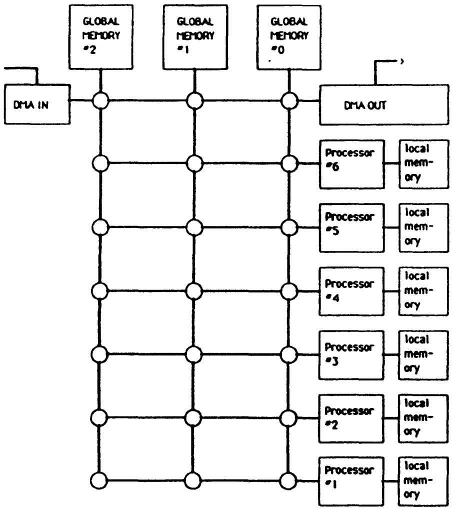

Figure 1 - MAPP System Architecture

Contained within the system are three global memories. The processors can each access these general purpose memories through a crossbar type port structure. Processor contention for access to global memory could cause a speed disparity among the processors if accesses are serviced in a completely random fashion. For the MAPP, speed disparity will not occur due to the discipline imposed by the global memory controller. The global memory controller prevents one processor from monopolizing global memory at any time. In order to access global memory, each processor must interface with the global memory controller. This controller contains a priority encoder that takes a "snapshot" of all the processor′s requests for access to global memory. If a processor fails to have its request honored in one snapshot it is guaranteed to have its request serviced in the next. There is no way for a processor to circumvent the action of the global memory controller.

At least 500 times a second, the MAPP system causes each processor to perform a self test. If a processor fails its own self test or if a processor detects a failure in another processor, a system-wide interactive test is performed. If a faulty processor is identified and confirmed during the system-wide test, it will be disabled automatically and the system will continue operation without it. This fault checking software, in addition to looking for actual

0190-3918/86/0000/0969 $01.00 © 1986 IEEE

hardware errors in each processor, requires that each processor respond within a certain period of time. This timed response checks a processors speed of operation and causes a processor to be flagged as faulty if it is operating below the speed of the other processors in the system. This self testing insures that each processor is operating at nearly the same speed.

## The Mutual Exclusion Method

The MAPP has several attributes that are useful when trying to float the master task. These attributes are both hardware and software based. First, each processor in the system is identical and runs at the same clock speed. The clocks are asynchronous, however. Second, the system periodically runs fault checking software that insures that each processor is operating normally. Third, in the MAPP system, the global memory controller insures that a processor cannot be arbitrarily delayed because of competition for memory accesses.

The devised mutual exclusion algorithm called Software Based Mutual Exclusion (SBME) uses a technique that can be categorized under the heading of busy waiting. Busy waiting is a general operation that requires a processor to loop several times while checking to see if another processor has acquired the master task. The SBME method uses a single location in global memory called MasterID as an indicator flag for the master task. If the master task is being performed by a processor, that processor´s ID number will be present at location MasterID. If no one is currently master, MasterID will contain a value of zero. The SBME algorithm is shown in figure 2 for the i´th processor of the system.

To acquire the master task, a processor reads location MasterID in global memory. If it is zero, the processor writes its ID number to MasterID immediately. Allowance is made for for the fact that another processor contending for the master task can write over the ID number in MasterID. The devised method requires that a processor loop and read MasterID several times until the danger of its ID being overwritten has passed. If the processor discovers a value in location MasterID different from its ID number, it drops out of contention. Any of the other processors that read MasterID after the first ID is written will avoid writing to it.

After a processor finishes the master task it clears MasterID in global memory. This allows another processor to assume the master task as soon as required. If a processor is ever stopped while operating outside the master task another processor would not be prevented from reserving the master task for itself.

The number of MasterID reads required for master task acquisition was determined, based on the number of contending processors. The variable m, in the SBME algorithm, is used to define the amount of time that a processor must wait before checking MasterID to see if it is master. The variable n determines the number of times that a processor must check MasterID before declaring itself as master.

```
processor i:

loop
   counter = 0

   read MasterID                ; Uninterruptable
   if MasterID > 0 exit         ; Section
   write ID to MasterID         ; of Code

 loop
   wait m cycles                ; See if anyone
   read MasterID                ; is trying to
   if MasterID  ne. ID exit     ; be Master
   increment counter
 until counter = n;

out: perform master task

   write 0 to MasterID          ; Allow another
                                ; to be Master

exit: do something else

endloop
```

Figure 2 - SBME Algorithm

A complex relationship exists between m and n to insure mutual exclusion. The relationship involves the memory speed of the global memory being accessed and the maximum number of processors that are represented in a global memory controller snapshot. A complete explanation of this relationship is beyond the scope of this short paper. Some discrete relationships between m and n are shown in Figure 3. The curves are shown for various delays of m and also for the total number of processors in the system. As m or the amount of delay between reads increases, the total number of reads, n, required to insure mutual exclusion decreases.

A trade off occurs when deciding upon the number of checks vs. delay periods that should be performed. The greater the number of checks, i.e. the more frequent the checking, the sooner a processor discovers that it is not master. However, more frequent checking also decreases the available bandwidth of global memory. Longer delays between checks would reduce memory bandwidth requirements but would tie up a processor longer when it was unsuccessful in acquiring the master task.

## Conclusion

Classical and contemporary mutual exclusion methods were reviewed as alternatives to the adopted method. Most were found to be unsuitable in that they imposed additional hardware requirements or are incompatible with the existing memory controller. One contending method, Dijkstra´s multiprocessor version of Dekker´s method, was suitable, but required longer acquisition time for present and expanded versions of the system.

The SBME method requires approximately 8.5 microseconds from the time a processor initially

```

                # OF CHECKS - n
```

Figure 3 - Worst Case Operation (7 or more Processors)

checks to see if anyone is master until the time it acquires the master task itself. As an alternate, the method patterned after Dijkstra took almost 49 microseconds. The primary reason for the time difference is that Dijkstra´s method for a best case required 15 accesses to global memory via read/write commands. A worse case for Dijkstra´s method could almost double the number of memory accesses required. The SBME method for a worse case requires only 6 read/write instructions. This difference is significant on the MAPP system, where read/write commands to global memory take twice as much time to execute as any other instruction.

The time required to acquire the master task in the MAPP system can be carefully controlled because of several factors:

1) The processors execute instructions at similar rates,
2) Each processor executes the same SBME code,
3) Instruction execution time is frequently tested,
4) The critical section of the SBME code, ie;

```
        read MasterID
        if MasterID > 0 return
        write ID to MasterID
```

is kept to a minimum and cannot be interrupted because all interrupts are disabled here.

Factors 3 and 4 as listed above require additional attention. The periodic system tests serve two purposes, they insure that the processors operating speeds are within limits and that if a processor fails as master that it can be disabled and a new processor can become master. When executing the mutual exclusion algorithm, a processor must not be interrupted between when it checks if someone is master and when it writes to MasterID. If a delay occurs here such as might result from a processor servicing an interrupt, one processor could assume the master task when it was not really available. An easy solution to this problem is to temporarily disable the interrupts while the critical section of code is being executed. If done properly, any interrupts that might have occurred during this time will still be pending and can then be serviced.

The SBME method always produces a "winner" whenever two or more processors vie for control of the master task. A processor´s value may be over written by another processor during the first part of the resolving routine. However, a valid ID number always remains in MasterID during conflicts. This ID belongs to the processor that ultimately acquires the task.

# A PARALLEL EXECUTION SCHEME FOR EXPLOITING AND-PARALLELISM OF LOGIC PROGRAMS

*Yow-Jian Lin and Vipin Kumar*

Artificial Intelligence Laboratory
Department of Computer Sciences
The University of Texas at Austin
Austin, Texas 78712

## Abstract

In this paper we present a parallel execution scheme for exploiting AND-parallelism of logic programs. This scheme follows the generator-consumer approach of the AND/OR process model. Using problem-specific knowledge, literals of a clause are linearly ordered at compile time. This ordering and run-time binding conditions are then used to dynamically select generators and consumers for different variables at run time. The scheme can exploit all the AND-parallelism available in the framework of generator-consumer approach. Compared with other execution schemes based on the same approach, our scheme is simpler, and potentially more efficient.

## 1. Introduction

Exploiting AND-parallelism in the execution of logic programs is difficult when literals of a conjunct share variables. One possible solution is to evaluate every subgoal of a conjunctive goal in parallel, and then perform join operation on the solutions of all the subgoals. This approach would uncover all the AND-parallelism in a logic program. But, for most practical problems, this approach requires excessive computation and is suitable only if unlimited resources are available. Therefore, various approaches for exploiting AND-parallelism in a more limited form have been proposed [2] [5] [7] [10] [11]. In the generator-consumer approach introduced by Conery and Kibler in the context of AND/OR process model [4] [5], if more than one literal in a clause body share a variable $V$, then one of these literals is designated as the generator of $V$ and the remaining literals are designated as the consumers of $V$. The execution of any consumer of $V$ is not started until the execution of the generator of $V$ has finished. Conery and Kibler use an ordering algorithm to identify the generator of each uninstantiated variable. Each time a non-ground binding is generated, the ordering algorithm is applied again to identify a new set of generators. Note that the run-time overhead of setting up the AND-parallelism in their approach could be very high, as the ordering algorithm may have to be repeatedly executed while interpreting a logic program. In order to avoid the problem of excess run-time overhead, several schemes have been presented [1] [6]. PLM of Aquarius project at UC Berkeley, proposed by Chang, et. al. [1], makes use of static data-dependency analysis. The execution graphs and backtracking paths are all derived at compile time, based on the worst case activation of each predicate. The restricted AND-parallelism (RAP), proposed by Degroot [6], creates one execution graph expression for each clause at compile time. It then dynamically generates parallel execution sequences based on these execution graph expressions. However, since PLM makes use of compile-time worst case analysis and Degroot's RAP utilizes limited execution graph expressions, these two schemes, unlike Conery and Kibler's scheme, can not always explore AND-parallelism to the fullest extent allowable in the generator-consumer approach. This paper presents an execution scheme to achieve the same degree of AND-parallelism as it is exploited in Conery and Kibler's execution model, but with less run-time overhead.

## 2. Execution Scheme

In this execution scheme, we are dealing with pure Horn Clause logic programs. On top of that, we allow variable annotations. User may also suggest a partial order on the execution of literals in a clause. Unlike Concurrent Prolog [11], the variable annotations for shared variables are not absolutely necessary; i.e., it is possible that a variable is shared by many literals in a conjunct and none of its appearance is annotated. The suggested partial ordering is also for execution efficiency only. But the ordering would not affect the semantics of the logic program.

Similar to the AND/OR process model proposed by Conery and Kibler, our scheme also includes three algorithms: ***ordering***, ***forward execution***, and ***backward execution***. In Conery and Kibler's approach, the ordering algorithm creates the data-dependency graph for a clause when the head of the clause unifies with a goal literal. The graph is used to select generators and consumers for different variables until some literal in the body produces a non-ground binding for a shared variable, at which time a new data-dependency graph has to be generated. In our scheme, the ordering algorithm is run at compile time. Using problem-specific knowledge (such as variable annotations, programmer-suggested ordering, etc.), it merely specifies a linear ordering for literals of each clause [9]. Our forward execution algorithm uses this linear ordering and run-time binding conditions to choose generators for variables shared by more than one literal, and the data-dependency graph is generated implicitly as the clause is executed. A simple but intelligent backward execution algorithm has also been developed for deciding which literals to re-solve in case some literal fails [8] [9]. Due to limited space, we focus only on the forward execution algorithm in this paper.

### 2.1. Forward Execution Algorithm

Suppose that the literals in the body of a clause have been ordered, and $P_i$ represents the $i$-th literal in the linear sequence. In addition, $P_0$ stands for the head literal. During the execution, there exists a token for each variable in the binding environment. Conceptually, if a literal holds the token of an uninstantiated variable $V$, it simply means that the literal is currently designated as the generator of $V$.

When a clause is called and the clause has non-null body, an AND process, corresponding to the head literal $P_0$, is created. Tokens for different variables in the clause (including free variables in the clause body) are given to $P_0$.[1] After $P_0$ has successfully unified the head literal with the given goal, it creates several descendant OR processes, one for each literal in the body, and then executes Procedure $S_0$ to pass tokens to literals in the body. A literal $P_i$ becomes executable when it receives tokens for all of its variables in the current binding environment. If $P_i$ shares variables with any literal appearing later in the linear sequence, then after its execution, $P_i$ also invokes Procedure $S_0$ to pass tokens.

This work was supported by Army Research Office grant #DAAG29-84-K-0060 to the Artificial Intelligence Laboratory at the University of Texas at Austin.

[1] For brevity, we will often use "$P_i$" to mean "the process corresponding to $P_i$".

**Procedure $S_0$**

$P_i$ does one of the following for each variable $V$ for which it has produced binding $T$.

i) **Variable V is bound to a ground term T.**
$V$ is substituted by $T$ in all the literals. No token has to be passed around.

ii) **Variable V is bound to a non-ground term T and T is dependent** *(i.e., there is another variable V1 in $P_i$ which is also bound to a non-ground term T1 where T and T1 share variables*[2]*).*
$V$ and $V1$ are substituted by $T$ and $T1$ in all the literals. For each new variable in $T$ which is not shared, a new token is created and passed to $P_m$ where $m = \min\{k \mid P_k$ had $V$ and $k > i\}$. Similarly, for each new variable in $T1$ which is not shared, a new token is created and passed to $Pn$ where $n = \min\{k \mid P_k$ had $V1$ and $k > i\}$. Tokens for new variables shared by $T$ and $T1$ are created and passed to $P_j$ where $j = \min\{k \mid P_k$ had $V$ or $V1$ and $k > i\}$.

iii) **Variable V is bound to a non-ground term T and T is independent** *(i.e., any variable in T is not shared by any other non-ground bindings produced for other variables of $P_i$).*
$V$ is substituted by $T$ in all the literals. The token for $V$ is then replaced by several new tokens, one for each new variable in $T$. These tokens are passed to $P_j$ where $j = \min\{k \mid P_k$ had $V$ and $k > i\}$.

Note that bindings of different variables can become dependent only if these variables are in the same literal. Therefore, the dependence checking for bindings can be done by each literal independently.

Depending on various binding conditions, different parallel execution sequence can be explored by this algorithm. An example is shown in Figure 1, where an arc with label $X$ means the token of variable $X$ has been sent along the direction of arc. Furthermore, a literal which has a dotted variable $V$ means that the literal holds the token of $V$. Given the same linear sequence of the literals (Figure 1a), this example shows two possible sequences of parallel execution. In the first sequence, the clause is called with bindings X/X, Y/Y, Z/Z. Token for X is passed to literal p2, token for Y is passed to p1, and token for Z is passed to p3. The binding of a free variable (such as W in this example) is always non-ground and independent in the beginning, therefore token for W is passed to p1. At this time both literals p1 and p3 have received tokens for all of their variables in the current binding environment, and can be executed in parallel (Figure 1b). Suppose that p1 generates bindings $y_0$/Y, $w_0$/W, and p3 generates binding $z_0$/Z. Since all new bindings are ground, no token has to be passed around. Both literals p4 and p5 are executable, as there are no variables in their current binding environments. Literal p2 is also executable, since it has received token for X from p0 previously. Therefore p2, p4, and p5 can all be solved in parallel (Figure 1c). The data-dependency graph corresponding to the first execution sequence is shown in Figure 1d.

In the second sequence, the clause is called with bindings V/X, V/Y, and $z_0$/Z. Since the bindings of variables X and Y are dependent (they share the same variable V), the tokens for X and Y are replaced by a single token for V, and the new token is passed to p1 (the first literal in the linear sequence which had either X or Y). The token for free variable W is passed to p1 again. This time literals p1 and p3 can be executed in parallel (Figure 1e). After the execution of p1, binding S/W and $v_0$/V is generated, and p2 and p5 can start executing in parallel (Figure 1f). After p2 generates binding $s_0$/S, p4 becomes executable (Figure 1g). The data-dependency graph corresponding to the second execution sequence is shown in Figure 1h.

## 3. Comparison With Other Approaches

### 3.1. Compile-time algorithm

At compile time, our scheme only applies the ordering algorithm once. Given problem-specific information represented as partial orders between literals, it is straightforward to apply the ordering algorithm to come up with a linear sequence of literals for each clause. Note that good linear sequences of literals are beneficial to other schemes as well. Conceptually, we are not doing extra work.

In PLM proposed by Chang, et. al. [1], the bindings of variables in a clause are classified into three types, where NGI means the binding is non-ground and independent, NGD means the binding is non-ground and dependent, and G means the binding is ground. Among these three types, NGD is worse than NGI, and NGI is worse than G. Programmers are asked to declare initial activation mode of each predicate, where the activation mode of a predicate $P$ is a possible binding condition of variables in $P$ when $P$ is activated. Using an iterative procedure, the compiler then derives the worst case activation of each predicate.[3] The data-dependency graph of each clause is then generated based on the worst case activation of its head literal. In order to provide reasonable initial activation mode of each predicate, programmers must be very much aware of what kinds of binding conditions can happen at run time. Moreover, the iterative procedure of doing data-dependency analysis tends to be time-consuming.

Degroot's approach [6] is even more complicated. The compiler is responsible for transferring each clause into an execution graph expression. However, in order to achieve all the AND-parallelism allowable in the generator-consumer approach, the execution graph expressions would have to be very complex and may have substantial run-time overhead due to redundant checkings. On the other hand, using simpler expressions may reduce the degree of AND-parallelism. Constructing a compiler which can produce reasonable execution graph expressions appears to be a nontrivial task.

### 3.2. Forward execution algorithm

Unlike other approaches, our scheme does not try to find if two literals are independent to be solved in parallel. Instead, our scheme just lets each literal decide whether it is executable. The parallelism comes out automatically when there are more than one literal ready to be executed.

The same clause

p0(X,Y,Z) :- p1(Y,W), p2(X,W), p3(Z), p4(W?,Z), p5(Y).

used as an example for the forward execution algorithm will be used again in the following to show advantages of our forward execution algorithm. We assume that the worst activation mode of p0 is

p0(NGD,NGD,NGD)

and the derived activation modes and exit modes[4] (based on the

[2] For simplicity, we are only considering the case in which two variables are bound to dependent terms. Extension to the case in which more than two variables are bound to dependent terms is obvious.

[3] The worst case activation, as defined in [1], refers to the binding condition where each variable has the worst type of its possible bindings.

[4] The derived exit mode of a predicate $P$ is the binding condition of variables in $P$ after the execution of $P$, based on a given activation mode. The derived activation mode of $P$ is the activation mode derived from the activation mode of the head literal and the derived exit modes of previously solved literals.

worst activation mode of p0) of p1 to p5 are

| **activation mode** | **exit mode** |
|---|---|
| p1(NGI,NGI) | p1(G,NGI) |
| p2(NGI,NGI) | p2(NGI,G) |
| p3(NGI) | p3(G) |
| p4(G,G) | p4(G,G) |
| p5(G) | p5(G) |

Note that if the activation mode of p3 is p3(G), its exit mode is also p3(G). The following discussion is based on our assumption of these activation modes and exit modes.

Suppose at run time when p0 is called, the bindings of variables X, Y, and Z are V/X, V/Y, and $z_1$/Z. Our forward execution algorithm will achieve the dynamic data-dependency graph shown in Figure 1h.

PLM of Chang, et. al. uses only one static data-dependency graph, which is generated at compile time based on the worst case activation. In our scheme, we take run-time binding conditions into account, and hence our scheme is able to exploit parallelism in cases where PLM would fail to do so. Figure 2 shows the static data-dependency graph used by PLM. Compared with Figure 1h, we can see that when the activation mode of p0 is "better", PLM fails to exploit possible parallelism.

Degroot's approach can explore different data-dependency graphs dynamically. However, due to the predetermined execution sequence of substatements it may not be able to start processing a subgoal as soon as the subgoal is ready to be executed. Suppose the following execution graph expression is produced by the compiler:

```
(GPAR(Y,Z)
     (SEQ         p1(Y,W)
                  (IF IPAR(Z,X)
                           (GPAR(W)  p2(X,W)  p4(W,Z))
                           (SEQ  p2(X,W)  p4(W,Z))))
     (IPAR(Z,Y)  p3(Z)  p5(Y)))
```

If at run time p0 is activated with the bindings V/X, V/Y and $z_1$/Z, then based on our assumption of activation mode and exit mode of each literal, the data-dependency graph of Figure 3 will be achieved by Degroot's approach. As we can see, the execution of p3(Z) is postponed even if it is executable from the very beginning. The execution of p5(Y) is also postponed due to the predetermined execution sequence of substatements. One of the drawbacks of these situations is that if the executable literals happen to fail, Degroot's approach will work longer in the failure branch of the solution tree.[5] Note that sometimes type checking could be redundant in Degroot's approach. For example, if GPAR(Y,Z) is true, then IPAR(Z,Y) is surely true. However since IPAR(Z,Y) has to be there to cover the case when GPAR(Y,Z) is false, the redundant type checking is unavoidable. Overall it appears that the run-time overhead in Degroot's approach is not much less than the overhead in our approach, even though Degroot's approach exploits only limited amount of AND-parallelism.

It is important to point out that, for any given clause, it is possible to create execution graph expressions in Degroot's approach which would be able to explore all the AND-parallelism allowable in the generator-consumer approach. Unfortunately, these expressions are too complicated, and would involve too many redundant run-time checkings.

Compared with Conery and Kibler's approach, our scheme as well as their scheme can explore AND-parallelism to the fullest extent allowable in the generator-consumer approach, as independent literals can always be executed in parallel. Moreover, if all the bindings produced by the generators are ground, then both schemes would achieve the same data-dependency graph for each clause. When generators can produce non-ground bindings, their scheme must execute the ordering algorithm every time a non-ground binding is generated, hence the data-dependency graphs achieved by both schemes could be different. Although repeated execution of the ordering algorithm may reorder the literals, it does not guarantee that a better data-dependency graph would be achieved. As we can see in Figure 4, during the execution of this particular example, the ordering algorithm must be executed three times (after p0 is unified with the goal and after the execution of both p1 and p2) by their scheme, but the resulting data-dependency graph is never better. When the heuristic rules used by their scheme are fallible, the new graph could be even worse. Furthermore, since the token passing scheme is simple, the run-time overhead of our algorithm in general is less than the overhead of Conery and Kibler's AND-parallel execution scheme.

In some cases, dynamically changing the linear sequence of literals could lead to better performance. However, when the choice of alternative linear sequences depends only on the activation mode of the head literal, techniques such as control alternatives used in IC-Prolog [3] would allow our scheme to use different optimal sequence for each possible activation. The only case in which dynamic reordering of literals can be helpful is when the linear sequence must be reordered with respect to the bindings produced by a generator in the clause body.

Our scheme also has the potential for distributed implementation, as the token passing scheme can be carried out by the corresponding process of each literal independently. In Conery and Kibler's approach, AND process must be responsible for coordinating the execution of conjunctive goals, and hence could become the communication bottleneck.

## 4. Concluding Remarks

We have presented a scheme of achieving limited AND-parallelism in logic programs. Compared with Conery & Kibler's approach, our scheme has less run-time overhead, and still achieves the same degree of AND-parallelism. Chang, et. al. [1] and Degroot [6] have also proposed schemes which reduce the run-time overhead presented in Conery and Kibler's scheme. However, these schemes tend to limit AND-parallelism, and require more complicated compile-time analysis than our scheme. An additional feature of our execution scheme is that the forward (and backward) execution algorithm can be implemented in a distributed manner. This is significant, as the centralized version of these algorithms can cause communication bottlenecks. We are in the process of designing message structures and communication schemes of the distributed version of these algorithms.

# A Parallel Execution Model of Logic Program Based On Dependency Relationship Graph

Seungbeom Kim, Seungryoul Maeng, and Jung Wan Cho

Department of Computer Science, KAIST

PO Box 150 Cheongryang, Seoul, Korea

*ABSTRACT*

In this paper, a parallel execution model based on the Dependency Relationship Graph(DRG) is proposed. Compared with another approaches, the execution ordering of AND subgoal is determined by the role of the shared variable. The DRG is an execution ordering graph of AND subgoals and guarantees near maximal AND parallelism. The necessary information for constructing DRG is generated automatically in compile time and used in run time. By this automatic control technique, the logic is completely separated from the control and the original flexibility and the power of logic programs are maintained without programmer's burden of control.

## 1. Introduction

The logic language is a concurrent language in which parallelism is embedded naturally. This parallelism originates from the nondeterminism which is the most powerful characteristic of the logic language. However, it cannot be fully exploited under the typical von Neumann architecture because of the complicated control mechanism for the nondeterministic behaviour of the logic program. Such restriction makes the current logic languages less powerful and inflexible than the original language based on Horn clause logic.

There are various approaches to the parallel processing of logic programs which support the natural parallelism efficiently. Especially, AND, OR parallelism have been the key issues. Compared with the OR parallelism, the AND parallelism requires some sophisticated control.

To perform the AND parallelism easily, the mode concept and the variable annotation method have been widely used [1], [2], [4], [12]. Since these methods require programmer's control for the program execution, the logic language loses one of its original purposes. In other words, the logic is incompletely separated from the control.

When there is no programmer's control information, some heuristic algorithms have been adopted [1],[2],[4],[12]. These heuristics, however, may decrease the AND parallelism by the eager ordering of AND subgoals. The problems of the heuristic algorithms will be described in section 2.

In summary, these conventional methods have following disadvantages.

i) Programmer's burden of control when the mode or variable annotation are used.

ii) Inflexibility of program by unidirectional use of one argument as input or output.

iii) Expense of the completeness.

iii) Decrement of the potential AND parallelism by the eager ordering of AND subgoals when heuristics are used.

## 2. Some considerations of AND parallelism

AND parallelism can be considered as a synchronization strategy of the shared variables. Without the programmer's control information, the conventional method of achieving AND parallelism is based on the heuristic algorithms, such as the connection rule [4]. Some careful considerations about the role of the shared variable can extract more AND parallelism than the heuristic search algorithms. In convenience, we will use the C-Prolog syntax except the cut symbol.

### 2.1 Problems and solutions of AND parallelism

Given a clause such as
f(X) :- p(X),q(X)., there are two problems when p(X), q(X) are executed in parallel. One is the binding conflict which attempts to instantiate(bind) a shared variable X to two different values [5]. The other problem arises when one subgoal is a deterministic dependent of the other subgoal like coroutine, so the execution ordering of AND subgoals is required [4], [11].

At first, we will discuss the solutions of the binding conflict and propose a solution called Lazy Ordering. For solving the binding conflict, the join technique can be used. If a program has a deterministic search space, the join technique would exhibit the greatest parallelism as

0190-3918/86/0000/0976 $01.00 © 1986 IEEE

well as higher efficiency [5]. In spite of assuring the maximal parallelism, this technique results in the explosion of the search space and known as an inefficient solution [4]. That is, the nondeterministic characteristics of the logic program makes the join technique impractical. There have been used many heuristic search algorithms to avoid the explosion of the search space and to solve the binding conflict. In logic programs, the heuristic search means the selection criteria of AND subgoals(literals).

If a search algorithm can expand nodes that generate fewer descendants, then it might save itself needless work by traversing fewer unsuccessful branches [14]. This heuristic reduces the search space and solves the binding conflict. However, if it is adopted as a selection strategy in every execution of AND subgoals, it is efficient only when the parallel execution of them causes the search explosion and the AND parallelism would be decreased. If we can find such explosion points and the heuristic is applied only to these points, the AND parallelism is increased and the effort to use the heuristic algorithms is reduced. That is, the use of the heuristic algorithm in every execution step of AND subgoals is an eager ordering which reduce the possibility of the AND parallelism.

As another search heuristic, the selection by number of uninstantiated variables has been used. This heuristic assumes that AND subgoals with fewer uninstantiated variables will generate fewer branches. Based on this algorithm, Conery suggests Connection rule which is the main ordering algorithm of AND subgoals [4]. Although Connection rule can find some AND parallelism, it can be thought as a sort of an eager ordering and the possibility of AND parallelism still remains.

The shrinked AND parallelism of the two heuristics originates from the application of these techniques to every execution step(eager ordering). To extract more AND parallelism, we should invest our attention to find the point of search explosion. For example program in Fig. 2.1(a), if all AND subgoals are executed in parallel, they reach such clause that are made up of only ground unit clause, e.g. s(X,U), t(U,Z), q(Z,Y), r(X,Z) in (b). In this situation, s(X,U) and r(X,Z) have an instantiated argument(X=a) but t(U,Z) and q(Z,Y) have no instantiated value. The explosion of search space takes place in the execution of t(U,Z) and q(Z,Y) and these clause are called the explosion points. Since these explosion points cause the search explosion, the further execution is delayed until some solutions are transferred. The principle of the Lazy ordering is to proceed the execution as possible.

The second problem between two AND subgoals arises when one cannot be executed until another subgoal generates a solution of shared variables. If the execution ordering is changed, an infinite loop or any meaningless operations will be occurred. If there is no programmer's control information, the above two heuristics cannot order these AND subgoals properly, as the following procedure illustrates:

```
append3(A,B,D,E) :-
      append(A,B,C),append(C,D,E).
append([A|B],C,[A|D]) :-
      append(B,C,D).
append([],A,A).
```

Consider the goal
:- append3(A,[2],D,[1,2]).

The first AND subgoal of append3 is to be append(A,[2],C) and the second AND subgoal append(C,D,[1,2]). According to Conery's algorithm, the left append(A,[1],C) is executed first and results in an infinite loop. If we previously know that the first append clause forms an infinite loop, the execution ordering should be right to left. This automatic ordering technique is suggested by Naish and used in Prolog environment to check infinite loops [11]. This technique is also useful in parallel environment. We will extend this technique and use as a solution for the second problem.

### 2.2 Relationships between AND subgoals

To extract more AND parallelism than the heuristics, the dependency relationship between AND subgoals should be redefined according to the role of the shared variables in each subgoal. By the definition of AND subgoal relationship, we can classify the problems of AND parallelism and adopt the proper strategies, e.g. the Lazy ordering or loop detection technique, which solve them and guarantee more AND parallelism.

When any two subgoals share a variable, four cases can be considered. The first case arises when the instantiated value of the shared variable of one subgoal play a role of pruning the search tree of the other subgoal immediately ( Fig. 2.2a). The second case is similar to the first case but the pruning of the search tree is delayed for some time (Fig 2.2b). The third case arises when the shared variables is used as a data channel from one subgoals to the other subgoal, that is, the relationship of the producer and the consumer (Fig 2.2c). In this case the consumer will perform meaningless operation like infinite loop without producer's solutions about the shared variable. Finally, the system and the evaluable predicate may not be executed until the shared variables are sufficiently instantiated (Fig 2.2d). According to these observation, we can derive the following definitions.

Definition 1) If there is no shared variable between two subgoals or if shared variables are already instantiated at execution time, the relationship between two subgoals is defined as an independent relationship. Let I(p,q) be the relationship which represents the independent relationship between two subgoal p,q.

Definition 2) If two subgoals share variables and are in one of the following three conditions, then the relationship between them is defined as a deterministic dependent relationship (tightly coupled relationship).

i) When instantiated value of one subgoal about shared variables reduces the search space of the other subgoal immediately.

ii) When the execution of the subgoal is impossible like the system predicate and evaluable predicate without the instantiated value of shared variable.

iii) In recursive clause, when one subgoal cannot be executed until the other subgoal generates some solutions of shared variable because an infinite loop is created by constructing variable continuously or by the repeated recursive call without the status change of its arguments.

To represent deterministic dependent relationship between subgoal p and q, Dx(p,q) will be used in first case and Sx(p,q) in second and third case, where x = {x1, x2,...,xn} and xi is a shared variable of p, q.

Definition 3) If there are shared variables between two subgoal p, q and the relationship is not the deterministic dependent relationship, the relationship between two subgoal p, q is defined as nondeterministic dependent and is represented by Nx (p,q), where x = {x1, x2, ..., xn} and xi is a shared variable of p, q (loosely coupled relationship).

## 3. A parallel execution model based on Dependency Relationship Graph(DRG)

### 3.1 Automatic generation of the control information

To find the dependency relationship between AND subgoals without programmer's control information, the control information should be generated automatically. From this control information we can derive the necessary condition for the valid execution of a clause in compile time and the DRG in run time.

The control information is generated in compile time by the analysis of variable matching patterns. There are four patterns when an argument in a goal clause matches with a corresponding argument in a candidate OR clause. The matching patterns are in table 3.1 and the abbreviated forms will be used.

### 3.2 The necessary condition of a procedure

In the point of operational semantics, a logic program is a finite set of procedures and each procedure has a set of OR alternative Horn clauses. To invoke a procedure, we can consider the following necessary condition of the procedure.

i) Necessary condition of a procedure

The necessary condition of a procedure is the union of the sets, where each element is the necessary condition of a OR alternative clause. The empty set means that at least one argument should be instantiated to invoke the procedure.

When a procedure is called, this condition play a role of a guard to derive a valid solution. If the condition of a procedure is violated, it is reasonable to delay the execution of this procedure until some solutions are generated from other procedures of which the necessary conditions are satisfied.

ii) Necessary condition of a clause

The necessary condition of a clause is a set of tuples and each tuple contains the argument numbers of the clause.

When a system or evaluable predicate, the necessary condition is a set of single tuple and the tuple is composed of the argument numbers which should be instantiated for valid execution.

When a self recursive clause, the necessary condition of the body recursive clause is determined first and the necessary condition of the head clause is obtained from those of body clauses. The recursive clause may cause an infinite loop because some arguments are repeatedly constructed. In this case, we should discriminate the real constructive argument from the pseudo constructive argument. The real constructive argument appears in such a clause that there is no generator clause for the variables in the body recursive clause except the head clause ,so the execution always makes an infinite loop without the instantiated value of 'mg' argument. On the other hand, the pseudo constructive argument means that the infinite loop can be avoided because the generator for the variables of the body recursive clause exists and the status of recursive call is changed in every recursion.

When a ground unit predicate (fact), there is no necessary condition. In other cases like sort([X|U],S) in the following example, the necessary condition is obtained by the Algorithm 1.

These necessary conditions play a role similar to that of the mode declaration or the variable annotation, but provides more powerful and general methodology. The usage of them will be described in the section 3.3 and 3.4.

### 3.3 Static Data Dependency Graph(SDDG)

This section defines the Static Data Dependency Graph(SDDG) and an algorithm to obtain the necessary condition of a clause. The necessary condition of a clause can be made only after those of body literals are determined.

Definition 3.1) For a given clause A :-B1,B2,B3,..Bn. Static Data Dependency Graph(SDDG) is a graph over the literal set(={A,B1,B2, ...,Bn}) with labeled arcs by the set of variables in the clause. An arc(p,q) is labeled by V iff p <> q and V is the set of shared variables between p,q.

Definition 3.2) The entry node in a SDDG is defined as follows ; For a given SDDG, a node Bj is an entry node Bi iff the dependency relationship between Bi and A(head) is Sv(Bi,Bj) or iff the necessary condition is an empty set and the arc(A,Bi) is Nv(Bi,Bj) or Dv(Bi,Bj) for the non empty set V.

Given a SDDG, the entry node should have some shared variables with the a node, but the adjacent node to the head node is not always an entry node. If some input from the head node cannot satisfy the necessary condition of an adjacent node in SDDG, this node cannot be an entry node.

Algorithm 1 : the necessary condition generation algorithm

input :
a SDDG
the control information of body clauses
the necessary conditions of body clauses
output :
N - the necessary condition of the clause

[step1] Determine the dependency relationship : For each literal of the SDDG, determine the dependency relationship with adjacent literals. Assume that U is the necessary condition of Bj, V is the set of shared variables between Bi, Bj.

If a subset u of U is also a subset of V then the dependency relationship between Bi, Bj is Su(Bi,Bj). If a subset of v of V plays a role of the argument pruning of Bj, the dependency relationship is Dv(Bi,Bj). The argument pruning can be detected by the control information 'gm' in the position of the shared variable. In other cases, the relationship is Nw(Bi,Bj), where w= V - (u union v).

[step2] Make necessary condition set:

s0) make a test set S from the necessary condition of the entry points of the head node A. S={t|t is a tuple} and the element of the tuple is the argument number of A.

s1) Select an element t from S. Delete t from S. Search entry nodes of A which are satisfied by t. If S is empty, terminate this algorithm.

s2) For newly determined entry nodes, search their entry nodes.

s3) Repeat s2 until there is no entry nodes.

s3) If there is no isolated node, t is inserted in the necessary condition N. The isolated node means a unsatisfiable node because there is no arc which satisfies the necessary condition of the node.

s5) goto s1

Example 1 )

```
1) sort(X,Y):-
      perm(X,Y),ord(Y).
2) perm([],[]).
3) perm(Z,[X|Y]):-
      delete(X,Z,Z'),perm(Z',Y).
4) delete(X,[X|Y],Y).
5) delete(X,[Y|Z],[Y|U]):-
      delete(X,Z,U).
6) ord([]).
7) ord([X]).
8) ord([X,Y|Z]):-
      X <= Y, ord([Y|Z]).
```

The necessary condition of delete(X,Z,U) is {<2>,<3>} and that of delete(X,[Y|Z],[Y|U]) is also {<2>,<3>}. The necessary condition of ord([Y|Z]) and ord([X,Y|Z]) is {<1>}. However, the perm(Z',Y) in 3) has an empty set because there is no real constructive term. The necessary condition of the perm(Z,[X|Y]) and that of the sort(X,Y) is {<1>,<2>}, which can be obtained by the Algorithm 1.

### 3.4 Dependency Relationship Graph(DRG)

This section describes the abstract run time algorithm to construct the DRG of AND literals(subgoals).

Definition 3.3) For a given SDDG of A :- B1,B2,...,Bn., Dependency Relationship Graph(DRG) is a directed graph over the literal set(={A,B1,B2,...,Bn) with the labeled arcs by the dependency relationships between nodes. The dependency relationship is defined in the previous section.

```
Algorithm 2 : The DRG construction Algorithm
input :
 a SDDG
 t - the tuple in which
 the instantiated argument numbers of the head are.
 the control information of body clauses
 ni - the necessary conditions of body clauses
 N  - the necessary condition of the head clause
 C  - Node set of the SDDG
output : a DRG
```

[step 1] Test if t satisfies N, then search entry nodes of the head node A which are satisfied by t. Otherwise, select a node which receives the input by t and let it be an entry node. If t is an empty tuple and N is not empty set, select the left most literal node and let it be an entry node. Make directed arcs from A to each entry node Bi labeled with St(A,Bi). From C, delete such entry nodes that are satisfied by only t.

[step 2] For newly determined entry node Bi, B2... Bn, search their entry nodes E1, E2, ...En in C. Make directed arcs from Bi to the corresponding entry node Eis labeled with Sv(Bi,Ei), Nv(Bi,Ei), Dv(Bi,Ei), where v is the set of shared variable between Bi, Ei. From C, delete such Eis that are satisfied by only the shared variable with Bis.

In Fig. 3.1, example programs and DRGs of goal statements are illustrated.

### 3.5 A parallel AND/OR process model based on DRG

In our model, a goal statement is solved via message communications between AND processes and OR processes. An AND process is created for solving a goal clause and generates a DRG which is the execution ordering graph of body literals. The OR process is created to solve a body literal and the solution generated in OR process is not only sent to the parent AND process, but flows along DRG directly.

There are five types of messages; start message, wait message, fail message, solution message and end message. Compared with Conery's model, the wait message, the end message are added and the redo message, the cancel message are deleted.

The wait message is created in following three cases;

i) OR process --> parent AND process : When the Nondeterministic subgoals reach the clauses which need the instantiated value from the ancestor(Lazy ordering).

ii) OR process --> parent AND process : When the variable solution from the generator causes the violation of the necessary condition. In this case, the reordering problem is solved automatically by generating the wait message.

iii) parent AND process --> child OR process : When the OR process waits the solution from the preceding OR processes, this process receives a wait message from the parent AND process instead of a start message.

The end message is generated by OR processes when it cannot find any further solutions. This message is sent to the parent AND process and to the succeeding OR processes. The redo message is eliminated because there is no backtracking mechanism in our model.

Fig. 3.2 shows the message transfer diagram of an AND process and Fig. 3.3 shows the message transfer diagram of an OR process.

### 3.6 Analysis of the proposed model

The proposed model is a process model based on Conery's AND/OR process model. Compared with Conery's model, the AND parallelism is enhanced by using DRG and the backtracking mechanism is removed. Instead of the redo message, the solution is sent to the parent process or to the succeeding OR process directly and the end message is used to indicates the end of solutions. Fig. 3.4 shows the message generation in solving qsort([2,1],S,[]) by Conery's model and the proposed model (program in Fig. 3.1). We can obtain the following results.

The total # of messages = 34
The total # of processes = 13
The total # of time step = 38
In Fig. 3.4(b),

The total # of messages = 40
The total # of processes = 13
The total # of time step = 23

From these results, we can find that the parallelism of the proposed model increases 1.65(38/23) times because the qsort([1],S,[2|Y]) and the qsort([ ],Y,[ ]) are executed in parallel. In Conery's model, they are executed in sequential because of the shared variable Y. Since there is only one solution in solving qsort([1],S,[2|Y]) the redo message in Conery's model is not diffused over all procedure, so the proposed model generates more messages. However, if there are many solutions and the backtracking takes place, the number of messages in the proposed model can be less than Conery's model. We obtain the following results in solving sort([2,1],Y) which is the ordinary sort in Fig.3.1.

Conery's model
total # of messages = 83
total # of process = 29
total # of time steps = 50

the proposed model
total # of messages = 78
total # of process = 27
total # of time steps = 23

The parallelism increases 2.01(50/23) times and the number of generated messages are less than Conery's model. The increased parallelism results from the pipelining solutions between OR processes. The parallelism of the proposed model will increase in proportion to the number of solutions. The redo messages for backtracking increase the total number of messages in Conery's model.

## 4. Conclusion

In procedural oriented approach [6], the AND parallelism is more important than the OR parallelism because the OR parallelism can be achieved better by the Goal rewriting approach. If the AND parallelism is restricted, the advantages of the procedural approach is decreased. However, the nondeterministic behaviour of the logic programs makes it difficult to control the program and the conventional heuristic algorithms cannot perform the full AND parallelism because the explosion of the search space takes place.

In this paper, we proposes a method to control the nondeterministic behavior of logic programs and an AND/OR process model based on this method. Compared with the other approaches, the proposed model performs near maximal AND parallelism by finding the dependency relationships between AND subgoals in execution time. The dependency relationships between AND subgoals are determined by the role of the shared variable. In the proposed model, the backtracking mechanism doesn't take place and the solution pipelining between OR processes is used. This mechanism, also, increases the parallelism of the proposed model. As a future study, the run time overhead should be reduced by compiling technique.

# DETECTION OF AND-PARALLELISM IN LOGIC PROGRAMMING[a]

Yu-Wen Tung and Dan I. Moldovan

Department of Electrical Engineering-Systems
University of Southern California
Los Angeles, California 90089-0781

**Abstract** -- In this paper, we propose an ordering algorithm based on the automatic detection of AND-parallelism in logic programming at compile time. This algorithm consists of three phases: (1) analysis and detection of input-output mode, (2) automatic detection of data dependencies, and (3) subgoal ordering. Existing algorithms for the analysis of AND-parallelism proposed by previous researchers rely on mode declaration by the programmer. Based on the ordering scheme proposed in this paper, parallel compilers for logic programs can be conceived. A performance analysis of the ordering algorithm is presented through several examples.

## 1. Introduction

In this paper, automatic detection of parallelism in logic programming is studied. Definitions of technical terms employed in this paper can be found in [1,11,12,13,19].

There are four kinds of parallelisms in Horn clause logic programming identified by Conery and Kibler [4], Ito and Masuda [9], Pollard [16] and other researchers. They are (1) OR-parallelism, (2) AND-parallelism, (3) stream parallelism; and (4) unification parallelism. Among these parallelisms, OR- and AND-parallelisms are more important than others. OR-parallelism means to execute alternative clauses simultaneously, and AND-parallelism means to execute many subgoals in a clause simultaneously. OR-parallelism is much more straightforward then AND-parallelism because there is no interaction between the processing paths. On the other hand, when two subgoals in a clause share some variables, the answers obtained by executing these subgoals simultaneously may conflict each other. Thus, AND-parallelism must be carried out carefully.

For realization of AND-parallelism, various schemes had been proposed [2,5,6,7,15,16] and they fall into one of the following two principles:

1. Whenever there is an output variable shared by two subgoals, these subgoals are executed in sequence. This is called none-shared-variable (NSV) scheme in [19], and most of the current works fall into this category, such as Conery's scheme [5].
2. Execute all subgoals simultaneously, and than "reconciliate" possible conflicts via extra unification. This is called reconciliation (REC) scheme in [19], and the work of Pollard [16] is an example.

According to the current research, the NSV scheme seems to outweigh the REC scheme for applications with strong declarative inference, such as knowledge-based expert systems [19]. Also, it is known that proper subgoal ordering is important in the NSV scheme [2,5,6,7,19]. However, most of these works rely on "mode declaration" to implement ordering for AND-parallelism [2,5,6,7]. The "mode declaration" is a programmer-provided control command which tells the machine the binding transfer direction of a variable in a clause. Although this approach is efficient, its machine-oriented nature is not desirable in a declarative language such as logic programming. In this paper, we propose the compile time ordering algorithm without programmer-specified "modes."

## 2. Concept of Data Dependencies

This work is based on the concept of input-output mode of each argument in a given subgoal and the data dependency relationships among subgoals, as explained below:

### 2.1 Input and Output

The concept of *input* and *output* in logic programming was first introduced by Kowalski [11]. It denotes the direction of the binding transfer during unification, in a way similar to the input and output arguments in procedure calling. Here we extend this concept to binding transfer through substitution and subgoal computation as well as unification. For simplicity, let $C^+$ denote the clause head of C, and $C^-$ denote the clause body of C: $C^+ \leftarrow C^-$. Consider the goal

$$\leftarrow A_1, \ldots, A_i, \ldots, A_k$$

where the selected atom $A_i$ is unified with some $C_i^+$, with a *most general unifier* (mgu) $\theta$. Any variable X in $C_i$ which is instantiated by $C_i\theta$ is called an ***input variable*** of $C_i$. Such an X is also called an ***input variable*** of atom $B_j$, $B_j \in C_i^-$. If an uninstantiated

[a] This research was supported by NSF Grant ECS-8307258, JSEP Contract F49620-85-C-0071.

variable Y in $C_i^+$ becomes instantiated only when some subgoal $B_j$ in $C_i^-$ is computed, then Y is called an ***output variable*** of $C_i^+$, and of $B_i$.

If a term has only input variables, it is called an ***input term***. Similarly, if it has only output variables, it is called an ***output term***, and a ***mixed term*** or ***i-o term*** if it has both. An example of a mixed term is f(X,b) and f(a,Y) with a unifier $\theta = \{X/a, Y/b\}$.

Although the computation of logic programs can be viewed as computing output arguments from given input arguments for each subgoal, the input-output mode of any given argument is not predetermined in any subgoal due to the fact that subgoals are "relations" rather than "functions." As a result, when two subgoals share the same variable X, they may not be executed at the same time if X is an output variable. This is due to a possible binding conflict. However, they may be executed simultaneously when X is an input variable to both of them. We say there exists some data dependency relation in the first case, but not in the second one. Below, four types of data dependencies in logic programming are defined, based on the concept of input and output.

## 2.2 Data dependencies

Consider a clause

$$p \leftarrow q_1, q_2, \dots, q_k$$

let v(p) be the set of variables that occur in p, $v(q_i)$ be the set of variables that occur in $q_i$, $1 \le i \le k$.

### Definition 2.2.1 Functional dependency:

We say there is a ***functional dependency*** between $q_i$ and $q_j$ if there exists a variable $x \notin v(p)$, where x is an output variable of $q_i$ and an input variable of $q_j$. The atom $q_i$ is called the ***producer*** of x and $q_j$ is called the ***consumer*** of x. The variable x is an ***intermediate result*** generated by $q_i$ and consumed by $q_j$.

### Example 2.2.1:

The following clause expresses the calculation of Fibonacci-numbers:

F(x+2,n) ← F(x+1,n1), F(x,n2), Plus(n1,n2,n)

where F(x,n) is a Fibonacci procedure that computes result n from a given input x, and Plus(n1,n2,n) is the addition procedure that adds two numbers n1 and n2, returning the result n. Clearly, the addition of n1 and n2 must be performed after F(x+1,n1) and F(x,n2) have been evaluated. Therefore, Plus(n1,n2,n) is *functionally dependent* on F(x+1,n1) and F(x,n2).

### Definition 2.2.2 Internal dependency:

We say there exists an ***internal dependency*** between $q_i$ and $q_j$ if there is a variable $x \in v(q_i) \cap v(q_j)$ and x is output in both $q_i$ and $q_j$.

### Example 2.2.2:

Assume a company is hiring people who must have engineering degrees plus five years or more experience each and with salary requirements no more than 50K a year each. The top level program could be written as:

candidate(x) ← degree(x), engrg(x), exp(x,5),
salary(x,50)

with a goal ← candidate(x). Clearly, x is an output variable and internal dependencies exist between any pair of atoms in the program clause body, because they all share variable x.

Next, the concept of the *coupling effect* is introduced. This effect makes two variables bearing different variable symbol names equal and can be viewed as one variable.

### Definitions of the coupling effect:

1. Two variables are said to be ***coupled*** if they become identical non-ground terms after a unification. For example, x and y are coupled if p(x,y) is unified with p(h(w),h(w)) or p(z,z).
2. Two variables are said to be ***coupled*** if their corresponding terms share one or more common variables after a unification. For example, x and y are coupled if p(x,y) is unified with p(z,f(z,w)).
3. Two variables are said to be ***coupled*** if they are unified with a pair of coupled variables. For example, if z and w are known as coupled, then x and y are coupled when p(x,y) is unified with p(z,w).

We can define ***coupled term*** in the same way. The phrase "coupled term" was introduced by Chang, Despain and DeGroot [2].

### Definition 2.2.3 Coupling dependency:

We say that there exists a ***coupling dependency*** between $q_i$ and $q_j$ if $x \in v(q_i)$, $y \in v(q_j)$, and x and y are output variables and are coupled.

Coupling dependency is a variation of the internal dependency. Coupling dependency cannot be discovered only by checking the given clause, hence it is also called ***hidden internal dependency***.

**Example 2.2.3:**

Consider the program:

C1: $p_0(x) \leftarrow p_1(x,x)$

C2: $p_1(y,z) \leftarrow p_2(y), p_3(z)$

All variables are assumed to be output variables. It is obvious that neither C1 nor C2 has functional or internal dependency. However, when $p_0$ is called, $p_1(x,x)$ is unified with $p_1(y,z)$ and y, z are coupled as a result. Therefore $p_2(y)$ and $p_3(z)$ have a coupling dependency. The coupling effect in C2 is introduced by a higher level goal in C1.

**Definition 2.2.4 Run-time dependency:**

We say there exists a ***run-time dependency*** between $q_i$ and $q_j$ if $x \in v(q_i)$, $y \in v(q_j)$, and x and y are output variables and are coupled at run time by a top level goal.

Run-time dependency is a coupling dependency introduced at run time, due to a goal with coupled terms (eg. p(x, x)). It cannot be detected directly from the program, and hence, is different from coupling dependency.

**Example 2.2.4:**

Consider the program:

$p_1(y,z) \leftarrow p_2(y), p_3(z)$

where the goal is $\leftarrow p_1(x, x)$, and x, y, z are output variables. In this example, $p_2(y)$ and $p_3(z)$ seem to be independent but are coupled at run time by x in the goal $\leftarrow p_1(x, x)$.

This is just a variation of Example 2.2.3 with a higher level goal $\leftarrow p_1(x ,x)$ unspecified at compile time.

Among the four types of data dependencies, internal dependency, coupling dependency and run-time dependency are similar to each other in the sense that all three are defined over *output variables*. They either denote some output variables shared by two subgoals or some output variables coupled with each other, and thus we also call them ***output dependencies*** as opposed to *functional dependencies*, which are defined over both input and output variables.

With the above definitions, it is clear that functional dependency represents inherent sequentiality and implies a partial ordering of subgoals. This partial ordering is "necessary" in the sense of implementation and not the logic. On the other hand, output dependency leads to many possible orderings, one more efficient than another. Together, these dependencies describe the limitation of the AND-parallelism and they are important in detecting the available parallelism. Below, some techniques of detecting such limitation are proposed.

## 3. Automatic Parallelism Detection Techniques

In this section we study techniques of designing a parallel compiler which detects AND-parallelism automatically. This compiler has three phases: in the first phase, it analyzes the input-output mode of arguments in a given program; in the second phase, it finds out the data dependency relations of the subgoals in each clause; and in the third phase, it determines an efficient execution ordering based on the data dependency and other supplemental criteria. This is described in detail below.

### 3.1 Automatic input-output mode analysis

Because the "use" of a relation is not deterministic, the binding transfer direction of a variable in the relation is not always fixed. However, if some binding transfer direction is proven possible (or impossible) in a given program, the binding transfer path can be traced and the binding transfer directions for other variables can be inferred. Several heuristic rules for inferring whether or not a given variable is input are proposed below. In describing the rules, consider a variable X and a subgoal q in either the head or the body of a clause C. By notation "$X \in q$" we mean "X occurs in q", and by "q<*r*>=<input>" we mean the *r*th position of q must be an input position.

The rules are:

1. Arithmetic and logic operations rule: arguments that *must be instantiated* as required by PROLOG systems should be input. For example, both X and Y are inputs in expressions "X * Y" and "X < Y."
2. Body producer-consumer rule: if $X \notin C^+$, $X \in C^-$, and X has two or more occurrences in $C^-$, then at least one position containing X must be input, and at least one must be output.
3. Head producer-consumer rule: if $X \in C^+$, $X \notin C^-$ and X has two or more occurrences in $C^+$, then at least one position containing X must be input.
4. Don't care rule: if a clause D is called by C, and D has a don't care symbol ("_" in PROLOG), then the corresponding position X in C must be input.
5. Variable consistency rule: if $X \in C^+$ and $X \in C^-$, and if all occurrences of X in $C^-$ are *inputs*, then at least one occurrence of X in $C^+$ must be input.

6. Position consistency rule: if predicate q in $C^+$ is also in $C^-$, then C is called a *recursive clause*, and the corresponding position of all q's must be consistent, i.e., if position *r* in any such q is known as input then q<*r*> must be input.
7. OR-bundle rule: if a set of $\{C_i\}$ is an OR-bundle -- i.e., all $C_i^+$ have the same predicate name and the same arity, and if a position in any $C_i^+$ is an input, then the position of all $C_i^+$ must be input.
8. Coupling rule: if variable X occurs in an atom q (either in $C^+$ or $C^-$) more than once and both are output variables, then X is a coupling variable.

The analysis of input-output modes for a given OR-bundle based on these rules is shown in Algorithm 1 below:

### ¶ Input-Output Modes Analysis Algorithm 1:

*Input* : A set of clauses which is an OR-bundle.
*Output* : All possible input-output modes of each arguments in the clauses.
*Method* :

1. Mark any known modes for variables in given clauses.
2. Select any variable with its mode unknown, apply Rules 1 through 8 to this variable. Mark <i> for variables that *must be input.* If there is ***at least one input*** in a set of positions, state "$p_1$<1> or ... or $p_r$<r> = <i>."
3. When no rule is applicable, mark <o> for those ***must be output*** terms and mark <i/o> for the rest.

<End of algorithm 1>

Based on this algorithm, the entire logic program can be analyzed. We may view the logic program as a directed graph, each clause is a node and each node has pointers to the nodes it calls. There is a cycle if a clause calls itself -- i.e. a recursive call. A root node is a clause that is not called by any other clause except the top level goal, and a terminal node is a unit clause that does not call any other clauses. A descendent node of node p is a node pointed to by p, but not p itself. Starting from the terminal nodes, we can analyze the clauses from bottom up until the root is found. This is shown in the next algorithm:

### ¶ Input-Output Modes Analysis Algorithm 2:

*Input* : A logic program.
*Output* : All possible input-output modes of each arguments in the program.
*Method* :

1. Determine the calling sequence of the logic program. Select a clause that does not have any descendent clause unchecked.
2. Use Algorithm 1 to analyze the input-output modes of arguments in that clause.
3. Go to Step 1 if there is any clause remains unchecked, exit otherwise.

<End of algorithm 2>

**Example 3.1.1 "append":**

C1: append([], L, L)
C2: append([x|L1], L2, [x|L3]) ← append(L1, L2, L3)

**Analysis**:

The calling sequence is trivial:

Apply Rule 3 tod x in C2:
  append<1> or append<3> = <i>
Apply Rule 3 to L in C1:
  append<2> or append<3> = <i>
Apply Rule 7:
  [case i] append<3> = <i>
  [case ii] append<1> = append<2> = <i>
  other cases append<1> = append<3> = <i>
  or append<2> = append<3> = <i>

  are subsumed in [case i].
therefore, append<1,2,3> = <i/o,i/o,i> or <i,i,i/o> and the analysis is done.

**Example 3.1.2 "matrix multiplication":**

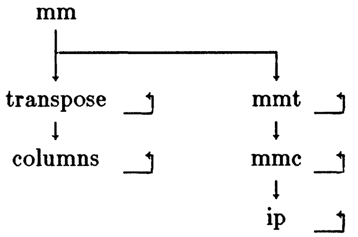
The following matrix multiplication program example is taken from Conery's thesis [5] (pp.122-123 and p.80):

C1: mm(a, b, c) ← transpose(b, bt), mmt(a, bt, c)
C2: mmt([], _ , [])
C3: mmt([a1|an], b, [c1|cn]) ← mmc(a1, b, c1),
                                mmt(an, b, cn)
C4: mmc (_ , [], [])
C5: mmc(a, [b1|bn], [c1|cn]) ← ip(a, b1, c1),
                                mmc(a, bn, cn)

```
C6:   ip([], [], 0)
C7:   ip([a1|an], [b1|bn], c) ← ip(an, bn, x),
                                 c is x + a1 * b1
C8:   transpose([[]|_], [])
C9:   transpose(m, [c1|cn]) ← columns(m, c1, rest),
                                 transpose(rest, cn)
C10:  columns([], [], [])
C11:  columns([[c11|c1n]|c], [c11|x], [c1n|y])
           ← columns(c, x, y).
```

**Analysis**:

the calling sequence is:



we may start from either "ip" or "columns", say "ip":
ip (C6 & C7):
Apply Rule 1 to the last atom of C7,
x, a1 and b1 are *input variables.*
Apply Rule 2, x in "ip" in C7 is *output.*
Apply Rule 6, since
a1 and b1 in $C7^{+}$ are *input variables*, so
an and bn in $C7^{-}$ are *input variables*,
ip<1,2,3> = <i,i,o>
Similarly, we obtain the following step by step:
mmc (C4 & C5): since ip<1,2> = <i,i>,
mmc<1,2,3> = <i,i,i/o>

mmt (C2 & C3): since mmc<1,2> = <i,i>,

mmt<1,2,3> = <i,i,i/o>

columns (C10 & C11):
columns<1,2,3> = <i,i/o,i/o> or <i/o,i,i>

transpose (C8 & C9):
transpose<1,2> =<i,i/o>

mm (C1):
mm<1,2,3> = <i,i,i/o>
and the analysis is done.

The above analysis shows that if "mm" is the top level goal, the first two positions must be input, and the third can be either input (verify if c is the product of a and b) or output (obtain c as the product of a and b). Also, since variable "bt" is an output from "transpose" and an input to "mmc," we know the producer-consumer pair must be <transpose, mmc>. This cannot be inferred by Conery's ordering algorithm. In fact his algorithm will obtain a wrong ordering in this example (see p.122 in [5]).

By performing the input-output analysis we can actually obtain all possible usages allowed in the program. For example, if the "transpose" in Example 3.1.2 is a top level goal, the second position of "transpose" need not be an output as in the case when "mm" is the top level goal. In this case, "transpose" can also be an input such that "transpose(b, bt)" means *verify if* bt *is the transposition of* b. This usage is allowed by the logic of the program.

Although it is difficult to prove that this algorithm guarantees to find all terms which must be input, it is clear that if an input term is erroneously taken as output, the penalty is only a reduced parallelism. The algorithm is very precise when applied to many example programs nevertheless.

### 3.2 Determination of data dependencies

The second phase of parallelism detection is the determination of data dependencies. Since all data dependencies are defined over input and output, once the input-output analysis is done, the detection of data dependencies becomes easy. Even the run-time dependency may be "guessed" at the compile time, although there are certain limitations.

Detection of functional dependency and internal dependency is trivial when the input-output modes are known, because both dependencies can be readily identified by their definitions based on these modes. If the mode of a term is "mixed," then both possibilities of input and output should be considered.

In the case of coupling dependency, a recursive check of subgoal invoking is required to find the "source" of coupling effect. This can be done by adding one procedure to the input-output mode analysis Algorithm 1: mark <c> on each coupled term found by the coupling rule; also mark <c> on each term related to known coupled terms found by the variable consistency rule and the position consistency rule.

In the case of run-time dependency, if there are only a few possible combinations of modes for the top level goal, then the compiler can figure several possible run-time dependencies which can be verified easily at run time. Below, we list some criteria useful in detecting the run-time dependency at compile time. By a *potential output term* is meant a term that is either an output term or a mixed term. The criteria are:

(i). When there are none or one potential output term in a goal, no run-time dependency can exist.

(ii). If there are two potential output terms, two possibilities exist -- one is that they are coupled at run-time and the other is that they are not. Both cases can be analyzed at compile time each leading to one possible ordering selected at run-time.

Since the number of possible mode combinations grows exponentially with the number of potential output terms **r**, this approach is not justified when **r** is large. However, most real world programs seem to have only a few potential output terms in the goal clause, and the compile time analysis is usually sufficient.

### 3.3 Subgoal ordering techniques

In the case of functional dependency, partial ordering is obtained at the time the producer-consumer dependency is detected. But in case of output dependencies, there is flexibility in determining the ordering, and which ordering leads to the highest efficiency is yet to be determined. Therefore we need some supplemental criteria, namely *groundability* and *subtree complexity*, for this purpose.

Consider an output shared variable X in a clause C as shown below:

$$p(X) \leftarrow q_1(X), q_2(X), ..., q_r(X)$$

Because of the output dependency due to X, only one atom can be selected from $q_1(X)$ through $q_r(X)$ for processing. Assume $q_i(X)$, with the substitution $\theta_i = \{X/t\}$, is the one selected.

If $\theta_i$ is a ground substitution, variable X in other $q_j$'s $(1 \leq j \leq r,\ j \neq i)$ is changed from output to input after $q_j$ is executed, and the data dependencies due to X between these $q_j$'s are removed. As a result, $q_j$'s can then be processed in parallel. Conversely, if $\theta_i$ is a non-ground substitution, the remaining $q_i$'s are still data dependent and they cannot be processed in parallel. Therefore, the key to the "efficiency" is to find a $q_i$ such that it has a ground substitution. If no such $q_i$ exists, a $q_i$ with $\theta_i$ that has more ground substitution components should be selected prior to another $q_j$ which has fewer such components. The measure of how close a substitution is to the ground substitution is informally called ***groundability***.

Consider the following clause as an example:

$$grandparent(X,Y) \leftarrow parent(X,Z), parent(Z,Y)$$

with a goal ← grandparent(X,peter). A left-to-right ordering will find all parent-child pairs first, then test for parent(Z,peter) for validity, rather than trying to find the parent of parent of Peter. Obviously, the better ordering is to do parent(Z,peter) first, as implied by its better *groundability*.

In the case that more than one $q_i$ have the same groundability, the ordering of these $q_i$'s might still matter. Assume that both $q_1(x)$ and $q_2(x)$ have ground substitutions, $q_1$ returns the ***binding*** in $k_1$ steps, $q_2$ returns in $k_2$ steps and $k_1 >> k_2$ (i.e., $q_1$ has a much larger computation tree than $q_2$). If $q_1$ is selected first, we can start to process the remaining $q_i$'s in parallel after $k_1$ steps. Assuming that the longest time taken by these $q_j$'s is $k_j$, then the total time is $(k_1 + k_j)$. If $q_2$ is selected first, the total time is then $\max(k_2 + k_j,\ k_2 + k_1)$. Suppose $k_j$ is in the same order as $k_1$, then the time ratio between $q_1$-first computation to $q_2$-first computation is about 2 to 1. Therefore the second measure regarding *how soon can a given subgoal return the answer*, called here ***subtree complexity***, will also be taken into account in our ordering algorithm. Here, *subtree* means the subtree of the AND/OR computation tree, and *complexity* means the inference steps required to solve a subgoal. While there is no easy way to obtain the exact computation complexity of a subtree prior to its execution, the complexity may be estimated for program clauses that have special patterns such as the following:

(a). Tail-recursion:

$$p([H|T], ...) \leftarrow q(H, ...), p(T, ..).$$

assume input list has a length n and q is some terminal node, then the complexity is $O(n)$ when the complexity of q is less than that of p.

(b). Head-tail recursion:

$$p([H|T], ...) \leftarrow p(H, ...), p(T, ..).$$

assume input list has a length n, then the complexity is $\Omega(\log n)$ and $O(n)$.

With the help of the groundability and the subtree complexity techniques, we can obtain an efficient partial ordering of subgoals in the case of output dependency. The subgoal ordering of the whole logic program can then be determined via these techniques as well as the result of phase 2. This is described below:

¶ **Ordering Algorithm**:

*Input* : A logic program.
*Output* : Partial ordering of the subgoals in each clause of the program.
*Method* :

1. Perform input-output mode analysis algorithm for the program.
2. Find functional, internal and coupling dependencies. The partial ordering of subgoals in functional dependency case is determined by producer-consumer order.
3. For other types of dependencies, determine the groundability for each atom. Let $sg_i$ and $sn_i$ be the number of ground and non-ground output variables in atom $q_i$, then:

(a). for those $q_i$ whose $sn_i = 0$, assume there are k1 such $q_i$'s, assign priority number 1 through k1 to them in an order from larger $sg_i$ to smaller $sg_i$, then

(b). for those $q_i$ whose $sn_i = 1$, or $sn_i = 2$ with these two terms coupled, assume there are k2 such $q_i$'s, assign priority (k1+1) through (k1+k2) to them, then

(c). for those $q_i$ whose $sn_i = 2$, assume there are k3 such $q_i$'s, k3 is small (say 1), assign priority (k1+k2+1) through (k1+k2+k3) to them for two cases: two variables never coupled -- ordering $\mathbf{O}_a$, and when coupled at run-time -- ordering $\mathbf{O}_b$, then

(d). for the rest of $q_i$'s, assume there are k4 such $q_i$'s, we only assume a no run-time coupling case as default case, assign priority (k1+k2+k3+1) through (k1+k2+k3+k4) to them.

4. If the same priority numbers result in the above step, perform subtree complexity algorithm-- less complexity receives less priority number (or higher priority).
5. Remove all but the highest priority groundable output variables from atom in step 3. This means if a variable can be instantiated by some atom, the variable becomes input after the execution of that atom and will not count toward dependency). Put all removed atoms as well as atoms that have input terms only into a set called "last set" which is the last to be processed.
   The compile time partial ordering is done.
6. If in step 3, k3≠0, say k3=1, assume x and y are two output variables, we attach a run-time test statement as below:

   (if (x couples y) then ordering $\mathbf{O}_b$
   else orering $\mathbf{O}_a$)
7. If in step 3, k4≠0, assume $x_1$, ..., $x_r$ are involved output variables, then we have:

   (if no coupling among [$x_1$, ..., $x_r$]
   then take the default ordering
   else complete the ordering at run-time)

<End of algorithm>

### 3.4 Performance analysis by example

Consider a logic program that has one non-unit clause:

candidate(X) ← degree(X), engrg(X), exp(X,5),
salary(X,50)

and many unit clauses serve as a database which includes 100 items of "degree(X)," 50 items of "engrg(X)," 10 items of "exp(X,5)" and 25 items of "salary(X,50)," as shown below:

| | | | |
|---|---|---|---|
| degree(John) | engrg(Bob) | exp(John,5) | salary(John,50) |
| degree(Bob) | engrg(Mary) | exp(Mary,3) | salary(Mary,35) |
| . | . | . | . |
| . | . | . | . |
| . | . | . | . |
| degree(Peter) | engrg(Peter) | exp(Peter,5) | salary(Peter,50) |
| <..100 items> | <..50 items> | <..10 items> | <..25items> |

Assume the goal clause is ← candidate(X). Now we employ the ordering technique:

1. X is an output variable, all four subgoals have internal dependency with each other.
2. There is no functional dependency.
3. All four subgoals have $sn_i = 0$, $sg_i = 1$.
4. Subgoals exp(X,5), salary(X,50), engrg(X), degree(X) have priority 1, 2, 3 and 4 respectively.
5. Subgoals salary(X,50), engrg(X) and degree(X) are put into the "last set."
6. Set {exp(X,5)} forms the first set, and the rest form the second set.

According to the ordering, the subgoal exp(X,5) will be selected first. Ten items are retrieved from the data base and are fed into the other three subgoals as their input binding sets. These three subgoals can be started as soon as the first answer from exp(X,5) is available. Assume that there is only one name, "Peter," that matches the goal, although "Bob" matches both "degree(X)" and "engrg(X)." For simplicity, assume all unifications take a time step, the above scheme takes 12 parallel unification steps using up to 100 processing units in this particular case. If we use NSV scheme with arbitrary ordering -- starting from "degree(X)" say, it may take 102 parallel unification steps using the same amount of processing units, much worse than the scheme proposed in this paper.

## 4. Conclusions

We had analyzed the AND-parallelism in logic programming by means of input-output and data dependencies, and we had also devised the automatic input-output mode detection technique which is then used to derive high efficiency subgoal ordering. Because most of the detection works can be done at compilation time, the resulting parallel machine need not be very complicated. Each processing unit in the parallel machine needs to do only unification and simple housekeeping as the run-time tasks are already minimized before a program is executed. Based on this parallelism analysis, a simple and efficient VLSI architecture for parallel logic programming was proposed in [19].

**ABSTRACT**

Parallel depth-first searches are widely used to solve combinatorial optimization and decision problems in artificial intelligence and operations research. These problems are represented by OR-trees and AND/OR-trees. The performance of parallel depth-first searches may be difficult to predict due to the nondeterminism and anomalies of parallelism. In this paper we have derived the performance bounds of parallel depth-first searches with respect to optimization problems represented as OR-trees and have verified these bounds by simulations. These bounds provide the theoretical foundation to determine the number of processors to assure a near-linear speedup. The conditions to cope with parallel-to-parallel anomalies are also investigated. For decision problems represented by AND/OR-trees, such as evaluating logic programs, we have studied an ordered depth-first search that rearranges nodes in each level of the AND/OR tree to minimize the expected search cost.

## 1. INTRODUCTION

Combinatorial-search problems can be classified into two types. The first type is decision problems that decide whether at least one solution exists and satisfies a given set of constraints [21]. Theorem-proving, expert systems, and evaluating a logic program belong to this class. The second type is combinatorial extremum-search or optimization problems that are characterized by an objective function to be minimized or maximized and a set of constraints to be satisfied. Practical problems such as finding the shortest path, planning, finding the shortest tour of a traveling salesman, job-shop scheduling, packing a knapsack, vertex cover, and integer programming belong to this class.

The non-terminal nodes in a search tree (or graph) can be classified as AND-nodes and OR-nodes. An *AND-node* represents a problem (or subproblem) that is solved only if all its descendant nodes have been solved, while an *OR-node* represents a problem (or subproblem) that is solved only if any of its immediate descendants is solved. Based on these two kinds of nodes, a combinatorial search can be classified into an AND tree, OR-tree, and AND/OR-tree search [25]. Note that a general dataflow graph contains AND-nodes and OR-nodes that relate the descendant nodes, as well as other nodes that relate the ascendant nodes.

In this paper we will concentrate on evaluating problems that arise in nondeterministic computations, namely, those problems that are represented as OR-trees or AND/OR-trees. As an AND-tree represents deterministic computations and all nodes in it must be evaluated, it will not be discussed here [14]. Due to space limitation, we will only present results on the depth-first search strategy. Results on other strategies with respect to OR-trees can be found elsewhere [15, 16].

An OR-tree is a state-space tree in which all non-terminal nodes are OR-nodes, while an AND/OR-tree is a problem-reduction representation that consists of AND-nodes and OR-nodes. Many AND/OR-tree search procedures, such as AO$^*$, SSS$^*$, and dynamic programming, can be formulated as a general branch-and-bound (B&B) procedure [8, 19], which is a well-known OR-tree search method. Likewise, evaluating a logic program can be represented as an OR-tree or AND/OR-tree search [7].

Both combinatorial OR-tree and AND/OR-tree search procedures can be characterized by four constituents: a branching rule, a selection rule, an elimination rule, and a termination condition. The first two rules are used to decompose problems into simpler subproblems and to appropriately order the search. The last two rules are used to to eliminate unnecessary subproblems. Appropriately ordering the search and restricting the region searched are key ideas behind any search algorithms.

The rules to guide the search and to prune unnecessary searches may differ for optimization and decision problems. In optimization problems, a lower bound of the objective value for each nonterminal node can be used to guide the search and to prune nodes that cannot lead to a better solution. Dominance tests, such as $\alpha-\beta$ pruning, can also be adopted as elimination rules. In decision problems, it was found that the ratio of the success probability of a subproblem to the estimated overhead of evaluating the subproblem is useful to guide the search [21, 1, 12]. The elimination rules are more restricted in decision problems, such as evaluating a logic program. Pruning a subproblem with a smaller success probability or a larger search cost may remove a possible (and possibly a unique) solution. In this case only when a terminal node is found to be true or false, AND-pruning or OR-pruning rules can be applied [12].

There are three basic selection strategies, namely, depth-first, breadth-first, and best-first searches. A generalized heuristic function can be used to unify these three kinds of search strategies and resolve ambiguities in the heuristic function [4, 10]. To resolve the ambiguity on the selection of subproblems, distinct heuristic values must be defined for the nodes to allow ties to be broken. A path number can be used to define an unambiguous heuristic function. The *path number* of a node in a tree is a sequence of (h+1) integers representing the path from the root to this node, where h is the maximum number of levels of the tree [10, 15]. For example, the path numbers of nodes A, B, C, and D in Figure 1c are 0000, 0100, 0200, and 0300, respectively. Note that the nodes having equal path numbers never coexist simultaneously in the search process. For a depth-first search, the generalized heuristic function is defined as

$$h(P_i) = (\text{path number, level number}) \qquad (1)$$

Although a best-first search expands fewer nodes than a depth-first search, it requires a secondary memory to maintain the large number of active nodes, hence the total time, including the time spent on data transfers between the main and secondary memories, to solve a problem may be longer than that required by the depth-first search. Simulations have shown that the best OR-tree search strategy depends on the accuracy of the problem-dependent lower-bound function [24]. Very inaccurate lower bounds are not useful to guide the search, while very

This research was supported by National Science Foundation Grants DMC 85-19649.

International Conference on Parallel Processing, 1986.

accurate lower bounds will prune most unnecessary expansions. In both cases the number of subproblems expanded by depth-first and best-first searches will not differ greatly, and a depth-first search is better as it requires less memory space.

Extensive studies have been conducted on OR-parallelism [2, 12, 15, 18], but very few studies have been done on analyzing the speedups and efficiency of OR-parallelism. Due to the nondeterminism, combinatorial OR-tree and AND/OR-tree searches are quite different from conventional deterministic numerical computations. Simulation results have revealed that using more processors in parallel depth-first searches might degrade the performance, even when the communication overhead is ignored [10]. The prediction of performance and methods to cope with anomalous behavior are important problems to be studied in designing multiprocessors for parallel depth-first searches and will be addressed in this paper.

To take advantage of the search efficiency of best-first searches while avoiding their memory overhead, an informed depth-first search can be used [20]. In this strategy best-first search is performed locally and depth-first search globally. A special case is one in which all sibling nodes are ordered according to heuristic values of the siblings (a more accurate definition will be given in Section 3). We will show that this *ordered depth-first strategy* is very effective to evaluate logic programs represented as AND/OR trees.

## 2. PARALLEL DEPTH-FIRST OR-TREE SEARCHES

To predict the number of processors needed to assure a near-linear speedup in a parallel depth-first search, we will derive the bounds on computational efficiency. The results in this section indicate the relationship among the number of iterations required in a parallel depth-first search, the number of processors used, and the complexity of the problem to be solved.

### 2.1. Model of Efficiency Analysis

In analyzing the performance bounds, a synchronous model is assumed, that is, all processors must finish the current iteration before proceeding to the next iteration. This performance results form a lower bound to that of asynchronous models.

The parallel computational model used here consists of a set of processors connected to a shared memory. In each iteration, multiple subproblems are selected and decomposed. The newly generated subproblems are tested for feasibility, eliminated by (exact or approximate) lower-bound tests and dominance tests,* and inserted into the active list(s) if not eliminated. In this model eliminations are performed after branching instead of after selection as in Ibaraki's algorithm [5] to reduce the memory space required.

We have proved that, for best-first searches, the performance is not largely affected by whether the active subproblems are kept in a single shared list or multiple lists [23,15]. However, for depth-first searches, the performance will be problem-dependent when multiple lists are used. In this paper the performance bounds are derived under the assumption that one list is used and that the nodes with the smallest heuristic values are selected in each iteration.

Since subproblems are decomposed synchronously and the bulk of the overhead is on branching operations, the number of iterations, which is the number of times that subproblems are decomposed in each processor, is an adequate measure in both the serial and parallel models. The *speedup* between using $k_1$ and $k_2$, $k_2 > k_1$, processors is thus measured by the ratio of the number of iterations when $k_1$ processors are used to that when $k_2$ processors are used. Once the optimal solution is found, the time to drain the remaining subproblems from the list(s) is not accounted for, since this overhead is negligible as compared to that of branching operations.

The results proved in this section show the performance bounds of parallel depth-first OR-tree searches for solving optimization problems. The proofs of these theorems require the following definitions on essential nodes. A node expanded in a *serial* depth-first search is called an *essential node*, otherwise it is called a *non-essential node*. The speedup of a parallel depth-first search depends on the number of essential nodes selected in each iteration. An iteration is said to be *perfect* if the number of essential nodes selected is equal to the number of processors, otherwise it is said to be *imperfect*. The *incumbent* at any given time in the search process is the best feasible solution obtained at that time. The incumbent is continuously updated until an optimal solution is found. We denote $T_b(k,\epsilon)$ and $T_d(k,\epsilon)$ as the number of iterations required to find a single optimal (or suboptimal) solution using k, $k \geqslant 1$, processors in a best-first and depth-first search, respectively, where $\epsilon$ is an *allowance function* specifying the allowable deviation of a suboptimal value from the exact optimal value. When an approximate solution is sought, i.e. $\epsilon > 0$, during the search of an OR-tree, an active node $P_i$ is terminated if

$$g(P_i) \geqslant \frac{z}{1+\epsilon} \qquad \epsilon \geqslant 0,\ z \geqslant 0 \qquad (2)$$

where z is an incumbent obtained at that time.

### 2.2. Parallel Depth-First Searches

The following theorem shows that the performance of parallel depth-first searches depends on the problem complexity and the number of distinct incumbents found during the search process.

**Theorem 1**: For a parallel depth-first OR-tree search with k processors, $\epsilon$=0, and a generalized heuristic function of $h(P_i)$ =(path number, level number), then

$$\left( \frac{T_b'(1,0)-1}{k} + 1 \right) \leqslant T_d(k,0) \leqslant \left( \frac{T_d(1,0)}{k} + \frac{k-1}{k}[(c+1) \cdot h - c] \right) \qquad (3)$$

where h is the height of the OR-tree, c is the number of the distinct incumbents obtained during the serial depth-first search, and $T_b'(1,0)$ is the number of essential nodes in a serial best-first search with lower bounds *less than* the optimal-solution value.

*Proof*: The sequence of iterations obtained during a serial depth-first search can be divided into (c+1) subsequences according to the c distinct monotonically decreasing incumbents obtained. Let the c feasible solutions and their corresponding parents be denoted by $F_1, \ldots, F_c$, and $P_1, \ldots, P_c$. Further, assume that $F_1, \ldots, F_c$ are obtained in the $i_1$'th, ..., $i_c$'th iterations, respectively. Hence iterations from 1 to $i_1$ belong to the first subsequence, and iterations from $i_j+1$ to $i_{j+1}$ belong to the (j+1)'th subsequence.

We now consider the j'th $1 \leqslant j \leqslant c$, subsequence. Let $\ell_{min}(x)$ be the level with the minimum level number in which some active essential nodes, whose heuristic values are between $h(P_{j-1})$ and $h(P_j)$, reside in the x'th iteration. For levels less than $\ell_{min}(x)$, all active nodes, whose heuristic values are between $h(P_{j-1})$ and $h(P_j)$, are non-essential. We show that Iteration x is imperfect only if all essential nodes, whose heuristic values are between $h(P_{j-1})$ and $h(P_j)$, in $\ell_{min}(x)$ are selected for expansion. Suppose that Iteration x is imperfect, the selected non-essential node must have heuristic value larger than $h(P_j)$, because otherwise this node would have to be eliminated by the feasible solution $F_{j-1}$ ($F_0$ is the initial feasible solution obtained by a heuristic method). Thus after Iteration x is carried out, $\ell_{min}(x)$ must be increased by at least one. Consequently, after at most h imperfect iterations, $F_j$, must be found.

During the last subsequence of iterations, since the optimal solution has been generated, all iterations are imperfect only if less than k nodes are selected in each iteration. In other words, an imperfect iteration implies that all currently active nodes are selected and expanded, and only descendants of these nodes can be active in the next iteration. Hence no active node remains after at most h imperfect iterations in the last subsequence. The previous analysis shows that at most $(c+1) \cdot h$ imperfect

* Dominance tests will not be discussed in this paper due to space limitation.

iterations can appear in a parallel depth-first search. Since at least one node in each iteration in the parallel case belongs to $\Phi^1$, the set of nodes expanded in the serial depth-first search [10, 15], the upper bound of $T_d(k,0)$ can be derived as

$$T_d(k,0) \leqslant \left\lceil \frac{T_d(1,0)-(c+1)\cdot h}{k} + (c+1)\cdot h \right\rceil$$

In the above discussion, the expansion of the root is counted in each of the (c+1) subsequences. Since the root is only expanded once, the above upper bound should be compensated by the additional number of times that the root is expanded (Eq. (3)).

The lower bound on $T_d(k,0)$ can be proved easily because all essential nodes in a serial best-first search with lower bounds less than the optimal solution must be expanded in the parallel depth-first search. □

For problems such as integer programming and 0-1 knapsack problems, all feasible solutions are located in the bottommost level of the OR-tree. In this case the following corollary shows that all essential nodes of a serial depth-first search must be expanded in a parallel depth-first search, and a tighter lower bound is obtained.

**Corollary 1**: In searching an OR-tree using a parallel depth-first search and a heuristic function of (path number, level number), if $\epsilon = 0$ and all feasible solutions are in Level h, then

$$\left\lceil \frac{T_d(1,\epsilon) - 1}{k} + 1 \right\rceil \leqslant T_d(k,\epsilon) \tag{4}$$

where h is the maximum number of levels of the OR-tree.
*Proof*: The proof is omitted due to the space limitation [13, 10].

The bounds in Theorem 1 are tight in the sense that we can construct examples to achieve the lower- and upper-bound of computational times. These degenerate cases occur rarely. Although c, the number of distinct incumbents, is unknown until the solution is found, c is usually small and can be estimated when integral solutions are sought. It has been observed that c is less than 10 for vertex-cover problems with less than 100 vertices. For most integer programming problems, $c \approx 1$. In these cases the range on $T_d(k,0)$ is tight, and a near-linear speedup can be achieved in a large range of k.

Let w be $T_d(1,0)/h$. w can be viewed as the "average width" of an OR-tree, which only consists of essential nodes. Eq. (3) can be rewritten as

$$\frac{T_d(1,0)}{T_d(k,0)} \geqslant \frac{k\cdot w}{w+(c+1)(k-1)} \tag{5}$$

From Eq. (5), it is easy to see that if w >> k and c is small, then the speedup is close to k; whereas if w << k, then the lower-bound speedup is close to w/(c+1).

In Table 1, the theoretical bounds derived above are compared with the simulation results of parallel depth-first searches to solve two 35-object knapsack problems. In generating the knapsack problems, w(i), the weights, were chosen randomly between 0 and 100 with a unform distribution, and the profits were set to be p(i) = (w(i) + 10). This assignment is intended to increase the complexity of the randomly generated problems. The results demonstrate that the bounds on parallel depth-first searches are tight, hence its performance can be predicted quite accurately. Table 1 also shows that the speedup depends strongly on w. In Case 1 $w \approx 2023$, and a near-linear speedup of 0.88k is achieved with 256 processors. In Case 2 $w \approx 188$, and a speedup of 0.29k is obtained with 256 processors. Note that when the number of processors is large, the number of essential nodes in each imperfect iteration of the parallel depth-first search is usually larger than one. In contrast to the upper bound in Eq. (3), which was derived with the assumption of one essential node in each imperfect iteration, $T_d(k,0)$ may be much smaller than the upper bound. Simulations have also revealed that for a number of OR-tree search problems, $T_d(k,0)$ may be very close to $T_b(k,0)$.

Table 1. Comparisons between theoretical bounds and simulation results on parallel depth-first searches for knapsack problems with 35 objects. ($T_b'(1,0)=T_b(1,0)$. During depth-first searches, c=22 in Case 1 and c=12 in Case 2.)

Analogous to the proof of Theorem 1, the upper bound on $T_d(k,\epsilon)$, $\epsilon > 0$, can be derived. To find the lower bound on $T_d(k,\epsilon)$, let $f_o$ be the optimal-solution value and $MINT_b(\epsilon)$ be the minimum number of nodes to be expanded in the approximate best-first search. $MINT_b(\epsilon)$ represents the number of nodes whose lower bounds are less than $f_o/(1+\epsilon)$, since these nodes must be expanded in the best case. $MINT_b(\epsilon)$ may be estimated from the distribution on the number of subproblems with respect to lower bounds. From the above analysis, we get

$$\left\lceil \frac{MINT_b(\epsilon)-1}{k}+1 \right\rceil \leqslant T_d(k,\epsilon) \leqslant \left\lceil \frac{T_d(1,\epsilon)}{k}+\frac{k-1}{k}[(c+1)\cdot h-c] \right\rceil \tag{6}$$

### 2.3. Coping With General Parallel-to-Parallel Anomalies

Some results on coping with serial-to-parallel anomalies have been published elsewhere [10, 11, 15]. We now present results on coping with parallel-to-parallel anomalies of depth-first OR-tree searches based on the performance bounds derived in the last section. When comparing the efficiency between using $k_1$ and $k_2$ processors, $1 \leqslant k_1 < k_2$, a $k_2/k_1$-fold speedup (ratio of the number of iterations in the two cases in our model) is expected. However, simulations have shown that the speedup can be (a) less than one (called a *detrimental anomaly*) [6, 17, 9]; or (b) greater than $k_2/k_1$ (called an *acceleration anomaly*) [6, 9]; or (c) between one and $k_2/k_1$ (called a *deceleration anomaly*) [6, 22, 17, 9]. So far, all known results on parallel OR-tree searches showed a near-linear speedup for only a small number of processors.

Anomalies are studied with respect to the assumption that all idle processors are used to expand active subproblems. In fact, detrimental anomalies cannot happen if some processors can be kept idle in the presence of active subproblems. The number of processors to be kept idle is problem dependent and is very difficult to find without first solving the problem.

Some anomalies on parallel depth-first OR-tree searches are illustrated here. A single list of subproblems is assumed. The behavior of using multiple lists is analogous to that of a centralized list. An example of an acceleration anomaly with an approximate depth-first or best-first search is shown in Figure 1a. When three processors are used, the optimal solution is found in the second iteration, and $P_4$ and $P_5$ are eliminated. If two processors are used, subtrees $T_4$ and $T_5$ have to be expanded. $T(2,0.1)/T(3,0.1)$ will be much larger than 3/2 if $T_4$ and $T_5$ are very large. Figure 1b illustrates a detrimental anomaly under an approximate best-first or depth-first search with $\epsilon=0.1$. When two processors are used, $f(P_8)$, the optimal solution, is found in the fourth iteration. Assuming that the lower bounds of nodes in $T_3$ are between 8.2 and 9, all nodes in $T_3$ will be eliminated by lower-bound tests with $P_8$ since $[9/(1+\epsilon)]<8.2$. When three processors are used, $P_3$ is expanded in the third iteration. $P_5$, $P_6$, and $P_7$ are generated and will be selected in the next iteration. If $T_3$ is large, $T(2,\epsilon) < T(3,\epsilon)$ will occur. A detrimental anomaly may occur even when lower-bound tests are inactive and is illustrated in Figure 1c. A similar example can be derived for acceleration anomalies.

In the last section, we have derived the performance bounds with respect to depth-first OR-tree searches. From these results, we can develop the relative efficiency between using $k_1$ and $k_2$, $1<k_1<k_2$, processors. First, we derive a sufficient condition to assure the monotonic increase in computational efficiency with respect to the number of processors. To simplify the sufficient condition, the following bounds on $T_d(k,0)$ are used.

$$\frac{T_b'(1,0)}{k} \leqslant T_d(k,0) \leqslant \left\lceil \frac{T_d(1,0)}{k} + (c+1)\cdot h \right\rceil .$$

**Corollary 2:**** Let $r_d' = T_b'(1,0)/T_d(1,0) \leqslant 1$. In a parallel depth-first search that satisfies the assumptions of Theorem 1, $T_d(k_2,0) \leqslant T_d(k_1,0)$ when

$$\frac{T_d(1,0)}{h} \geqslant \frac{(c+1)k_1k_2}{r_d'k_2 - k_1} \quad \text{and} \quad r_d' > \frac{k_1}{k_2}, \quad 1<k_1<k_2 \qquad (7)$$

where c is the number of the distinct incumbents obtained during the serial depth-first search.

From Corollary 2, we can conclude that the existence of parallel-to-parallel detrimental anomalies in depth-first searches depends on $T_b'(1,0)$, $r_d'$, and c. If $r_d' \approx 1$, c is small, and $T_b'(1,0)$ is very large, then Eq. (7) will be satisfied. Our simulation results reveal that for some problems, such as the 0-1 knapsack and vertex-cover problems, $T_d(1,0)$ is close to $T_b'(1,0)$, hence $r_d' \approx 1$. Moreover, if the feasible-solution values must be integers, then c is often small. For this kind of problems, detrimental anomalies can be prevented for parallel depth-first searches when $T_b'(1,0)$ is large and $k_2$ is relatively small. However, the range of parallel processing within which no detrimental anomalies occur for depth-first searches is smaller than that for best-first searches [13].

From Theorem 1, we can also derive a necessary condition for acceleration anomalies with respect to $k_1$ and $k_2$ processors.

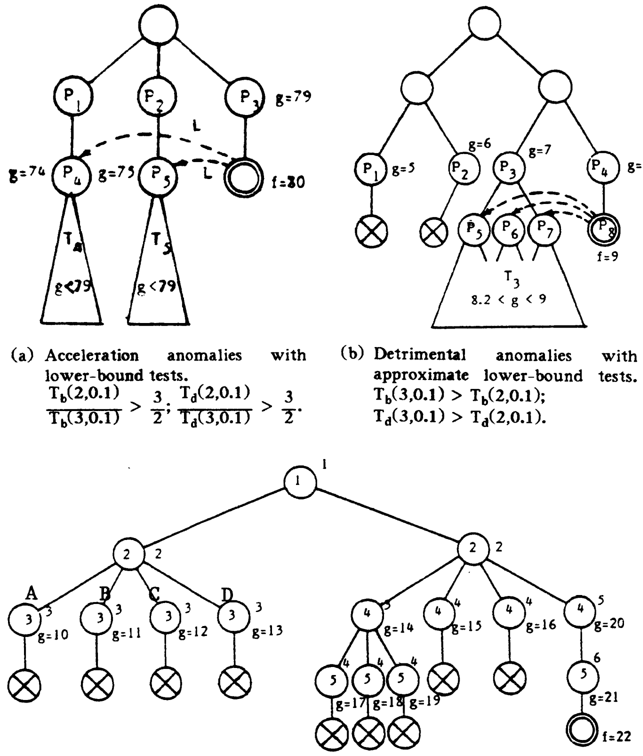
**Corollary 3:**** In a parallel depth-first search that satisfies the assumptions of Theorem 1, $T_d(k_1,0)/T_d(k_2,0) > k_2/k_1$ only if

$$\left\lceil T_d(1,0)-T_b'(1,0) \right\rceil > \left\lceil k_2-1-(k_1-1)[(c+1)\cdot h-c] \right\rceil \quad 1<k_1<k_2 \quad (8)$$

If all solutions are located at the bottommost level of the OR-tree, then the corresponding necessary condition is simplified by Corollary 1 as

$$\left\lceil (c+1)\cdot h - c \right\rceil > \frac{k_2-1}{k_1-1} \qquad 1<k_1<k_2. \qquad (9)$$

Obviously, the necessary condition in Eq. (8) is readily satisfied, and $T_d(k_1,0)/T_d(k_2,0)$ may be much greater than $k_2/k_1$.



(a) Acceleration anomalies with lower-bound tests. $\frac{T_b(2,0.1)}{T_b(3,0.1)} > \frac{3}{2}$; $\frac{T_d(2,0.1)}{T_d(3,0.1)} > \frac{3}{2}$.

(b) Detrimental anomalies with approximate lower-bound tests. $T_b(3,0.1) > T_b(2,0.1)$; $T_d(3,0.1) > T_d(2,0.1)$.

(c) Detrimental anomalies without lower-bound tests in a depth-first or best-first search, $T(4,0)=5$, $T(5,0)=6$.
(Number inside node is the evaluation order using four processors; number outside node is the evaluation order using five processors.)

Figure 1. Examples of anomalies.

Usually, if $k_1$ and $k_2$ are close to each other and h is large, then acceleration anomalies may occur quite often.

When a suboptimal solution is sought, the following corollary shows the required sufficient conditions.

**Corollary 4:**** In parallel depth-first searches that satisfy the assumptions of Theorem 1 with the exception that $\epsilon>0$, $T_d(k_2,\epsilon) \leqslant T_d(k_1,\epsilon)$ when

$$\frac{T_d(1,\epsilon)}{h} \geqslant \frac{(c+1)k_1k_2}{r_dk_2 - k_1} \quad \text{and} \quad r_d > \frac{k_1}{k_2}, \qquad 1<k_1<k_2 \quad (10)$$

where $r_d = \mathrm{MIN}T_b(\epsilon)/T_d(1,\epsilon)$. $T_d(k_1,\epsilon)/T_d(k_2,\epsilon) > k_2/k_1$ when

$$\left\lceil T_d(1,\epsilon)-\mathrm{MIN}T_b(\epsilon) \right\rceil > \left\lceil k_2-1-(c+1)(k_1-1)\cdot h \right\rceil \qquad (11)$$

If all feasible solutions are located at the bottommost level of the OR-tree, the necessary condition to allow acceleration anomalies is the same as that stated in Eq. (9). Further, a weaker sufficient condition to eliminate detrimental anomalies can be derived from Corollary 1.

$$\frac{T_d(1,\epsilon)}{h} > \frac{(c+1)k_1k_2}{k_2 - k_1} \qquad (12)$$

## 3. ORDERED DEPTH-FIRST SEARCH FOR EVALUATING LOGIC PROGRAMS

In our previous paper [12] we have developed an optimal search strategy to evaluate logic programs modeled as AND/OR-trees using the heuristic information p(x), the success probability of a subgoal (or clause) x, and c(x), the estimated overhead of evaluating the subgoal (or clause). The heuristic information to guide the search is defined as follows.

** The proof is omitted due to space limitation and can be found elsewhere [13, 16].

$$\Phi_a(x) = \frac{p(x)}{c(x)} \qquad \text{(x is descendant of an OR—node)} \tag{13}$$

$$\Phi_o(x) = \frac{1 - p(x)}{c(x)} \qquad \text{(x is descendant of an AND—node)} \tag{14}$$

The logic program is first transformed from the AND/OR-tree representation into a two-level AND/OR-tree. The root of the transformed tree is an OR-node and represents the selection of clauses, and its descendants are AND-nodes and represent different solution trees in the logic program. The descendents of the OR-node are ordered according to decreasing values of $\Phi_o$, and the descendants of the AND-nodes are ordered according to decreasing values of $\Phi_a$.

Although the above strategy minimizes the expected search time, there are two implementation problems. First, the transformed AND/OR-tree significantly expands the number of nodes in the original AND/OR-tree. In fact, the number of potential solution trees is a hyper-exponential function of the height of the tree. To apply the above search strategy on the original AND/OR-tree, a global list is required to maintain the order of all possible solution trees, and the storage overhead is prohibitively large [12]. Second, if two solution trees $T_1$ and $T_2$ have nearly equal $\Phi_a$ or $\Phi_o$, then exchanging the search order of $T_1$ and $T_2$ may not significantly improve the expected search overhead. As an example, suppose that the success probabilities and the estimated overheads of all solution trees rooted at a nonterminal node are uniformly distributed between 0.01 and 0.99 and 1 and 10 units of cost, respectively, and that there are a million possible solution trees from this node. Suppose further that two solution trees can be viewed as having nearly equal $\Phi_a$ or $\Phi_o$ if their difference is less than 0.001. Then, approximately, every thousand solution trees have nearly equal $\Phi_a$ or $\Phi_o$. Obviously, it is unnecessary to store the exact order of all solution trees.

In this section we will address two problems. First, given an ordered depth-first search strategy and assuming that all sibling nodes in the AND/OR-tree are independent, what is the order to search the nodes in each level of the AND/OR-tree to minimize the expected search time? Second, for a logic program with shared variables and clauses, how should the subgoals and clauses be ordered to minimize the average search cost of a depth-first search?

### 3.1 Assumptions

In a logic program, if there are n clauses whose heads match (sub-)goal A, then they can be ordered according to the given heuristic values. Likewise, if there are m subgoals in the body of a clause B, $B :- B_1, ..., B_m$, then the m subgoals can also be ordered.

The assumptions made in the search strategy are described here.

(1) For a given representation of the AND/OR-tree, a depth-first search is used. When nodes in each level are ordered according to the heuristic values, the search is called an *ordered depth-first search.*

(2) A *producer-consumer* model is used to bind values to variables. A variable is a producer if it has not been bound to any value, otherwise, it is a consumer. For each variable not defined in the head, only its leftmost occurence can be the producer, as a depth-first search is used. All other occurences of this variable in this clause are consumers. For example, in the clause A(x,y):-B(x,z)C(z,y)D(x,y), variable z in subgoal B must be a producer, while variable z in subgoal C is a consumer. Depending on whether a variable defined in the head is a producer or a consumer, the variable in the corresponding subgoal will be a producer or a consumer. For example, if x is a producer in A, then x in B is a producer, while x in D is a consumer. We use a subscript '+' to indicate that the mode of a variable is a producer and a '—' to indicate that its mode is a consumer. As an example, $A(x_+,y_-) :- B(x_+,z_+)C(z_-,y_-)D(x_-,y_-)$. When a variable in a subgoal is a consumer, it is necessary to verify in this subgoal whether the subgoal is TRUE or FALSE for such a binding of value. In contrast, when a variable in a subgoal is a producer, it is necessary to find a binding of value to the variable such that this subgoal is TRUE.

(3) The probability of a subgoal to return TRUE and the average minimum overhead to determine whether a subgoal is TRUE or FALSE are independent of the bound values.

(4) The overhead to test whether a subgoal in a clause is TRUE or FALSE for a given binding of values to variables or to generate a binding of values to variables is assumed to be independent of other subgoals in this clause, provided that the modes of its variables are unchanged. Likewise, the overhead to verify the head of a clause is independent of other clauses with the same head when the modes of its variables are unchanged. These assumptions are valid when results in one subgoal or clause are passed to other subgoals or clauses through the binding of values to variables.

(5) The probability that a subgoal in a clause is TRUE for a given binding of values to variables is assumed to be independent of other subgoals in this clause. Similarly, the probability that the head of a clause is TRUE is independent of other clauses with the same head. These assumptions are not valid in general logic programs because subgoals have shared clauses and variables, but are made here to simplify the model.

### 3.2. Optimal Ordering of Depth-First Searches in AND/OR-Trees

In this section we discuss a special case in the optimal ordering of depth-first searches for AND/OR-trees, assuming that the success probabilities and expected overheads of all nodes are independent of each other, and that a node, once evaluated, will not be evaluated again. This special case exists in a logic program when it does not have any logic variables and shared clauses. For each node in the AND/OR-tree, suppose that it has n descendent nodes, then there are n! possible evaluation orders for a depth-first search. Our objective is to select the optimal order of descendents for each node in the AND/OR-tree such that the average overhead to verify the root to be TRUE or FALSE is minimized.

Various heuristic functions can be used to arrange the order of descendent nodes. Examples include the success probability, the lower bound on cost, and the number of immediate descendents. The following theorem shows that $\Phi_a$ and $\Phi_o$ (for AND-nodes and OR-nodes, respectively) are the heuristic functions to order the search such that the expected search cost is minimized.

**Lemma 1**: Suppose that node K is an OR-node (resp. AND-node) with n (resp. m) immediate descendent AND-nodes (resp. OR-node) ordered as $K_1, ..., K_n$ (resp. $K_1, ..., K_m$), and $K_i$ is searched before $K_{i+1}$ in a depth-first search. Let $p_i$ and $c_i$ be the success probability and search cost of node $K_i$, and $q_i=(1-p_i)$. If all $p_i$s and $c_i$s are independent of each other and $p_i/c_i < p_{i+1}/c_{i+1}$ (resp. $q_i/c_i < q_{i+1}/c_{i+1}$), $1 \leqslant i \leqslant n$ , then the expected search cost can be reduced when $K_{i+1}$ is searched before $K_i$.

*Proof*: Let C and C' be the expected costs of searching the descendents of node K in the order $K_1, ..., K_n$ and that in the order with $K_i$ and $K_{i+1}$ interchanged. Assume that node K is an AND node. Then

$$C = \sum_{k=1}^{n} \left( \prod_{j=1}^{k-1} q_j \right) \cdot c_k \qquad \text{and} \tag{15}$$

$$C' = \sum_{k=1}^{i-1} \left( \prod_{j=1}^{k-1} q_j \right) \cdot c_k + \left( \prod_{j=1}^{i-1} q_j \right) \cdot (c_{i+1} + q_{i+1}c_i) + \sum_{k=i+1}^{n} \left( \prod_{j=1}^{k-1} q_j \right) \cdot c_k \tag{16}$$

Subtracting Eq. (15) from (16) yields

$$C' - C = \left( \prod_{k=1}^{i-1} q_k \right) \cdot (p_i c_{i+1} - p_{i+1} c_i) > 0$$

The proof when node K is an OR-node is analogous. □

Some special cases of this ordering strategy have been observed by Simon and others [21, 3, 1].

**Theorem 2**: Assume that a depth-first search is used to search an AND/OR-tree, that the probabilities of success and search costs of all sibling nodes are independent of each other, and that a node, once evaluated, will not be evaluated again. The ordered sequence in which all OR-nodes, $x_i$s, are ordered by decreasing $p(x_i)/c(x_i)$ and all AND-nodes, $y_i$s, are ordered by decreasing $q(y_i)/c(y_i)$ will minimize the expected search cost over all possible ordered sequences, where $p(x)$, $q(x)$, and $c(x)$ are the success and failure probabilities and average search cost for node x.

*Proof*: Without loss of the generality, assume that the root (in Level 0) is an OR-node and that each OR-node (resp. AND-node) has n (resp. m) immediate descendent AND-nodes (resp. OR-nodes). For the n AND-nodes (resp. m OR-nodes), there are n! (resp. m!) possible oredered sequences, $s_1, \ldots, s_{n!}$ (resp. $s_1, \ldots, s_{m!}$). Let $c^i_{j,AND}$ (resp. $c^i_{j,OR}$) be the minimum expected cost of the j'th AND-node (resp. OR-node) in sequence $s_i$ over all possible ordered sequences of descendents of this node. Let $c_{r,OR}$ be the minimum expected cost of a depth-first search of the root over all possible ordered depth-first searches of the given AND/OR-tree. Since the expected search cost of a node is the cost of searching the subtree rooted at this node to return TRUE or FALSE, it is independent of the search order of other sibling nodes. Hence, if all nodes in the k'th level have been ordered optimally, then this optimal order remains unchanged when determining the optimal order in levels smaller than k. That is, the principle of optimality is satisfied. The minimum expected cost of the root r can be found from a dynamic programming formulation.

$$c_{r,OR} = \min_{s_i \in \{s_1,\ldots,s_{n!}\}} \left[ \sum_{j=1}^{n} \left( \prod_{k=1}^{j-1} q^i_k \right) \cdot c^i_{j,AND} \right] \quad \text{where} \tag{17}$$

$$c^i_{j,AND} = \min_{s_u \in \{s_1,\ldots,s_{m!}\}} \left[ \sum_{v=1}^{m} \left( \prod_{w=1}^{v-1} p^u_w \right) c^u_{v,OR} \right] \tag{18}$$

where $p^i_k$ and $q^i_k$ are, respectively, the success and failure probabilities of the k'th node in the i'th ordered sequence $s_i$. $c^u_{v,OR}$ can be evaluated in a similar fashion as in Eq. (17). Eq's (17) and (18) can be solved by a bottom-up evaluation.

For any nonterminal OR-node (resp. AND-node), K, since all its immediate descendents $K_1, \ldots, K_n$ (resp. $K_1, \ldots, K_m$) are independent of each other, then from Lemma 1 and applying adjacent pairwise interchanges, the optimal search order should satisfy $p(K_i)/c(K_i) > p(K_{i+1})/c(K_{i+1})$ (resp. $q(K_i)/c(K_i) > q(K_{i+1})/c(K_{i+1})$). □

The above ordering strategy only holds when all nodes are independent. In general, a logic program has shared variables and shared clauses. Hence, the subgoals and clauses have dependent search costs and success probabilities. Moreover, a subgoal may be searched more than once because a given binding of values to variables may succeed with this subgoal but fail with other subgoals. In the next section, we will discuss a heuristic method to find an efficient search order.

### 3.3. Ordered Depth-First Search of Logic Programs

To find an appropriate order of depth-first search in a logic program, the main problem is to develop a function to compute the expected search cost and success probability of a clause or a subgoal, assuming that the costs and success probabilities of all its immediate descendents in the AND/OR-tree representation are known. The difficulty lies in the shared variables and clauses in different subgoals of a logic program. The search cost of a subgoal may depend on the modes of its variables and cannot be evaluated as in Eq. (15). For a subgoal with a producer variable, it is necessary to generate one (or all) binding of value for the given variable; whereas a subgoal with a consumer variable has to test whether the given binding is TRUE. The latter cost is usually larger than the former one. The cost functions are more complicated when there are multiple variables. Here, a subgoal can have a combination of producer and consumer variables.

Owing to the distinction between producers and consumers and that a clause may be used with their variables set in different modes, the success probabilities and costs must be defined for all combinations of modes of variables. For example, there are four success probabilities and four expected search costs for clause with head A(x,y), namely, $p_A(x_+,y_+)$, $p_A(x_+,y_-)$, $p_A(x_-,y_+)$, $p_A(x_-,y_-)$, $c_A(x_+,y_+)$, $c_A(x_+,y_-)$, $c_A(x_-,y_+)$, and $c_A(x_-,y_-)$, where a subscript '+' indicates that a variable is a producer, and '−' indicates that it is a consumer. Let **L** be the set of variables in a subgoal, and $\mathbf{L}_+$ and $\mathbf{L}_-$ be the subsets of producer and consumer variables. For a clause with head $A(\mathbf{L}_+,\mathbf{L}_-)$, all variables in $\mathbf{L}_-$ have been bound (called a ***binding-set***) before this clause is searched, whereas all variables in $\mathbf{L}_+$ must be bound after the subtree rooted at clause A has been searched.

In Figure 2 we have shown a Prolog program to query granddaughter(•,•). In Table 2 the average search costs for various modes of variables X and Y in granddaughter are shown. For different modes, the orders in which the depth-first search should be performed may be different. We have shown the order that minimizes the search cost for two of these combinations of modes. The structures for the other two combinations are different. The values in Table 2 illustrate that the difference in costs between the best and the worst orders can be a factor of one to seven.

For node A(**L**), $p_A(\mathbf{L}_+,\mathbf{L}_-)$ is defined as the probability to successfully generate a binding-set of $\mathbf{L}_+$ under the condition that the given binding-set of $\mathbf{L}_-$ is TRUE, namely,

$$p_A(\mathbf{L}_+,\mathbf{L}_-) = p_A(\mathbf{L}_-)\, p_A(\mathbf{L}_+ \mid \mathbf{L}_-) \tag{19}$$

| +,+ | 11.5 | 20.6 | 16.6 | 4.4 |

Table 2. Average Costs of evaluating granddaughter(X,Y) in Figure 2 for all combinations of bindings of variables and all possible solutions returned. (Each traversal of a subgoal or clause has unit cost. Each producer variable only produces one binding at a time.)

$p_A(L_-)$ is the probability that the binding-set of $L_-$ on A is true. $p_A(L_+ | L_-)$ is defined as n/(n+1), where n is expected number of binding-sets of $L_+$ in subgoal A for a given binding-set of $L_-$. In this case we are approximating the distribution on the number of distinct binding-sets of $L_+$ for a given binding-set of $L_-$ as a geometric distribution with parameter p. For such a geometric distribution, its expected value is p/(1−p), which implies that p=n/(n+1). In the special case when all variables in L are producers, then $p_A(L_+)$ = m/(m+1), where m is the total number of generated binding-sets.

For $A(L_+,L_-)$, its expected cost, $c_A(L_+,L_-)$, is defined as the expected cost of generating a successful binding of variables in $L_+$, given the binding of variables in $L_-$. If all variables in L are consumers, then $c_A(L_-)$ is the expected cost of testing whether a binding-set is TURE.

For clarity, we illustrate a heuristic method to compute the various costs. In this method all probabilities are assumed to be independent. For a clause A(x,y) :− B(x,z),C(z,y) with known costs and probabilities for subgoals B and C, the expected cost of A can be computed by modeling the test process as an absorbing Markov chain [26]. If *one solution is sought*, then the absorbing Markov chain in Figure 3a is used. The two sink nodes ($s_0$ and $s_1$) represent the states of success and failure. After a finite number of steps, the process must enter one of these absorbing states. To find the expected cost, we need to calculate the expected number of times that the process is in transient states $s_2$ and $s_3$. In this example P, the transition matrix, Q, one of its submatrices denoting the process in the transient states, and R, another submatrix denoting the transitions from the transient states to the absorbing states, are

$$P = \begin{vmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & q_2 & 0 & p_2 \\ p_3 & 0 & q_3 & 0 \end{vmatrix} = \begin{vmatrix} I & 0 \\ R & Q \end{vmatrix}; \; Q = \begin{vmatrix} 0 & p_2 \\ q_3 & 0 \end{vmatrix}; \; R = \begin{vmatrix} 0 & q_2 \\ p_3 & 0 \end{vmatrix} \qquad (20)$$

Let $n_j$ be the expected total number of times that the process is in state $s_j$, and $M_i[n_j]$ be the mean of $n_j$ when the chain is started in $s_i$. From the theory of absorbing Markov chains [26], $N = \{M_i[n_j]\} = (I - Q)^{-1}$. N is called the *fundamental matrix*. In our example

$$N = \begin{vmatrix} \frac{1}{1-p_2q_3} & \frac{p_2}{1-p_2q_3} \\ \frac{q_3}{1-p_2q_3} & \frac{1}{1-p_2q_3} \end{vmatrix} \qquad (21)$$

As a result, the expected cost is $(c_2+p_2c_3)/(1-p_2q_3)$, where $c_i$ is the cost associated with state $s_i$. If B is searched before C, then A has expected cost

$$c_A(x_+,y_+) = \frac{c_B(x_+,z_+) + p_B(x_+,z_+) \cdot c_C(z_-,y_+)}{1 - p_B(x_+,z_+) \cdot q_C(z_-,y_+)} \qquad (22)$$

If subgoal C is searched before B, then A has expected cost

$$c_A'(x_+,y_+) = \frac{c_C(z_+,y_+) + p_C(z_+,y_+) \cdot c_B(x_+,z_-)}{1 - p_C(z_+,y_+) \cdot q_B(x_+,z_-)} \qquad (23)$$

Comparing $c_A$ and $c_A'$, the order with the smaller cost is used. Expected costs of clause A with variables in other modes can be computed similarly.

When *all solutions* in a subgoal have to be found, the process can also be modeled as an absorbing Markov chain. Figure 3b shows the absorbing Markov chain for the above example.

To compute the success probability of a clause, if $b_{i,j}$ is the probability that the process starting in transient state $s_i$ ends up in absorbing state $s_j$, then from the theory of absorbing Markov chains, $\{b_{i,j}\} = B = N \times R$. In our example, $b_{2,0} = p_2p_3/(1-p_2q_3)$, and $b_{2,1} = q_2/(1-p_2q_3)$. If subgoal B is searched first, then the success probability of node A is

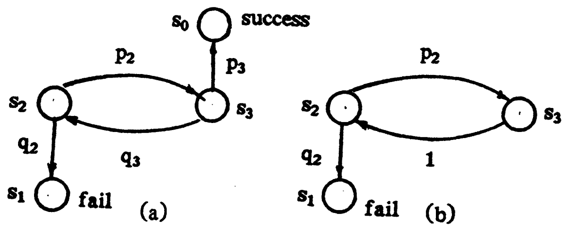

Figure 3. Example to compute the search cost and probability using an absorbing Markov chain.

$$p_A(x_+,y_+) = \frac{p_B(x_+,z_+)p_C(z_-,y_+)}{1 - p_B(x_+,z_+)q_C(z_-,y_+)} \qquad (24)$$

In general, if a subgoal has k variables, then $2^k$ combinations of probabilities and costs corresponding to all combinations of modes of the variables have to be found.

The above example illustrates the use of an absorbing Markov chain to order the search of descendents of an AND-node, which represents the evaluation of a clause. In contrast, to order the descendents of an OR-node, which represents the selection of multiple clauses with the same head, it is observed that once a descendent of an OR-node has been searched for a given binding-set, it will not be searched again. Unlike descendents of AND-nodes, there is no backtracking involved for a given binding-set. According to Theorem 2, descendents of an OR-node should, therefore, be searched in decreasing order of ratios of success probability to cost. The cost and probability of an OR-node can be computed in a similar fashion as in Eq. (15) when it has at least one consumer variable. When all its variables are producers, the average cost is taken as the average cost of each of its descendents weighted by the fraction of the total number of binding-sets that can be generated.

The basic idea in a systematic method to determinate an appropriate ordering of the subgoals and clauses is to associate with each subgoal and clause a table of the expected costs and probabilities for all combinations of modes of variables, and to use the appropriate costs and probabilities depending on the modes set for the variables. The best order with the minimum expected cost is chosen from all possible permutations of descendents. The number of permutations may be large. In this case heuristic information, such as the number of variables in a subgoal, can be used to eliminate inefficient candidate permutations. Note that the cost of each node in the AND/OR-tree representation depends only on the costs and probabilities of its descendents, provided that the descendents only depends on each other through shared variables. Here, the selection of the best order in a given level does not influence the computation of costs in levels above. That is, the computation of the minimum cost satisfies the principle of optimality, and the optimal order can be found by dynamic programming. In practice, subgoals are generally dependent on each other through shared clauses, which results in over-estimation of the costs. The proposed scheme is still applicable as a heuristic method to arrange the order in the search process. Statistic sampling has to be used to estimate the cost and probability of a node after the order of its descendents is determined. This reduces the accumulation of errors as nodes in higher levels of the AND/OR-tree are ordered.

A final point on the ordering of nodes in the AND/OR-tree representation of logic programs is that different orders may be found depending on the modes of the variables. Either an 'average' order may be used or multiple program statements may be generated for different cases to reflect the preferred order.

## 4. CONCLUSIONS

In this paper we have studied the computational efficiency of parallel and ordered depth-first searches to solve optimization and decision problems. The performance bounds and conditions to cope with anomalies in searching optimization problems represented as OR-trees have been derived and verified by simulations. Speedups have been found to be related to the problem complexity and the number of incumbents obtained during the search process. For a problem with a high complexity and a small number of incumbents, such as integer programming problems, a near-linear speedups can be achieved with respect to a large number of processors.

An ordered depth-first search strategy has been studied with respect to decision problems represented as AND/OR-trees. When the success probabilities and costs of sibling nodes are independent of each other, and a node, once searched, will not be searched again, the sibling nodes should be ordered according to ratios of probability and cost to minimize the expected total search cost. Due to shared clauses and variables in a Prolog program and that backtracking is allowed, it is difficult to find the optimal depth-first search order. An absorbing Markov chain to model the effects of backtracking and a dynamic programming method to order the search have been developed.

## ABSTRACT

Given an array of size $n$ with entries either marked or unmarked, we compute the number of marked entries and assign to each (marked entry) a unique index between one and the number of marked entries. If there are $k$ marked entries, then our algorithms require $O(\log k)$ time, which is independent of $n$, using $n$ processors and a CRCW model.

## 1. Introduction

As the study of parallel algorithms matures, it is important to develop efficient basic techniques that can be used as building blocks for more complex algorithms. One basic algorithm is to compute the size of a subset and pack it into an array. That is, given an array with entries either marked or unmarked, compute the number of marked entries and assign to each (marked entry) a unique index between one and the number of marked entries.

Assume that there are $k$ marked entries in an array of size $n$. We are given $n$ processors and a CRCW model of parallel computation. That is, each processor can read or write any cell in shared memory in a single cycle. If two or more processors try to write to the same cell during the same cycle, then one arbitrarily wins. Actually, our algorithms require a slightly weaker model in which two processors are allowed concurrent write of common values only.

Using a simple binary summation tree, it is easy to solve this problem in $O(\log n)$ time. On the other hand, using a simple locking mechanism, it is also easy to solve the problem in time $O(k)$; each processor is assigned a unique cell of the array and if the entry is a one, then the processor locks a counter variable. When the lock is granted, the processor just increments the counter by one and unlocks the variable.

We desire a solution whose running time is independent of $n$ and is logarithmic in $k$. Such a solution already exists, however, it uses randomness and assumes the stronger model of CRCW. Rudolph and Steiger [2] give a parallel algorithm that terminates in $O(\log k)$ time with high probability. Moreover, they use only $k$ processors. We present a deterministic solution to this problem with the same time bounds. Note that a trivial consequence of our result yields an algorithm for computing parity.

The outline of the paper is as follows. We first describe an algorithm for computing the the "prefix maxima" of an array. This is then used to develop an $O(\log\log n + \log k)$ time algorithm. For $k \geq \log n$ this algorithm gives the desired result. We then present a second algorithm for the case of $k < \log n$. Running the two algorithms in tandem gives the final result.

## 2. Prefix Maxima

Given an array $A[1..n]$ of numbers, we define prefix maxima, $MAX_i(A)$, to be a set of $n$ values, the i-th of which is the maximum of the first $i$ elements of $A$:

$$MAX_i(A) = \text{Maximum}\{A[1], ..., A[i]\} : 1 \leq i \leq n.$$

A simple sequential scan algorithm solves this problem in $O(n)$ steps; this section gives a parallel algorithm using $n$ processors and terminates within $O(\log\log n)$ parallel steps.

**Lemma 1:** The prefix maxima vector can be found in $O(1)$ parallel steps using $n(n^2-1)/6$ processors and a CRCW model of parallel computation.

**Proof:** Note that we can compute all $MAX_i(A)$ in parallel. For the i-th prefix of $A$ we do the following:

First, $i(i-1)/2$ processors perform all distinct comparisons between $A[x]$ and $A[y]$, $1 \leq x < y \leq i$, in one parallel step. Next, the same number of processors check, for each $j$, $1 \leq j \leq i$, whether $A[j] = \text{Maximum}\{A[1], ..., A[i]\}$ by parallel computation of an *AND* function. Writing the correct value of $MAX_i(A)$ requires one more step.

The above procedure can be performed in parallel for all $i$, $1 \leq i \leq n$, with $F(n)$ processors, where

$$F(n) = \sum_{i=1}^{n} i(i-1)/2 = n(n^2-1)/6 .$$

If, on the other hand, there are fewer than a cubic number of processors, but at least a linear number, i.e. $n \leq p \leq F(n)$, an adaptation of the max computation of Valiant [4] (and as implemented by Shiloach and Vishkin [3]) can be used. The following algorithm evaluates the array $M[1..n]$ for the input $A$ such that $M[i] = MAX_i(A)$:

0190-3918/86/0000/1000 $01.00 © 1986 IEEE

```
Procedure $PreMax(p, A, n, M)$
    Step 1: If $p \geq F(n)$ then use lemma 1 to compute $M[1..n]$ in one parallel step and return.
    Step 2: Divide the array $A[1..n]$ into minimal number $l$ of distinct segments $S_1, .. S_l$ which satisfy the following conditions [3]:
        $(i)$ $|S_i| - |S_j| \leq 1$ for $1 \leq i \leq j \leq l$
        $(ii)$ $\sum_{i=1}^{l} F(|S_i|) \leq p$
    Step 3: Let $b_i$, $e_i$, $n_i$, be the indices of the beginning, ending, and size of each segment $S_i$.
    Step 4: For each $i$ in $[1..l]$ do in parallel
            $PreMax(F(n_i), A[b_i .. e_i], n_i, M[b_i .. e_i])$
    Step 5: Let $A'[1 .. l]$ be the maximum value in each segment:
        For each $i$ in $[1..l]$ do in parallel:        $A'[i] = M[e_i]$
    Step 6: Apply the algorithm recursively on $A'$:
            $PreMax(p, A', l, M')$
    Step 7: Merge results from steps 4 and 6:
        For each $i$ in $[2..l]$ and $j$ in $[b_i .. e_i]$ do in parallel
            $M[j] := \text{Maximum}(M[j], M'[i-1])$
```

It is not hard to see that this algorithm terminates in $O(\log\log n)$ parallel time: Step 1 requires constant time as shown in lemma 1. Finding $l$ and then computing $b_i$ and $e_i$ for all $i$: $1 \leq i \leq l$ in steps 2 and 3 require $O(1)$, i.e. constant, parallel time. The recursive call in step 4 is terminated in constant time since there are enough processors for each segment to compute all the prefix maxima in constant parallel time as in step 1. The exact allocation of processors in step 4 may require some computational work, but it can be done by the first $l$ processors in constant time. Steps 5 and 7 again take constant parallel time.

Note that step 7 correctly evaluates $M[1..n]$: At the end of step 6, each $M[j]$ contains the maximal value of $A[b_j]..A[e_j]$. $M'[j-1]$ is the largest of $M[e_1]..M[e_{j-1}]$. Since these $M$ values are the maximal in their segment, then at the end of step 7, $M[j]$ is the biggest of $A[1..j]$.

The algorithm requires constant parallel time except for the recursive call in step 6 on the auxiliary array $A'$. We need to bound the number of recursions. The recursion terminates when the number of processors, $p$, is larger than the number of items cubed. Let $T(\alpha,n)$ denote the parallel time for running the algorithm on $n$ values using $\alpha n$ processors. From the definitions it is easy to check that

$$\sum_{j=1}^{l} F(|S_j|) \leq n^3/l^2 \text{ for all } l \leq n.$$

We can bound the value of $l \leq l_0$ where $n^3/l_0^2 = p$ Thus, $l$, the size of the array in the next iteration would be smaller than $n/\alpha^{½}$. Since, the number of items drops by a factor of $\alpha^{-1/2}$ and the number of processors remains constant, then the new ratio between processors and items will be $\alpha^{3/2}$. Thus we get:

$$T(\alpha,n) = 1 + T(\alpha^{3/2}, n/\alpha^2)$$

The recursion is guaranteed to terminate when $\alpha$ is bigger than $n^2$, and this will occur within

$$\frac{(\log\log n^2 - \log\log\alpha)}{\log\log(3/2)} = O(\log\log n) \text{ steps}.$$

If $1 \leq \alpha < 2$, the above equation is ill defined. We can force $\alpha$ to be 2 by using virtual processors: some or all of the processors will act like 2 virtual processors and thereby raising the processor to item ratio and only doubling the time. A more careful and much more tedious counting shows that the number of steps required even in the case of $\alpha=1$ is $O(\log\log n)$.

For $p \leq n$ divide the array into $p$ almost equal segments. Assign one processor to each segment and, in parallel, compute the prefix maxima on each segment sequentially. Then compute the prefix maxima of the maximum values of each segment; there are $p$ of them. Computing the prefix maxima of the full array can be done as in step 7 in the previous algorithm. The running time is $O(n/p) + O(\log\log p)$.

## 3. Computing the Subset Size in Parallel

The Subset size problem is to find the number of elements in a set which satisfy some predicate. This can be formulated as follows: Given an array $A[1..n]$ with binary values, compute how many entries contain the value 1. The subset will be denoted by $S$ and its size by $k$. In addition, each entry with a value of 1 is to be assigned a unique integer in the range 1 to $n$.

We present two algorithms for solving this problem. One is efficient when the number of set elements is large (SubSet_I) and the other (SubSet_II) is efficient when it is small. Both these algorithms can be executed in parallel to ensure an efficient algorithm for any set cardinality.

### 3.1. Algorithm Subset_I

As usual we will assume $p \geq n$. First we reduce the problem of finding subset size to the prefix maxima problem. Then, we form a linked list of the subset elements. Finally, we apply recursive doubling to compute the size and assign ordinal numbers to each element.

The following algorithm outputs $k$, and the array $R[1..k]$ where where $D[R[i]]$ is the i-th element of $D$ that contains a 1. The arrays $A[1..n+1]$ and $P[1..n+1]$ are used as temporary storage.

```
Procedure $SubSet\_I(p, D, n, R, k)$.
    Step 1: Compute the auxiliary array $A[1..n+1]$ as follows:
        For each $i$ in $[1..n+1]$ do in parallel:
            If $i > 1$ and $D[i-1]=1$ Then $A[i] := i-1$
            Else $A[i] := 0$
    Step 2: Apply the previous algorithm to produce the linked list
            $PreMax(p, A, n, P)$
        Note that $P[i]$ will come to contain the max value of all the elements in cells $A[j]$, where $j < i$. This value is also the index of the first cell containing a 1 to the left (smaller index) of $D[i]$.
    Step 3: Apply recursive doubling to the linked list represented by the array $P[1..n]$. The head of the list is stored in $P[n+1]$. This will result in the array $R$ of the requested form and will yield the value $k$.
```

It is easy to see that $SubSet\_I$ requires $O(\log\log n + \log k)$ time using $n$ processors: Step 1 requires $O(1)$ time, step 2 requires $O(\log\log n)$ time as previously shown, and step 3 can be done in logarithmic time of the length of the linked list, i.e. $O(\log k)$.

### 3.2. Algorithm SubSet_II

When $k \le \log n$ the $\log\log n$ term in running time of *SubSet_I* dominates. Fortunately, when $k$ is this small, we can create the linked list faster. The basic idea is to compact the set elements into a smaller array so that more processors can be used to quickly solve the problem. Algorithm *SubSet_II* gives the precise details of the computation of $k$ and $R[1..k]$ as before. The algorithm uses the temporary arrays: $D', D'', R', R''$, size of which will be determined at run time.

```
Procedure SubSet_II $(p, D, n, R, k)$
    Step 1: If $p \ge F(n)$ then apply SubSet_I to D:
                $SubSet\_I(p, D, n, P, k)$
    Step 2: Find the maximal $l$ for which $p \ge F(l)$.
    Step 3: Split the array $D[1..n]$ into $l$ disjoint consecutive segments $S$ which may vary in size by no more than 1.
    Step 4: Compute the array $D'[1..l]$ as follows:
        for each $j$ in $[1..l]$ and $i$ in $[1..|S_j|]$ do in parallel:
            If $S_j[i] = 1$ Then $D'[j] := 1$ Else $D'[j] := 0$
    Step 5: Apply algorithm SubSet_I to $D'$:
                $SubSet\_I(p, D', n, P', k')$
    Step 6: Compress the array $D$ into $D''$, using the ordinal number of non empty segments, as found in step 5. $D''[1..k' * \lceil (n/l) \rceil]$, will contain only the segments $S_j$ of $D$ before step 6, that have at least one element set to 1 in them.
    Step 7: Apply SubSet_II recursively to $D''$:
                $SubSet\_II(p, D'', k' * \lceil (n/l) \rceil, R'', k)$
    Step 8: Map $R''$ into $R$ to fit the original indexes of $D$ (before the compression in step 6.
```

As before steps 2 and 3 take a constant parallel time. Step 4 is really a computation of an OR function which can be done in parallel in constant time. In step 6 and 8 we make a compressed copy of an array and compute the opposite transformation. Since the ordinal number of each segment copied is given in the array $P'$, those steps can be done in parallel using $n$ processors in constant time.

In step 1 and 5 we apply algorithm *SubSet_I*, there are always enough processors to do the linking phase in it in a constant time. The counting in *SubSet_I* takes $O(\log k)$ in step 1, and $O(\log k')$ in step 5. Since $k' < k$ we can conclude that the total running time of *SubSet_II* is $O(\log k)$ except for the recursive call in step 7.

Since $F(l) \le l^3$ and $p \ge n$ we have $l < n^{1/3}$ at step 2. The algorithm is applied recursively in step 7 to an array sized $k' \lceil (n/l) \rceil$. Denote the size of the array after the $i^{th}$ recursive iteration by $n_i$. It is clear that $n_i \le n$ for all $i > 0$, now $n_0 = n$, $n_1 \le k n_0^{2/3}$, $n_2 \le k n_1^{2/3}$. A simple induction gives:

$$n_i \le k^3 n^{(2/3)^i}$$

The recursive calls are guaranteed to stop if $n_i \le n_0^3 \le p$. For $k \le n^\beta < n^3$ the recursion will terminate in the $\log(1/3 - 3\beta) - \log(2/3)$ step. The total running time of the algorithm is therefore $O(C_\beta \log k)$ were $C_\beta$ is a constant depending only on $\beta$. For example taking $\beta$=0.07 would give $C_\beta$=5.

Note that asymptoticly $\log n < n^\beta$ for any $\beta$. This algorithm can be used in those application where the $k$ is known in advance to be smaller than $\log n$. When no estimate can be made about $k$, one would run the two previous algorithms in parallel, and terminate as soon as one of them terminates, requiring a total time of $O(\log k)$ for any size $k$.

For $p < n$ creating the linked list and computing the size of the subset can be done by dividing the array into $p$ segments. Each processor will make a linked list and will count the number of elements in his segment. After that Use the *SubSet_I* and *SubSet_II* algorithms for chaining the linked lists of all segments which contain one or more elements from the subset. The total running time is therefor $O(n/p) + O(\log k)$.

### 4. Conclusion

We view the algorithms presented as building blocks to more complex ones. One application is when there is a multiway predicate, and subsets of the processors are to go off and solve independent subproblems. Before they can work together, however, they must know how many processors are cooperating, it is advantageous if each has a unique index.

The algorithm can be improved somewhat, but only by a constant factor, by using a technique to compute the maximum of $n$ items, all in the range 1 to $n$ with $n$ processors in constant time. (Note that in this paper we require about $n^2$ processors to compute the max.) This result can be found in a fuller version of this paper [1].

# REDUCTION TECHNIQUES FOR SELECTION IN DISTRIBUTED FILES

**Nicola Santoro and Ed Suen**

Distributed Computing Group
Carleton University
Ottawa, Ontario, K1S 5B6
Canada

## Abstract

The problem of selecting the K-th smallest element of a set of N elements distributed among d sites of a communication network is examined. A distributed reduction technique for selection is a distributed algorithm which tranforms this problem to an equivalent one where either K or N (or both) are reduced. A collection of distributed reduction techniques is presented; the combined use of these algorithms yield new solutions for the selection problem for both point-to-point and shout-echo networks. In particular, $O(d + \delta \log(\kappa/d))$ and $O(\log \kappa)$ upper-bounds on the distributed selection problem are derived for point-to-point networks having a spanning star graph (e.g., complete networks) and shout-echo networks, respectively, where $\kappa \le \Delta = \mathrm{Min}\{K,N-K+1\} \le K$ and $\delta \le d$. These results represent an improvement on the existing bounds for those networks; furthermore the existing selection algorithms for other point-to-point networks (e.g., rings, meshes, trees) can be made more efficient by using one of the proposed reduction techniques as a pre-processing phase.

## 1. Introduction

The classical problem of selecting the K-th smallest element of a set F drawn from a totally ordered set has been extensively studied in serial and parallel environments. In a distributed context, it has different formulations and complexity measures.

A ***communication network*** of size d is a set $S=\{S_1, \dots, S_d\}$ of ***sites***, where each site has a local non-shared memory as well as processing and communication capabilities.

A ***file*** of cardinality N is a set $F=\{f_1,\dots,f_N\}$ of records, where each record $f \in F$ contains a unique key k(f) drawn from a totally ordered set; for convenience, $k(f_i)<k(f_j)$ shall be denoted by $f_i<f_j$.

A ***distribution*** of F on S is a d-tuple $X=<X_1,\dots,X_d>$ where $X_i \subseteq F$ is a subfile stored at site $S_i$, $X_i \cap X_j= \emptyset$ for $i \neq j$, and $\cup_i X_i = F$.

Order-statistics queries about F can be originated at any site and will activate a query resolution process at that site. Since only a subset of F is available at each site, the resolution of a query will in general require the cooperation of several (possibly all) sites according to some predetermined algorithm. Since local processing time is usually negligible when compared with transmission and queueing delays, the goal is to design resolution algorithms which minimize the amount of communication activity rather than the amount of processing activity.

The **distributed selection problem** is the general problem of resolving a query for locating the K-th smallest element of F. The tuple <N, K, N[1], ..., N[d]> is called the problem ***configuration***, and $\Delta = \mathrm{Min}\{K,N-K+1\}$ is called the problem ***size***, where N[i] is the cardinality of $X_i$. Any efficient solution to this problem can be employed as a building block for a distributed sorting algorithm [9].

The complexity of this problem (i.e., the number of communication activities required to resolve an order-statistics query) depends on many parameters, including the number of sites, d, the size N of the file, the number N[i] of elements stored at site $S_i$, the rank K of the element being sought, and the topology and type of the network.

Solutions to this problem have been developed for both the point-to-point and the shout-echo models of computation.

In ***point-to-point*** networks, associated with S is a set $L \subseteq S \times S$ of direct communication lines between sites; if $(S_i,S_j) \in L$, $S_i$ and $S_j$ are said to be ***neighbours***. Sites communicate by sending messages; a message can only be sent to and received from a neighbour. The couple G=(S,L) can be thought of as an undirected graph; hence, graph-theoretical notation can be employed in the design and analysis of distributed algorithms in the point-to-point model. Different solutions and bounds exist for the distributed selection problem in the point-to-point network depending on the topology of the network [2,6,15]. In particular,

0190-3918/86/0000/1003 $01.00 © 1986 IEEE

Frederickson [2] presented algorithms which require O(d $(\log d)^2 \log N$) messages in a *ring*, O(d $(\log d)^{1/2} \log N$) messages in a *mesh*, and O(d log(2N/d)) messages in a *complete binary tree*. All these bounds apply to the worst case; the analysis of the expected communication complexity has been carried out in [11,15].

In ***shout-echo*** networks, each site can broadcast a message and reply to a received message; the process of broadcasting a message and receiving a (possibly distinct) reply from all sites constitutes a basic communication activity called shout-echo. Several papers investigating the selection problem in this network have appeared [1,5,7,8,10-14]; an O(log Δ) bound has been established by Marberg and Gafni [5] who also prove a $\Omega(\log n_2)$ lower bound if the messages are constrained to carry only file elements, where $n_2$ is the second largest number of elements stored at the sites.

In this paper, a selection procedure based on various reduction techniques is proposed, and used to obtain efficient solutions both in the shout-echo and in the point-to-point models. The algorithm is based on the serial technique developed by Frederickson and Johnson for selection in an array with sorted columns [3], and employs some of the existing distributed selection algorithms as subroutines. Using the proposed algorithm, the following upper-bounds on the distributed selection problem are obtained:

1) 9.64 δ log(κ/d) + O(d) messages in networks having a spanning star graph (e.g., star networks, complete networks);
2) 6.82 logκ + O(1) basic communication activities in a shout-echo network;

where $\kappa \le \Delta$ and $\delta \le p = \mathrm{Min}\{\Delta, d\}$ are, respectively, the rank of the desired element and the number of sites under consideration in the problem configuration produced from the execution of Procedure SET-UP (see section 2.1). These results improve the existing bounds of 19.28 p log Δ - 9.64 p log d + O(d) and 10.64 log Δ + O(1) for these networks, respectively. Note that, while always $\kappa \le \Delta$, sometimes $\kappa << \Delta$. Consider for example the configuration <10032,5937,10000,20,5,5,2>; in this case κ=33 while Δ=Min{K,N-K+1}=4096.

Furthermore, it is observed that selective application of the proposed reduction techniques can also yield slight improvements to the existing bounds for rings, meshes, and complete binary trees established in [2].

The paper is organized as follows. In the next section a collection of reduction techniques is presented and analysed; the combined use of these techniques yields a new selection procedure. In section 3, this procedure is employed to obtain the new bounds in the shout-echo networks. Finally, in section 4, the application of some of the reduction techniques to point-to-point networks is discussed.

## 2. A selection procedure

In this section, a selection algorithm is proposed which can be used to obtain efficient solutions both in the shout-echo and in the point-to-point models.

The algorithm consists of four phases: **set-up, cut, filtration**, and **termination**; the first three phases are reduction techniques. The set-up phase (procedure SET-UP) enforces a set of constraints on the problem configuration; this might require a modification of the entire problem configuration. The cut phase (procedures CUT1 and CUT2) has the overall effect of further reducing the problem configuration so that the cardinality of the set of elements among which the sought element is to be found is linear in the rank of this element. Finally, the filtration phase (procedure FILTER) iteratively reduces the problem under consideration to one that can be efficiently solved at just one site by the termination phase. Assume, without loss of generality, that the original problem is finding the K-th smallest element (a "min" problem). The symmetrical problem of finding the K-th largest (a "max" problem) can be treated in a similar manner.

### 2.1 Set-up phase

A problem configuration <N, K, N[1],...,N[d]> is said to be **regular** if N[i]≤Δ for 1≤i≤d, where Δ=Min{K,N-K+1} is the problem size. The goal of the SET-UP procedure is to tranform the initial problem configuration to a regular one.

Let C=<N,K, N[1],..., N[d]> be the initial problem configuration and, without loss of generality, let Δ = K. If this configuration is not regular, then for all sites $S_i$ with N[i]>K the N[i]-K largest elements can obviously be removed from consideration without altering the problem integrity (i.e., the K-th smallest element will have the same rank among the remaining elements); this observation has also been made in [3,5]. After this simplification, the resulting configuration will be C'=<N',K, N'[1],..., N'[d]> where N'[i]=Min{N[i],K} and $N'=\sum_i N'[i]$.

It is possible, however, that this new configuration is not regular once we change the problem type (i.e., select the

$(N'-K+1)$-th largest instead of the $K$-th smallest element). For example, it may occur that $\Delta'=\mathrm{Min}\{K,N'-K+1\}<K$ and that $N'[i]>\Delta'$ for some i; in this case, the $N'[i]-\Delta'$ *smallest* elements can still be removed from consideration from that set without altering the problem integrity (i.e., the $(N-K+1)$-th largest among the original element will be the $\Delta'$-th largest of the remaining elements). Notice that such a modification will change the value of $N'$ and thus possibly $K'$; hence, the new configuration might again be not regular.

In the following, the variable $T_j$ will represent the type of the problem at iteration j: $T_j$="max" ("min") will indicate that the $K_j$ largest (smallest) element is to be determined; the function *other* on problem types is defined as follows: *other*["max"]="min" and *other*["min"]="max".

```
PROCEDURE SET-UP
initialization:
        $N_0:= N; K_0:=K; N_{i,0}:=N[i]; T_0=$"min";
j-th iteration ($j\geq1$):
        $K_j := \mathrm{Min}\{N_{j-1} - K_{j-1}+1, K_{j-1}\}$;
        if $K_j=K_{j-1}$ then $T_j:=T_{j-1}$ else $T_j:=$other$[T_{j-1}]$;
        $N_{i,j}:= \mathrm{Min}\{N_{i,j-1}, K_j\}$;
                <Meaning: remove from consideration
                the $K_j-N_{i,j-1}$ largest (if $T_j$="min") or
                smallest (if $T_j$="max") elements still
                under consideration at site $S_i$>
        $N_j:= \Sigma_i N_{i,j}$;
        $\beta_j=|\{ N_{i,j-1}>K_j\}|$;
        if $\beta_j>0$ perform the next iteration, otherwise
        execute the termination step.
termination:
        $d:= \mathrm{Min}\{d,K_j\}$.
                <Meaning: If $d>K_j$ and $T_j$="min"
                ("max"), consider the smallest
                (largest) element still under
                consideration at each site; among these
                elements, identify the $d-K_j$ largest
                (smallest) and remove from
                consideration the corresponding sites>
END SET-UP
```

It will now be shown that the procedure will iterate a constant number of times. The j-th iteration will be called a **flip** if $K_j=N_{j-1}- K_{j-1}+1<K_{j-1}$; i.e, if the type of the problem is changed.

**Property 1** Let $j\geq1$. If the $(j+1)$-th iteration is not a flip, the procedure terminates at that iteration.

Proof. If the $(j+1)$-th iteration is not a flip, $K_{j+1}=K_j\geq N_{i,j}$; hence $\beta_{j+1}=0$ and the algorithm terminates. ♦

**Property 2** Let $j>1$. If the $(j+1)$-th iteration is a flip, then $\beta_j=1$.

Proof. Let the $(j+1)$-th iteration be a flip; then $\beta_j>0$, otherwise the algorithm would have terminated at the j-th iteration. Let $\beta_j>1$, and let $S_a$ and $S_b$ be two sites with $N_{a,j-1}>K_j$ and $N_{b,j-1}>K_j$; then, $N_j\geq N_{a,j} + N_{b,j}= 2 K_j$. That is, $N_j-K_j+1\geq K_j+1>K_j$ which would imply $K_{j+1}=\mathrm{Min}\{K_j, N_j-K_j+1\} = K_j$ contradicting the fact that the $(j+1)$-th iteration was a flip. Thus, $\beta_j=1$. ♦

**Property 3** Let $j>1$. Then the j-th and the $(j+1)$th iterations cannot both be flips

Proof. By contradiction, let both the j-th and the $(j+1)$th iterations be flips; that is

$$K_j = N_{j-1}-K_{j-1}+1 < K_{j-1} \qquad (1)$$

and

$$K_{j+1} = N_j-K_j+1 < K_j \qquad (2)$$

By property 2, $\beta_{j-1}=1$; that is, only one site, say $S_a$, had been reduced in the $(j-1)$-th iteration. Since $N_{a,j-1}=K_{j-1}$, site $S_a$ will be reduced also in the j-th iteration; and since iteration $(j+1)$ is a flip, then (by property 2) $\beta_j=1$; that is, $S_a$ will be the *only* site to be reduced in the j-th iteration. Thus, $N_j=N_{j-1}-(N_{a,j-1}-K_j)= N_{j-1}-K_{j-1}+K_j$; by substituting this expression for $N_j$ in inequality (2), it follows $K_j > N_j -K_j +1= N_{j-1}-K_{j-1}+K_j -K_j +1 =N_{j-1}-K_{j-1}+1$ contradicting relation (1). ♦

**Theorem 1** Procedure SET-UP performs at most three iterations.

Proof. Let it perform at least two iterations. If the second iteration is not a flip, (by property 1) the algorithm terminates at the end of this iteration; on the other hand, if the second iteration is a flip then (by property 3) the third iteration is not a flip and (by property 1) the procedure terminates after the third iteration. ♦

**Theorem 2** Let $\kappa$ and $\delta$ be, respectively, the rank of the desired element and the number of sites under consideration in the problem configuration produced by the Procedure SET-UP. Then, there will be at most $\kappa\delta \leq \kappa^2$ elements still left under consideration.

Proof. The configuration obtained from Procedure SET-UP is regular; i.e., at most $\kappa$ elements are still under considerations at each site. Since in the termination step of the procedure $\delta \leq \kappa$ sites are kept under consideration, the theorem follows. ♦

### 2.2 Cut phase

Let $<N, K, N[1], ..., N[d]>$ be the problem configuration. If this configuration is the result of the SET-UP phase, then $N[i] \leq K = \kappa$, $1 \leq i \leq d$, and $d = \delta \leq \kappa$. The CUT phase is the distributed translation of the CUT procedure of the algorithm by Frederickson and Johnson for selection in matrices with sorted columns [2]. This phase is composed of two sub-phases. The initial sub-phase CUT1 reduces the number of elements under consideration to at most $\mathrm{Min}\{K \log d, K \log n\}$, where $n = \mathrm{Max}\{N[i] \mid 1 \leq i \leq d\}$; sub-phase CUT2 guarantees that at most 4.5K elements remain.

The j-th iteration of procedure CUT1 is applied only to a subset, $\xi^j$, of the sites. The $i_j = \lceil 2^j(K+1)/d \rceil$ - th smallest element from each of these sites is collected. If a site has less than $i_j$ elements then $+\infty$ will be used. Among these values, the median is found and all values at all sites greater than or equal to the median are removed from consideration. The next iteration is then applied to half the sites participating in this iteration.

Using the values $i_j$ produced by CUT1 ($0 \leq j \leq q$), each subfile $X_m$ of site $S_m$ can be broken down into the subsections $\Gamma_{m,j} = \{x \mid x \in X_m, S_m[i_j] \leq x < S_m[i_{j+1}]\}$, where $S_k[w]$ denotes the w-th smallest element at $S_k$ and $i_0=1$. Assign the weight $i_{j+1}$-$i_j$ to the initial $S_m[i_j]$ subsection element. Procedure CUT2 operates on this set of initial subsection elements $\{S_m[i_j] \mid 1\leq m \leq d, 0 \leq j \leq q\}$; among these, it finds an element $x^*$ whose overall rank is at least K and at most 4.5K, using a weighted selection algorithm (e.g., see [4]). Finally all elements larger than $x^*$ are removed from consideration.

**PROCEDURE CUT1**
(to be performed only if N>4.5K)

```
1. Initialization
        $\xi^0 := S$; $i_0 := 1$.

2. Stage j  ($1 \leq j \leq q$)
    2.0  IF $\lceil 2^j(K + 1)/d \rceil > n$ or $|\xi^{j-1}| \leq 1$ THEN
             go to the termination step.
    2.1  $i_j := \lceil 2^j(K+1)/d \rceil$;
    2.2  Let $V^j$ denote the set of all $S_i[i_j]$, the $i_j$th
         ranked element of site $S_i$, where $S_i \in \xi^{j-1}$.
         Find the median v of $V^j$
    2.3  Send the median v to all sites.
         Upon receipt of this median v, each site
         eliminates all elements not smaller than v.
    2.4  Let $\xi^j = \{S_i \mid S_i \in \xi^{j-1}$ and $s_i[i_j]<v\}$.
         Perform the next iteration by repeating step 2.

3.Termination
        Let $i_{q+1} = n + 1$

END CUT1
```

**Property 4.** The K-th element of the original problem is also the K-th element of the result of CUT1.

Proof. At step j, $V^j$ contains at least $d/2^{j-1}$ elements, each having rank at least $2^j(K+1)/d$. Thus the median of $V^j$ has overall rank at least $(2^j(K+1)/d)(d/2^j) = (K+1)$; that is, the K-th smallest element must be smaller than the median of $V^j$. Since we only remove elements which are greater or equal than the median, the lemma follows. ♦

**Property 5** The number of stages of procedure CUT1 is at most $\mathrm{Min}(\lceil \log d \rceil, \lceil \log n \rceil)$.

Proof. There are two conditions for termination in step 2.0. The first condition, $\lceil 2^j(k+1)/d \rceil > n$, guarantees that at most $j < \lceil \log n \rceil$ iterations are performed. Since $|\xi^j| \leq \lfloor |\xi^{j-1}|/2 \rfloor$, for $j \geq 1$, the second condition, $|\xi^{j-1}| \leq 1$, ensures at most $\lceil \log d \rceil$ iterations. ♦

**PROCEDURE CUT2**
(to be performed only if N>4.5K)
Let $V^0$ denote the $i_0$th element from every site $S_i \in \xi^0$.

```
1    Select $x^*$ from the elements $\cup_{j=0,q} V^j$ by a 4K-th
     weighted selection, where an element $x \in V^j$
     has weight $i_{j+1} - i_j$.

2    Send the element $x^*$ to all sites. Upon receipt of
     this element $x^*$, each site eliminates all elements
     larger than $x^*$.

END CUT2
```

**Property 6** If K is the rank of the element to be selected, then CUT2 retains at most

4.5K elements, and the Kth element among these elements is also the Kth element of the input problem to CUT2.

Proof. By Lemma 2 in [3] ♦

### 2.3 Filtration phase

The filtration stage is the last reduction technique used by our algorithm. It comprises of a sequence of iterations; each iteration reduces the number of elements under consideration by a constant factor until the number of candidate elements is less than or equal to a desired number, $N_f$. The choice of $N_f$ depends on the type of network under consideration. Let <N, K, N[1], ..., N[d]> be the problem configuration. If this configuration is the result of the CUT phase, then $N \leq 4.5K$.

The chosen filtration procedure is the technique developed in [5]. It should be noted that the distributed translation of the serial procedure REDUCE in [3] could also be used as a filtration technique; the choice here of the former technique rests on the fact that it guarantees a larger fraction of elements to be removed at each iteration. A full description and analysis of this technique can be found in [5]; an informal description is provided below.

```
PROCEDURE FILTER
(Iterate until either the sought element is found or $N \leq N_f$)

    1.  Among the medians of the elements still
        under consideration at each site, find the
        (N/2)-th weighted element x using
        weighted selection.

    2.  Determine the overall rank r of x. If r= K
        then terminate (x is the sought element).
        Otherwise, eliminate from consideration
        the elements not greater than x (if r<K) or
        not smaller than x (if r>K), and adjust K
        (if r<K) and N. If $N \leq N_f$, terminate,
        otherwise proceed with the next iteration.
END FILTER
```

**Property 7** The number of iterations required by procedure FILTER to reduce N elements to $N_f$ elements is $2.41\log(N/N_f)$.

Proof. Since at least 1/4 of the elements are removed from consideration after each iteration (see [5]), the property follows. ♦

### 2.4 Termination phase

Once the filtration phase is concluded, if the sought element has not yet been found, the $N_f$ elements still under consideration can be collected at a site where the final selection is performed.

To perform this phase efficiently, the actual value $N_f$ (a parameter in the FILTER procedure) will depend on the type of network under consideration. As shown later, the choice for shout-echo is log $\kappa$ (where $\kappa$ is the value determined after the set-up phase), and for point-to-point networks the choice is d, where d is the original number of sites.

## 3. Shout-echo networks

In shout-echo networks, each site can broadcast a message and reply to a received message; the process of a site broadcasting a message (the "shout") and receiving a reply from all other sites (the "echo") constitutes a primitive communication activity, called a shout-echo. Marberg and Gafni presented a selection algorithm (procedure FILTER in this paper); they also assume that a preliminary reduction (equivalent to the first iteration of the set-up phase followed by the termination stage) has already been performed (i.e., $N \leq \Delta^2$). Their algorithm, in the worst case, requires $4.82\log\Delta^2 + \log \Delta = 10.64 \log \Delta$ shout-echos [5].

An improvement in this bound for selection in shout-echo networks can be obtained by using the selection procedure described in the previous section. All phases can be easily implemented using shout-echo primitives.The procedure can actually be simplified in this implementation; in fact, it is not necessary to perform the specific element elimination steps of CUT1 (steps 2.2 - 2.4), in the shout-echo model: by taking $\xi^j = S$, for all j, CUT2 may be performed immediately. However, an increase of local storage space for file elements from O(d) to O(d log d) is needed at the initiating site, where d is the number of sites still under consideration when CUT is executed. By choosing $N_f = \log\kappa$ in the FILTER procedure, the following result yields.

**Theorem 3** The number of shout-echoes used in the selection algorithm is at most $6.82\log\kappa + O(1)$, where $\kappa \leq \Delta$ is the problem size obtained after the set-up phase.

Proof. The initialization and termination stages, as well as each iteration of procedure SET-UP can be implemented using only a constant number of shout-echoes. Since the procedure SET-UP can be performed in a constant number of iterations (by Theorem 1), SET-UP requres O(1) shout-echoes. After this procedure is executed, the size of the problem is $\kappa \le K$; the number of sites still under consideration is $\delta \le \kappa$; and the maximum number of elements at any one site is $n \le \kappa$.

During each iteration of CUT1, the collection of the elements $V^j$, $1 \le j \le q$, and the broadcast of the median can be done with one shout-echo. Since the number of iterations in CUT1 is bounded by $\mathrm{Min}\{\lceil \log\delta \rceil, \lceil \log n \rceil\} \le \log\kappa$, the total number of shout-echoes needed to perform CUT1 is at most $\log\kappa + O(1)$. Since the only communication activities needed in CUT2 are the collection of the elements $V^0$ and the broadcast of $x^*$, only a constant number of shout-echoes are needed to perform this procedure. Therefore at most $\log\kappa + O(1)$ shout-echoes are needed to perform the procedure CUT. By Property 6, the CUT procedure allows at most $4.5\kappa$ elements to remain. By Property 7, the number of iterations used by the FILTER procedure is at most $2.41\log\kappa + O(1)$. Since each iteration uses 2 shout echoes, the number of shout echoes used by the FILTER procedure is $4.82 \log\kappa$. Since CUT takes at most $\log\kappa + O(1)$ shout echoes, and transferring the remaining $\log\kappa$ elements will take no more than $\log\kappa$ shout echoes, therefore the number of shout echoes used in the selection algorithm is at most $6.82 \log\kappa + O(1)$. ♦

## 4. Point-to-point networks

In sec. 4.1, a point-to-point selection algorithm for the star graph shall be presented; this algorithm can obviously be employed in any other network having a spanning star graph (e.g., complete networks). In sec. 4.2, the application of the SET-UP procedure to the existing algorithms for rings, meshes, and (complete binary) trees shall then be examined.

### 4.1 Star networks

In point-to-point networks, the communication primitive is the transmission of a message to a neighbouring site. For networks whose topology is a star (or contains a spanning star subgraph), the shout-echo algorithm by Marberg and Gafni [5] can be transformed so to employ $19.28p \log \Delta - 9.64p \log d + O(d)$ messages, where $p = \mathrm{Min}\{K,d\}$. An improvement in this bound is obtained by executing all four phases (as for shout-echo networks) and choosing $N_f = d$ in the filtration phase, where d is the original number of sites.

**Theorem 4** The number of messages used in the selection algorithm in a star network is at most $9.64\ \delta \log(\kappa/d) + O(d)$ where $\kappa \le \Delta$ is the rank of the desired element and $\delta \le p$ is the number of remaining sites, respectively, in the problem configuration produced from the execution of the Procedure SET-UP.

Proof. Since the procedure SET-UP can be performed in a constant number of iterations (by Theorem 1), SET-UP can be performed in O(d) messages. During each iteration of CUT1, the collection of the elements $V^j$, $1 \le j \le q$, and the broadcast of the median can be done with $2|\xi^{j-1}|$ messages. Since $|\xi^j| < |\xi^{j-1}|/2$ by step 2.4 and $|\xi^0| = \delta \le d$ by step 1, CUT1 uses at most $O(\delta)$ messages. Furthermore, since the only communication activities in CUT2 are the collection of the elements of set $V^0$ and the broadcast of $x^*$, at most $O(\delta)$ messages are needed for procedure CUT.

By Property 6, the CUT procedure allows at most $4.5\kappa$ elements to remain. Therefore by Property 7, the number of iterations used by the FILTER procedure is at most $2.41\log(\kappa/d) + O(1)$. Since each iteration of FILTER uses $4\delta$ messages, the number of messages used by the FILTER procedure is bounded by $9.64\delta\log(\kappa/d)$. As the transmission of the remaining d file elements in the termination phase requires at most O(d) messages, the theorem follows. ♦

### 4.2 Other topologies

The existing algorithms for selection in other networks [2,6] can be made more efficient if the SET-UP procedure is used prior to their execution.

The initialization and each iteration step of procedure SET-UP can be easily implemented in rings, meshes and complete binary trees using O(d) messages; the termination step, however, should be implemented using the existing topology-dependent algorithms for selection when there is only one element at each site (e.g., [2]).

This implementation of procedure SET-UP will thus require $O(d\ (\log d)^3)$ messages in the *ring* topology to reduce the number of elements, N, to at most $\kappa\delta \le \kappa^2$. If the existing ring selection algorithm is then applied to the remaining elements, then at most $O(d(\log d)^2\log\kappa)$ messages are needed. The resulting $O(d\ (\log d)^2\log(\mathrm{Max}\{\kappa,d\})$ improving the existing bound of $O(d(\log d)^2\log N)$.

Similarly in the *mesh*, SET-UP will take O(d(logd)$^{3/2}$) messages to execute, thus enabling the existing algorithm to terminate in O(d(logd)$^{1/2}$logκ) messages; the resulting O(d (log d)$^{1/2}$log(Max{κ,d}) improves on the existing O(d(logd)$^{1/2}$logN) bound.

In the *complete binary tree*, SET-UP will require O(d) messages to reduce N to at most κδ, whereupon the exsting algorithm is called to complete the selection in O(dlogκ).The resulting O(dlogκ) bound improves on the existing O(d log(2N/d)) bound whenever κ<N/d.

## 5. Conclusions

The problem of selecting the K-th smallest element of a set of N elements distributed among d sites of a communication network has been examined. A collection of distributed reduction techniques has been presented; the combined use of these algorithms has been shown to yield new solutions for the selection problem for both point-to-point and shout-echo networks. The complexity of these solutions has been analysed and it has been shown to represent an improvement on the existing bounds.

There are still many open problems. For example, an efficient algorithm for arbitrary tree networks has not yet been developed. Another important open problem is to determine a lower bound for the distributed selection problem in point-to-point networks; the only existing lower bound is for complete binary trees [2].

# Optimal Parallel Algorithms for Constructing a Balanced m-way Search Tree

Eliezer Dekel and Shietung Peng
University of Texas at Dallas
and
S.Sitharama Iyengar
Lousiana State University

Abstract : We present parallel algorithms for constructing balanced m-way search trees. These parallel algorithms have time complexity O(1) for an n processors configuration.

## 1. INTRODUCTION

The idea of using tree structure to represent symbol tables, dictionaries or directories has been extensively studied[K]. In all these structures we have a collection of records that are to be manipulated with regard to a certain key field in the record. Common operations on these structures are SEARCH, INSERT and DELETE. The tree structure supports efficient INSERT, SEARCH and DELETE operations. In some implementations the operations are designed so that a balanced tree is maintained through the process. Another approach is to periodically rebalance the tree. In our discussion we refer to these structures as dictionaries. The operations INSERT,SEARCH and DELETE will be referred to as basic dictionary operations.

Many types of balanced m-way search trees are reported in the literature [K,HS]. In our discussion we refer to the following:

Def 1.1 : An m-way search tree, T, is a tree in which all internal nodes are of degree $\le$ m. If T is empty then T is an m-way search tree. When T is not empty it has the following properties: (1) T is a node of type $A_0, (K_1,A_1), (K_2,A_2), \ldots,$ $(K_{m-1},A_{m-1})$ where the $A_i$, $0 \le i < m$ are pointers to the subtree of T and the $K_i$, $1 \le i < m$ are key values. (2) $K_i < K_{i+1}$, $1 \le i < m-1$ (3) All key values in subtree $A_i$ are less than value $K_{i+1}$ $0 \le i < m-1$ (4) All key values in the subtree $A_{m-1}$ are greater than $K_{m-1}$. (5) The subtrees $A_i, 0 \le i \le m-1$ are also m-way search trees.

Def 1.2 : A balanced m-way search tree is an m-way search tree with minimal height.

While many parallel architectures have been proposed and studied ,we deal directly with only the MIMD model. We assume there is a large common memory that is shared by all processors. Any processor can access any word in common memory, but access the same memory word simultaneously is not allowed.

Recently, Moitra and Iyengar[MI] explored a technique of transforming a sequential algorithm for balancing a binary search tree into an efficient parallel algorithm. Furthermore, they have shown that the resulting parallel algorithm has a time complexity O(1) when a tree with N elements is balanced with N PEs. An O(log N) time set up overhead is incurred when a new N is considered. In this paper, we generalized the results of [MI] to a general m-way search tree. We also improve the computation such that no setup overhead is required.

This paper is organized as follows. In section 2, we review some properties of m-way search trees. In section 3, we develop the general m-way search tree rebalancing/construction algorithm. In section 4, we discuss the implementation of these algorithms on an MIMD machine.

## 2. M-WAY SEARCH TREES

Dictionary searches are more efficient when they are done on a balanced tree. In order to keep the tree balanced, the insertion and deletion algorithms are designed to leave the tree balanced. Because of this requirement it is more convenient to consider balanced m-way search trees that are not necessarily of minimal height (e.g. B -trees). These trees lend themselves to easier splitting and combining. While this is true in the serial case we show that in the parallel case the complete m-way tree proves to be an efficient choice.

Def 2.1 : A level labeling of an m-way search tree is a labeling in which nodes are numbered serially, top down left to right. The root node is always labeled 1.

Lemma 2.1 : When the nodes of a complete m-way tree are labeled by level labeling then the m children of node i (if they exist) are labeled $(i-1)*m + 2 + j$ $,0 \le j \le m-1$.

Def 2.2 : In an m-way tree T, the (i,j)'th node refers to the jth node from the left on the ith level, if it exists. We refer to this indexing method for m-way search trees as two dimensional indexing.

Def 2.3 : Inorder traversal of an m-way search tree is defined by the following recursive procedure:

```
procedure MINORDER (T)
{* T is an m-way tree as defined in def.1.1 *}
if T <> nil
then  call MINORDER ($A_0$);
      for I= 1 to M
```

0190-3918/86/0000/1010 $01.00 © 1986 IEEE

```
        begin
        if no $K_i$ key then exit;

        visit($K_i$);

        MINORDER ($A_i$)
        end;
end. {* MINORDER *}
```

Def 2.4 : An index can be associated with each key in an m-way search tree. If this index corresponds to the order in which MINORDER visits the keys we call the indexing, Inorder indexing.

Lemma 2.2 Suppose node I is at level r of a full m-way search tree of height n. Let the inorder index associated with key $K_i$ in I be $X_i$. Then $X_{i+1}-X_i=m^{n-r}$ for $1 \leq i < m-1$.

Lemma 2.3 a) Let nodes I and J be two adjacent sibling nodes at level r of a full m-way search tree of height n. Let $I.X_{m-1}$ be the inorder index of the last key in node I and $J.X_1$ the inorder index of the first key in node J. Then

$$J.X_1 - I.X_{m-1} = 2 * m^{(n-r)}.$$

b) The above claim is true for any two adjacent nodes at level r.

Theorem 2.1 Consider a full m-way search tree of height n. The inorder indexes for keys in node i at level r (node (r,i)) are: $(i-1)*m^{(n-r+1)}+j*m^{(n-r)}$, where $1 \leq i \leq m^{(r-1)}$; $1 \leq j < m$

Corollary 2.1 A key with inorder index t is at level r of a full m-way search tree if and only if $t \bmod m^{(n-r+1)} \neq 0$ and $t \bmod m^{(n-r)} = 0$.

Corollary 2.2 Let t be the inorder index associated with a key at level r of an m-way tree of height n and let $q = \lfloor t/m^{(n-r+1)} \rfloor$. Keys with the same r value (Cor.2.1) and q value are in the same node, in the m-way search tree. Moreover the two dimensional indexing of this node will be (r,q+1).

Corollary 2.3 Let t be the inorder index associated with a key at level r of an m-way tree of height n. The position of the key within the node is given by s,

$$s = \lfloor (t \bmod m^{(n-r+1)}) / m^{(n-r)} \rfloor,$$

$1 \leq s \leq m-1$.

Lemma 2.4 Let n be highest level in a complete m-way tree. The inorder indexes associated with keys in node (n,p) are $(p-1)*m + j$, where $1 \leq j < u$, (n,v) is the last node in this level, $v \leq m^{(n-1)}$. $u = m-1$ for all nodes except (n,v).

## 3. ALGORITHMS FOR REBALANCING AN M-WAY SEARCH TREE.

We associate a PE with each node in the m-way balanced search tree.Let each PE calculate the inorder indexes for keys that should reside in the node. We consider a full m-way search tree and assume that each PE knows the height and degree of the tree.

ALGORITHM 1

(* Assume that there are $(m^h-1)/(m-1)$ PEs. The number of keys that are to be associated with this tree are $m^h-1$.*)

(I): (* each PE computes the two dimensional index of the node it is associated with, i.e. there is a mapping from i, the PE index, to (q,r),$1\leq i \leq \lceil n/(m-1) \rceil$, $1 \leq q \leq m^{(h-1)}$, $1 \leq r \leq h$ *)

```
 for each PE i do
 begin
 j ← $\lfloor \log_m i \rfloor$ (* i is the PE index*)

 if i > $(m^{(j+1)}-1)/(m-1)$
 then  r ← j+2;
       q ← i-$(m^{(j+1)}-1)/(m-1)$;
 else  r ← j+1;
       q ← i-$(m^j-1)/(m-1)$;
 end.
```

(II): (* Each PE represents a node (r,q). Node (r,q) has m-1 inorder indexes associated with it. Each inorder index is associated with a unique key. The inorder index for key $K_s$ in node (r,q) is held in $X_s$, $1 \leq s \leq m-1$. *)

```
 for each node (r,q) do
    for  s ← 1 to m-1 do
    $X_s$ ← $((q-1)*m+s) * m^{(h-r)}$;
```

(III): (* The m pointers for node (r,q) are stored at $A_s$, $0 \leq s \leq m-1$ *)

```
 for each node (r,q) do
    for  s ← 0 to m-1 do
    if r < h then
          $A_s$ ← node ((q-1)*m+s+1,r+1)

          else
          $A_s$ ← null
```

Theorem 3.1 Algorithm 1 correctly constructs the required full m-way search tree within O(1) time if O(n) PEs are available.

We now consider the general case where the number of keys can be any positive integer. Algorithm 2 will produce a complete m-way search tree for the given number of keys. Only the last node in the tree (greatest level label) can have less then m-1 keys associated with it. We assume that each PE knows the number of keys and the degree of the search tree. These values might be passed to the PE as procedure parameters.

### ALGORITHM 2

```
(* The input keys have inorder indexes in
the range [1 : n], n can be any positive
integer *)
(I): Compute the two dimensional index of
each node as in (I) of algorithm 1.
(II): (* Compute the parameters,u,v and
w, of the tree. They stand for the
number of keys in the last node, the
number of the full nodes in the last
level and the inorder index of the right
most key in the last level. *)
 for each PE i do
 begin
 $h \leftarrow \lfloor \log_m n \rfloor$ ;
 if $n = m^{(h+1)}-1$ then (* full tree *)
 execute II and III of algorithm 1 and
 stop ;
 $c \leftarrow n-(m^h-1)$ ;
 $u \leftarrow c \bmod (m-1)$ ;
 $v \leftarrow \lfloor c/(m-1) \rfloor$ ;
 if $u = 0$ then $w \leftarrow v*m -1$ else $w \leftarrow$
 $v*m+u$ ;
 end.
(III): (* Compute the inorder indexes
that are directly influenced by the last
level. These will be associated with
nodes in the left part of the tree *)
 for each node (q,r) do
 begin
 $s \leftarrow 1$ ;
 loop
    $temp \leftarrow ((q-1)*m+s) * m^{(h-r+1)}$ ;
    if $temp > w$ or $s = m$ then exit ;
    $X_s \leftarrow temp$ ;
    $s \leftarrow s+1$;
 forever
 end
(IV): (* Compute the inorder indexes for
the rest of the tree *)
 for each node (q,r) with $r < h+1$ do
 begin
 $s \leftarrow m-1$ ;
 loop
    $temp \leftarrow ((q-1)*m+s) * m^{(h-r)} + c$ ;
    if $temp \le w$ or $s = 0$ then exit ;
    $X_s \leftarrow temp$ ;
    $s \leftarrow s-1$ ;
 forever
 end.
(V): (* Compute pointer values*)
 for each node (q,r) do
 begin
 if $u = 0$ then $q_1 \leftarrow v$ else $q_1 \leftarrow v+1$ ;
 (* node $(q_1,h+1)$ contains w *)
 $q_2 \leftarrow \lfloor (q_1-1)/m \rfloor + 1$;
 (* $(q_2,h)$ is the parent of $(q_1,h+1)$*)
 $j \leftarrow (q_1-1) \bmod m$ ;
 (* $A_j$ of $(q_2,h)$ points to $(q_1,h+1)$ *)
 for $s \leftarrow 0$ to $m-1$ do
 if $r < h$ or ($r = h$ and $q < q_2$)
 or ($r = h$ and $q = q_2$ and $i \le j$)
 then $A_s \leftarrow$ node $((q-1)*m+s+1,r+1)$
 else $A_s \leftarrow$ null ;
 end.
```

Lemma 3.1 The following are true for a complete m-way search tree : (i) The right most node of level $h+1$ is node$(v,h+1)$ when $u = 0$ and node$(v+1,h+1)$ otherwise. (ii) The last element of the right most node at level $h+1$ is w.

Theorem 3.2 Algorithm 2 correctly constructs the required complete m-way search tree within O(1) time if O(n) PEs are available.

## 4. IMPLEMENTATION AND CONCLUSIONS

In section 3, we have presented an optimal parallel algorithms for rebalancing or constructing balanced m-way search trees. If n keys are to be associated with the tree then the construction can be carried out in O(1) time using O(n) PEs. A more detailed discussion can be found in [DPI]. When the dictionary is stored in external memory. The storage structure is chosen so that the number of I/O operations are minimized. An m- way search tree is a popular choice. m is selected to fit the physical characteristics of the external storage [HS]

The above observations can be translated quite effectively to practice in our MIMD environment. The system can initiate any number of searches in a "pipelined" fashion. Each search is conducted using only one PE. leaving one machine cycle between consecutive requests. Search results can be obtained in a pipeline interval of O(1). While some PEs are conducting searches other PEs are free to perform other tasks.

Our solution is applicable for a general purpose machine environment. The m-way search tree is kept in external storage. At any point of time k PEs are available, $0 \le k \le P$ (P is the maximal number of PEs available on the a machine.). In such a machine the operating system can be instructed to allocate only one processor for a search operation and as many PEs as available or required ( whichever is the minimum), in case a new tree has to be constructed or an existing tree rebalanced.

## ABSTRACT

This paper presents a stream-oriented parallel processing scheme for relational database operations (relational operations). By combining the stream processing principle with demand-driven control, this scheme exploits the pipeline concurrency inherent in a query and makes it possible to execute relational operations with limited resources. This paper presents a basic algorithm for this stream-oriented parallel processing scheme and discusses its features and effectiveness.

## 1. Introduction

The relational data model [1] proposed by E. F. Codd has received much attention as a practical data model based on a set theory. However, many problems remain to be solved in applying the model to practical applications. In particular, improvement of the performance in executing relational operations is essential in implementing a relational database system.

Most conventional parallel processing schemes for relational operations were designed to improve the execution performance of an individual relational operation, such as the join, selection or projection operations ([4],[6],[7],[8] et al.).

This paper presents a novel parallel processing scheme called the stream-oriented parallel processing scheme (stream scheme). This scheme is based on the stream processing principle [2], and exploits the parallelism inherent in a query. The stream scheme is attractive not only for the design of a dedicated database machine but also for the design of a distributed query processing system [10]. In particular, when memory and processor resources are limited, this scheme acts to the best of its ability making efficient use of those resources. The conventional schemes do not alleviate problems due to the complexity of resource management, such as memory overflow when executing relational operations. For example, processing performance decreases drastically when the amount of main memory available is less than that required to process the operand relations. By combining the stream processing principle with demand-driven control, the stream scheme enables relational operations to be executed with limited available memory and to effectively exploit the parallelism of pipeline processing.

This scheme can also be applied to query processing in a sequential machine. In such a case, relational operations are described as concurrent processes, and each relational operation for query processing is executed in quasi-parallel.

In the stream scheme, since the scheme to execute an individual relational operation is not restricted, efficient conventional schemes can be employed as the internal processing scheme for a relational operation.

The main features of the stream scheme are as follows:

(1) Intermediate data does not cause memory overflow even in query processing in which the join operation, Cartesian-product operation or union operation creates a large intermediate relation.

(2) Concurrent pipeline processing is performed between relational operations in a query. The scheme exploits parallelism by adapting to existing system resources.

(3) This scheme enables a relational operation to be activated when a subset (several tuples) of each operand relation is ready to be processed. As a result, the response time required to obtain the earlier parts of resulting tuples of a query can be shorten.

## 2. An Algorithm for Relational Operations

A query can be thought of as a tree whose nodes represent a set of relational operations. The leaves of the tree only reference source relations of the database. In the stream scheme, a query is executed as shown in Fig.1. We define the consuming node of intermediate tuples produced by a node as the "upper node"(upper relational operation node), and the producing node of intermediate tuples as the "lower node"(lower relational operation node). Each node has one or two input buffers. When a relational operation node receives a demand from the upper node, it accesses a page in its input buffer and then executes the relational operation until it completes the production of one resulting page of tuples in the output buffer. The output buffer is then treated as the input buffer for the upper node. Here, "access a page" means that a node is ready to perform a relational operation on a page in its input buffer.

0190-3918/86/0000/1013 $01.00 © 1986 IEEE

Individual relational operation nodes do not create a whole intermediate relation for a single demand. Each one creates only one page of tuples for a single demand. Individual buffers do not require the capacity to store an entire intermediate relation. The size of each page is set to half of the corresponding buffer size, that is, each buffer has two storage areas so that two pages can be stored. As the sizes of buffers assigned to relational operation nodes are different, the page sizes are also different. Immediately after a node begins to access a page in one of two areas of its input buffer, it sends a demand to the lower node to refill the other area of the input buffer with the subsequent page. In this algorithm, it is assumed that the double buffering mechanism is supported in every buffer. That is, while the node accesses a page in one area of its input buffer to execute a relational operation, the lower node can store a page in the other area of the same buffer at the same time.

As a result, concurrent pipeline processing is performed between relational operation nodes. By using demand-driven control, unary relational operations (the selection, restriction and projection operations), and binary relational operations (the join, union, intersection, difference and Cartesian-product operations) can be concurrently executed with limited memory resources. In particular, this algorithm shows attractive advantages in executing the join, union and Cartesian-product operations, which are the most time- and resource-consuming operations.

## 2.1 Unary Relational Operations

A unary relational operation node has one input buffer and one output buffer. Unary relational operations are executed by the following algorithm.

Step (1) When the unary relational operation node receives a demand from the upper node, it repeatedly executes Steps (2) and (3) until one page made up of the resulting tuples is created and stored in the output buffer.

Step (2) A single page is accessed in one area of the input buffer. At this time, the other area of this input buffer becomes available and a demand is pre-issued to the lower node to refill the other area of that buffer with the subsequent page. As a result, pipeline concurrent processing is implemented between this unary relational operation node and the lower node.

Step (3) The relational operation is executed on the page that has just been accessed in Step (2), and the resulting tuples are stored in the output buffer. Once a page in the input buffer is manipulated in this step, the page is deleted from the buffer. If the output buffer is filled with a page of resulting tuples, the execution is suspended at this point and the node waits for the next demand from the upper node. Otherwise, Steps (2) and (3) are executed repeatedly. If the page being manipulated is the last one of the operand relation, the execution of this relational operation is terminated.

For the projection operation, if the primary key attribute is not included as an operand attribute, it is necessary to eliminate duplicate tuples. Therefore, the resulting tuples in the output buffer of the projection node must not be deleted even after the upper node have completed manipulating those tuples. That is, the projection node must reserve the output buffer area to provide storage for all of the tuples resulting from the projection operation.

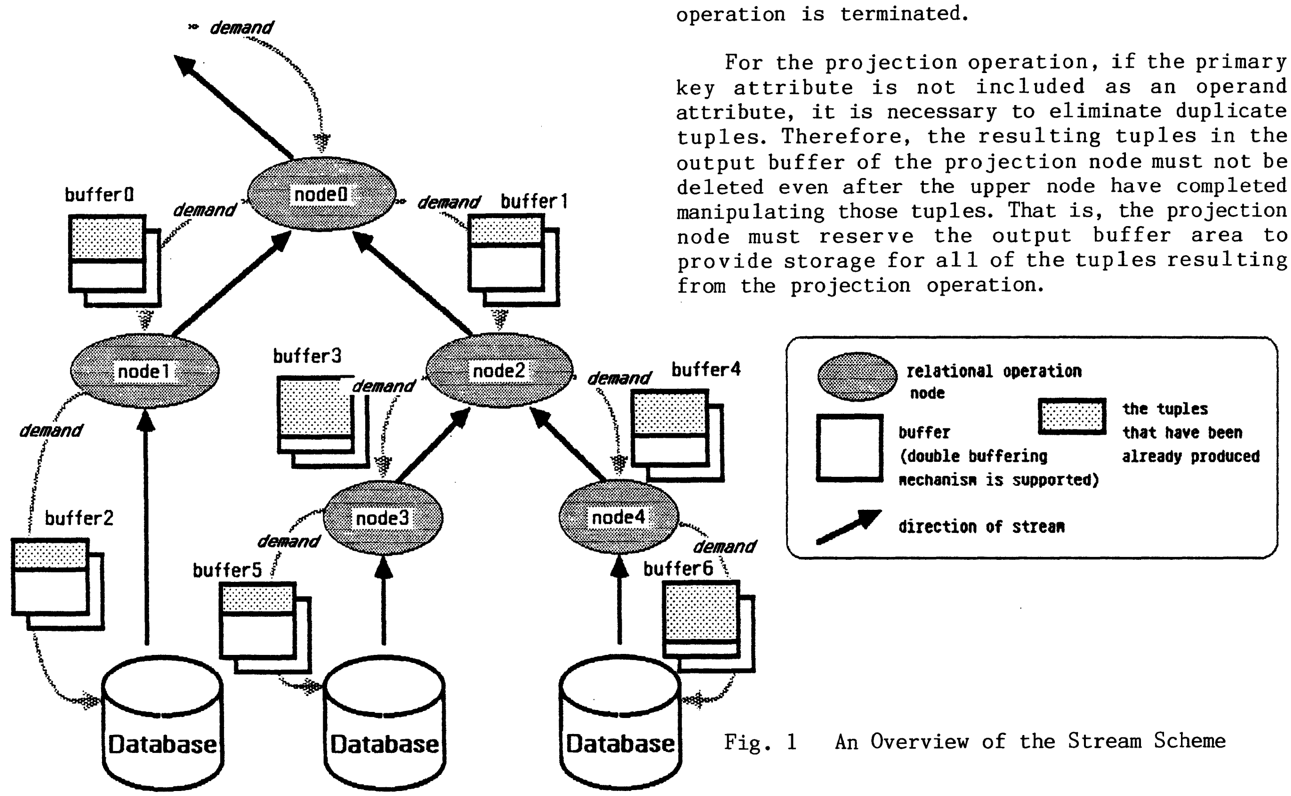

Fig. 1 An Overview of the Stream Scheme

### 2.2 Binary Relational Operations

In binary relational operation nodes, the operation is carried out by comparing each page of the outer-relation with all of the pages of the inner-relation. That is, the nested-loop algorithm is applied to the page-level granularity. The comparison algorithm applied to the tuple-level granularity within a page is not restricted.

The sort-merge, nested-loop or hashing algorithms can be used to compare the tuples of two different pages. Even dedicated multiprocessors can also be utilized to compare two operand pages. Each binary relational operation node has two input buffers and one output buffer. One of the input buffers is used for storing outer-relation pages and the other for storing inner-relation pages. Binary relational operations are executed by the following algorithm.

Step (1) When the binary relational operation node receives a demand from the upper node, it executes Steps (2), (3) and (4).

Step (2) One outer-relation page is accessed in one of two areas of the input-buffer with the subsequent outer-relation page. Then, a demand is pre-issued to the lower node which produces outer-relation pages to refill the other area of that buffer. By issuing the demand in advance before executing the relational operation, the production of the following operand page in the lower node overlaps with the execution in this relational operation node.

Step (3) One inner-relation page is accessed in one of two areas of the input-buffer. Then, a demand is pre-issued to the lower node to refill the other area of the input-buffer.

Step (4) The relational operation is executed by comparing the outer-relation page accessed in (2) with the inner-relation page accessed in (3). The resulting tuples are stored in the output buffer. When one of two areas of the output-buffer is filled as the result of the demand received in (1), the execution is suspended until the next demand is issued from the upper node. Otherwise, (3) and (4) are executed repeatedly. If the inner-relation page being compared with the outer-relation page is the last page and the outer-relation page is not the last one, then the lower node which creates inner-relation pages is initialized and control returns to (2). (This means the reproduction of the inner-relation by the lower node. The inner-relation is reproduced in order to compare all inner-relation pages with each outer-relation page. If all of the outer-relation pages are stored in the input buffer, this reproduction is not required.) If both of the pages being compared with each other are last pages, the execution of the relational operation is terminated.

## 3. Design Considerations

### 3.1 Stream Processing

This section discusses the basic concepts and properties of the stream scheme. In Fig.1, the relational operation nodes (node-1, node-3 and node-4) for a query can be executed in parallel because these relational operations are independent. Furthermore, the concurrency among relational operation nodes which are vertically connected can also be exploited in the stream scheme.

A stream is an ordered sequence of data which are arranged according to the order of production. In this scheme, each element of a stream corresponds to a tuple or a page in a relation. Therefore, the ordered sequence of tuples or pages is manipulated as a stream. In processing relational operations, it is not necessary to wait for the production of complete operand relations. Processing of relational operations can start immediately after an earlier part of the stream is constructed.

Criteria for exploiting parallelism are given here. We will consider a subquery consisting of two join operation nodes as shown in Fig.2. It is assumed that the two operations are executed in different processors and each operation is executed by using the nested-loop algorithm for tuple-level granularity in comparing two operand pages. For the sake of simplicity, it is also assumed that communication overhead between processors does not exist. This is a reasonable assumption because execution process of a relational operation can overlap the communication process. Furthermore, the execution time is much longer than communication time when a single processor is used in each node. If a multiprocessor is allocated to each node, the communication overhead may affect the parallelism of stream processing.

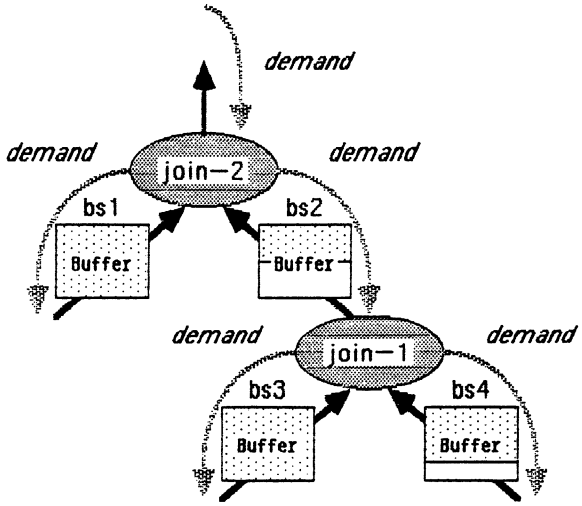

Fig. 2 Pipeline Concurrency in a Subquery

If the join-1 node completes producing the next operand page while join-2 node executes the comparison of two operand pages currently stored in the input buffers, pipeline delay will be eliminated. That is, in the join-2 node, the suspension of the relational operation execution which occurs due to the absence of the next inner-relation page causes pipeline delay. The criterion is given by the following formula. "jsf1" represents the join selectivity factor of the join-1 node. The number of tuples of an intermediate relation is jsf1*(the number of tuples in the outer-relation)*(the number of tuples in the inner-relation). "bs1" and "bs2" are the sizes (the number of tuples) of buffers to store an outer-relation page and an inner-relation page in the join-2 node.

1) The number of times the tuples in an inner-relation page and the tuples in an outer-relation page are compared in the join-2 node is

$$bs1*bs2. \qquad (1)$$

2) The number of times of comparisons in the join-1 node to produce an inner-relation page for the join-2 node using the nested-loop (1/jsf1 is the average number of times of comaparisons to generate one tuple by the nested-loop) is

$$bs2/jsf1. \qquad (2)$$

3) The condition to continue processing in the join-2 node without suspension is

$$(1) = (2), \text{ that is,}$$
$$bs1 = 1/jsf1. \qquad (3)$$

In general, the criterion to exploit the maximum parallelism between two relational operation nodes is

buffer size for an outer-relation page
= 1/join selectivity factor of the lower node. (4)

If this criterion is satisfied between two nodes in two different processors, highly concurrent processing can be realized.

If the sort-merge algorithm or the hashing algorithm is used in the comparison between an inner-relation page and an outer-relation page, approximately the same criterion as that used for the nested-loop algorithm is given. If a multi-processor is used to implement the nested-loop algorithm in each node and the communication overhead among processors is not considered, the criterion is

$$bs1 = P2/(jsf1*P1). \qquad (5)$$

(P1 and P2 are the numbers of processors allocated to the join-1 and join-2 nodes, respectively.)

### 3.2 Demand-driven Control

The stream constructed by the pipeline processing can be controlled according to the buffer capacity by demand-driven control. The stream flowing on the pipeline is limited and the computation on the stream can be carried out in a limited resource environment. That is, buffer overflow does not occur even if the join, Cartesian-product or union operations create a large intermediate relation. However, if a whole outer-relation is not stored in the input buffer in processing a binary relational operation, the inner-relation must be reproduced as described in Subsection 2.2. In this case, a source relation, or an intermediate relation produced by applying selection and projection operations prior to the binary relation, must be re-accessed. Therefore, when the reproduction of an intermediate relation causes a heavy overhead, the input buffer for outer-relation pages should have enough capacity to store the whole outer-relation. In such a case, we may change Step (4) of the algorithm described in Subsection 2.2 as follows:

To avoid having to reproduce the inner-relation, all of the outer relation pages are produced all at once in Step (2). At this time, the outer-relation pages overflowing from the input buffer are stored in secondary storage. In Step (4), each of the outer-relation pages is compared with the inner-relation page, which was accessed in Step (3), until the output-buffer is filled. When the output buffer is full, the execution is suspended until the next demand is issued from an upper node. If the outer-relation page being compared is the last page, control returns to Step (3). If both pages being compared are last pages, the execution of the relational operation is terminated.

### 3.3 Design Approaches

Two approaches to the design of a relational database system based on the stream scheme can be considered. One approach is based on developing a distributed query processing system on conventional computers connected to a local area network. In general, in the local area network environment, the number of processors used for database processing is restricted. Also, the capacity of main memory allocated to each processor is restricted. The stream scheme is attractive in such a resource-limited environment. This approach is presented in [10].

The other approach is based on developing a dedicated machine for the stream scheme. One candidate for a dedicated machine is to design a dataflow machine with demand-driven control mechanism. It is well known that the dataflow computation is suitable for the exploitation of the parallelism inherent in a functional program. Relational operations can be described in a functional programming language providing the specifications of eager and lazy evaluation mechanisms[9]. Furthermore, the eager and lazy evaluation mechanisms are useful for realizing pipeline processing and demand-driven control[11]. Therefore, by specifying these mechanisms in describing the programs of relational operations, the stream scheme is implemented on a dataflow machine supporting eager and lazy evaluation mechanisms.

## 4. Performance Considerations

### 4.1 Effects of Stream Processing

The stream scheme was experimentally examined under the UNIX 4.2BSD on the Sun-2 workstation[14]. The experimental environment for stream processing is summarized as follows:

(1) Each relational operation node is described as a coroutine, and pipeline processing among relational operation nodes is simulated.
(2) A whole outer-relation is retained in an input buffer, that is, an inner-relation do not have to be reproduced.
(3) In the join node, the sort-merge algorithm is used to compare an inner-relation page with an outer-relation page. An inner-relation page and an outer-relation page are first sorted on joining attributes, respectively. After that, these pages are joined by using the merge operation. It is assumed that the sort-merge algorithm is implemented by a sequential process.
(4) In this environment, the situation in which the demand-driven control is not employed can also be simulated. We call this situation "non-demand-driven case". In the non-demand-driven case, though relational operation nodes are activated on the basis of the page-level granularity in the same manner as the demand-driven case, the production of pages is not controlled by the demand-driven mechanism. Therefore, although pipeline concurrency can be exploited, intermediate pages may cause buffer overflow.
(5) The communication time between processors is set to 16.6 msec/2k bytes. It is assumed that communications are performed exclusively. That is, when two processors are communicating, no other processors can communicate with each other.

The sample query shown in Fig.3 is chosen from the benchmarks described in [13]. This query consists of two join operations and two selection operations. The parameter settings of source relation sizes, join selectivity factors (jsf), selection selectivity factors (ssf) and buffer sizes are shown in Table 1. Tuples in all relations are 64 bytes long, each including two 4-byte integer attributes as joining attributes. All integer attributes have uniformly distributed values, but the range of their distributions varies in order to provide different join selectivity factors.

The experimental results are shown in Table 2. As the join selectivity factors (jsf1 and jsf2) of the join nodes(join-1, join-2) increase, the first response time (the time to obtain the first resulting page of a query) becomes shorter in the stream scheme. On the other hand, the response time (the time to obtain all of the resulting pages) becomes longer as the increase of the jsf because the number of tuples in the intermediate relation manipulated by the join-1 node becomes larger. However, in comparing the case of jsf1=jsf2=0.002 with the case of jsf1=jsf2=0.001, though the number of tuples in the intermediate relation manipulated by the join-1 node doubles, the increase of the response time is smaller. This is because join-1 and join-2 processings overlap due to pipeline effect.

In comparing the experiment-1 (buffer1 = buffer3 = buffer5 = 10(tuples)) with the experiment-2 (buffer1 = buffer3 = buffer5 = 100(tuples)), the first response time in the experiment-1 is shorter than that in the experiment-2. This is because the time to activate the join-2 and join-1 nodes can be shorten in the small buffer case. On the other hand, the response

FR Time : First Response Time (sec)
R Time : Response Time (sec)

time in the experiment-1 becomes longer than that in the experimental-2. This is because the communication overhead between two nodes cause overhead in the smaller granularity case. Furthermore, since the sort-merge algorithm is used in comparing two operand pages, the total number of times of comparisons increases in the smaller granularity case.

In comapring the response time in the demand-driven case with that in the non-demand-driven case in Table 2, the response times of both cases are almost the same. This result shows that the overhead due to the transfers of demands did not affect to the response time. In general, the time to transfer a demand between processors is much shorter than the time to transfer a page. Therefore, the transfers of demands do not cause heavy overhead.

Another major interest is in comparing the memory requirement in the demand-driven case with that in the non-demand-driven case. Fig.4 shows the memory requirement for the inner-relation pages of each join node in the experiment-1, and Fig.5 shows that in the experiment-2. In the demand-driven case, a query can be executed with the fixed sizes of buffers. On the other hand, in the non-demand-driven case, the memory requirement for the buffer increases as increasing the join selectivity factor. Though the response times in both cases are approximately the same, the memory requirement in demand-driven case is much smaller than that in the non-demand-driven case. In particular, in the non-demand-driven case, when the time to produce a page in the lower node is much longer than the time to consume the page in the upper node, the input buffer of the upper node must have an enough capacity to store the large amount of the intermediate pages. Since the selection operation node (selection-2) which is the lower node producing the inner-relation pages of the join operation (join-2 node) produces pages very fast, the input-buffer(buffer-5) of the join-2 node must store many inner-relation pages. In the join-1 node, as the join-2 node produces the intermediate pages of the inner-relation of the join-1 node faster as increasing the join selectivity factor, the memory requirement becomes

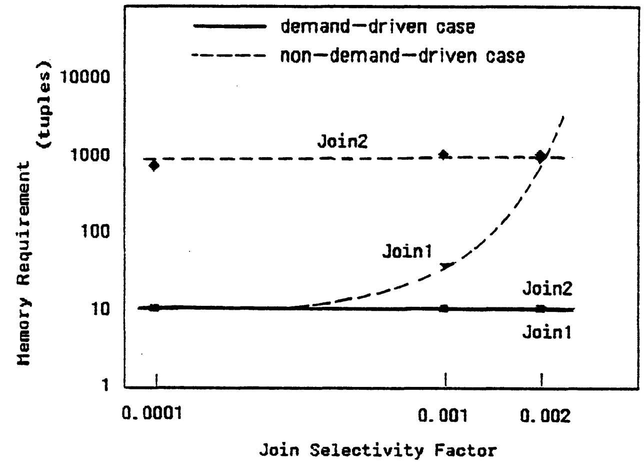

Fig. 4 Memory Requirement (Experiment-1)

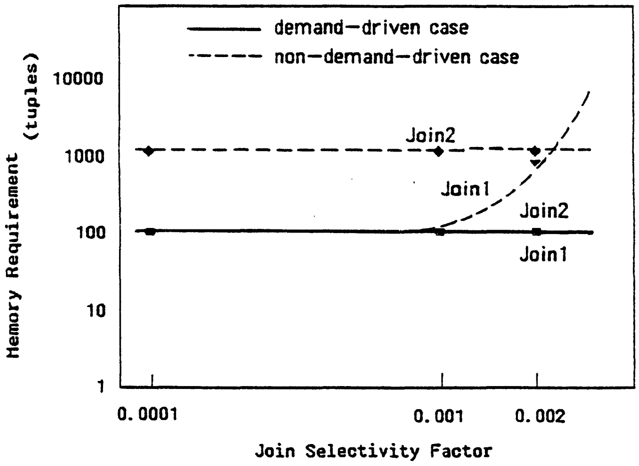

Fig. 5 Memory Requirement (Experiment-2)

larger. In those situations, the superiority of the stream scheme is distinguished.

## 4.2 Comparisons with Conventional Schemes

In this evaluation, it is assumed that each relational operation node is constructed with a multiprocessor. It is also assumed that the source relations, or intermediate relations whose sizes were reduced by applying selection or projection operations prior to the join operation are retained in the main memory. The performance of the stream scheme in executing the join operation is represented as follows: T1 and T2 are the numbers of tuples in the outer-relation and the inner-relation of the join node, respectively; Im is the number of tuples in the outer-relation of the upper relational operation node if the upper node is a binary relational operation. Otherwise, Im is set to B; B is the number of tuples that can be stored in a buffer(It is assumed that the size of each buffer is the same.); "jsf" is the join selectivity factor of the join node being evaluated; "jsf2" is the join selectivity factor of the lower join node; P1 is the number of processors allocated to the join node being evaluated; P2 is the number of processors allocated to the lower join node; P is P1+P2; Cm is the time required to broadcast a tuple to the processors; Ro is the comparison time between two tuples; Sw is the swapping time of a tuple; and Wr is the storing time of a resulting tuple.

The total number of times tuples are compared is

$$T1*T2*(Im/B).$$

The memory requirement is

$$3*B.$$

The swapping time of tuples in operand intermediate relations is

$$0.$$

The processing time of the join in the multiprocessor node is

$$Cm*B + Ro*B/(jsf2*P2) + Wr*B/P2 \\ +(T1/B)*(T2/B)*\max(Cm*B+Ro*(B*B/P1)+Wr*jsf*B*B/P1, \\ Cm*B+Ro*B/(jsf2*P2)+Wr*B/P2).$$

In most conventional schemes for relational operations, the granularity for the operand data of each relational operation is set to a relation. In this case, after the relational operation node completely produces a whole intermediate relation, then the subsequent relational operation is activated. Therefore, parallelism of pipeline processing between relational operations is not exploited, and furthermore memory swapping is necessary between main storage and secondary storage when memory overflow occurs due to intermediate relations. If the granularity of data in activating a relational operation is set to a page, the advantages of pipeline concurrency inherent in a query can be utilized[3],[12]. An execution scheme that implements this pipeline processing by using the data-driven control mechanism has been proposed[5]. However, pipeline processing using data-driven control may cause heavy overhead when executing a query.

A binary relational operation node is required to compare each outer-relation page with all of the inner-relation pages. Therefore, even if only one inner-relation page and only one outer-relation page remain to be produced, all of the other produced outer-relation pages and all of other produced inner-relation pages must be kept in storage. As a result, every node of a query may be forced to keep large amounts of intermediate data in storage.

We compare the stream scheme with a typical conventional scheme which employs the relation-level granularity when activating a relational operation. We assume this conventional scheme implements a relational operation using parallel nested-loop algorithm[4]. This algorithm is employed in many database machines. If it is employed, each tuple of the outer-relation is compared with every tuple of the inner-relation. In the conventional scheme, the total number of times tuples are compared is

$$T1*T2.$$

The memory requirement is

$$T1+T2+jsf*T1*T2.$$

The swapping time of tuples in intermediate relations is

$$Sw*((T1-B)+(T1/B)*(T2-B) + (jsf*T1*T2-B)).$$

The processing time of the join operation in a multiprocessor is

$$Cm*T1 + Ro*T1*T2/P + Wr*jsf*T1*T2/P.$$

The total number of times tuples are compared in the conventional scheme is O(T1*T2) and that in the stream scheme is O(T1*T2*Im/B). "Im/B" indicates the number of times the inner-relation is reproduced when the whole outer-relation is not retained in the input buffer. The stream scheme overcomes this overhead because of utilization of pipeline processing, and the prevention of memory overflow.

As described in Section 2, memory overflow due to intermediate relations does not occur in the stream scheme. In the conventional scheme, on the other hand, if the intermediate relation becomes larger than the buffer size, memory swapping must be done between secondary storage and the buffer. The O(T1*(T2-B)/B) number of tuple swapping times is required. The number of swapping times is almost the same as the number of times tuples are compared in the nested-loop algorithm. In general, since the tuple swapping time is much longer than the tuple comparison time, the memory overflow causes heavy overhead. That is, the superiority of the stream scheme is distinguished when memory overflow occurs in the conventional scheme.

The advantage of the stream scheme increases in proportion to the increase of the join selectivity factor. This is because the stream of tuples continuously flows through the pipeline among the relational operation nodes in the larger jsf case. On the other hand, in the conventional scheme, the size of the intermediate relation increases according to the increase of the join selectivity factor. As the result, the subsequent relational operation node must munipulate a larger intermediate relation, and the processing time of the subsequent node becomes longer. Therefore, when the join selectivity factor is large, the stream scheme is more effective than other schemes. Furthermore, even when the join selectivity factor is small, the processing time required in the stream scheme to execute a query is almost the same as in the conventional scheme. In such a case, the number of reproduction times(Im/B) becomes less because Im becomes smaller as the join selectivity factor decreases. That is, when the join selectivity factor is small, the stream scheme executes a query in almost the same fashion as the conventional scheme.

## 5. Conclusions

We have presented a stream oriented execution scheme for relational database operations. This scheme is based on the stream processing principle. By combining stream processing with demand-driven control, this scheme exploits pipeline concurrency and makes it possible to execute relational operations with limited resources while avoiding the complexity of resource management. In this paper, we have presented a basic algorithm for the stream-oriented parallel processing scheme and have also discussed the features and the effectiveness of the stream scheme.

As mentioned in Subsection 3.3, two implementation approaches for the stream scheme can be considered. A distributed query processing system based on the stream scheme is currently being developed in a local area network environment[10].

We believe that concepts included in the proposed stream-oriented parallel processing scheme will contribute to the development of relational database systems.

## Acknowledgements

The authors would like to thank Professor Takashi Masuda (Univ. of Tsukuba) for valuable discussions and suggestions. Special thanks are due to Kazuhiko Kato (Univ. of Tsukuba) for his valuable discussions and support in evaluating the performance of the stream scheme.

## Abstract

A partition and replicate strategy for processing distributed queries referencing no fragmented relation is sketched. An optimal algorithm is given to decide which relation is to be partitioned into fragments, which copy of the relation is to be used, how the relation is to be partitioned and where the fragments are to be sent for processing. The time complexity of the algorithm is $O(N_d\ m \log m + r \log r)$, where $N_d$ is the total number of copies of the relations referenced by the query, m is the number of sites and r is the number of relations. Under the situations that all sites have the same processing speed and the cost functions for data transmission and local processing cost are linear, the time complexity of the algorithm is reduced to $O(r\ |AS(Q)| \log |AS(Q)| + r \log r)$, where $|AS(Q)|$ is the number of sites having a copy of a relation referenced by the query.

## 1. Introduction

Distributed query processing is an important factor for the performance of a system with the databases distributed in a network. Many distributed query processing algorithms [ApHY, BeCh, BeGo, BlLu, CDFG, ChBH, Chan1, Chan2, ChHo, ChHu ChLi1, ChLi2, ChLi3, EpSW, GoSh, HeYa, KeYa, Luk2, SDD1V1, SDD1V2, Woka, Wong, WOHL, Yaos, YCTB, YLCC, YuOz] have been proposed. Most of these algorithms assume that the data communication cost is dominant and make use of semijoins to reduce the amount of data transfer. While such an assumption is reasonable for long-haul networks where data communication costs are high, it may not be valid for fast local networks. In contrast the "fragment and replicate" (a fragmented relation remains to be fragmented, while other relations are replicated at the sites of the fragmented relation) query processing strategy was used in distributed Ingres [EpSW]. Its main feature is to allow parallel processing. However, for many queries, substantial data transfer is required before parallel processing can take place unless many relations are duplicated in many sites.

We have developed two algorithms. The first algorithm, the semijoin algorithm [YCTB, YCTBL], is an extension to the SDD-1 algorithm [SDD1V2] which assumes that the most important cost is the number of bytes transmitted between network nodes. The algorithm was extended to support fragmented and replicated relations. The other algorithm, the replicate algorithm [BrTY, YGCC] is derived from distributed Ingres [EpSW]. It assumes that local processing cost dominates network costs and uses fragmented relations to maximize the amount of parallelism in operations.

We have done the performance analysis for these two algorithms [BrTY, TBCD]. We found that the replicate algorithm outperforms the semijoin algorithm in a fast local network environment. Thus, in a fast local network, it is preferable to use a fragment and replicate algorithm. However, if no relation referenced by a query is fragmented, it is necessary to decide the relation and its copy to be partitioned into fragments, how the relation is to be partitioned and where the fragments are to be sent for processing. This paper provides answers to the above questions and gives an optimal algorithm in time $O(N_d\ m \log m + r \log r)$, where $N_d$ is the total number of copies of the relations referenced by the query, m is the number of sites and r is the number of relations. Under the special case that all sites have the same processing speed and the cost functions for data transmission and local processing cost are linear, the time complexity reduces to $O(r\ |AS(Q)| \log |AS(Q)| + r \log r)$, where $|AS(Q)|$ is the number of sites having a copy of a relation referenced by the query.

## 2. Problem definition and notations

A relation $R_i$ is partitioned into a number of fragments $\{F_{ij}\}$ if $|R_i| = \sum_j |F_{ij}|$.

Suppose $\{R_1, R_2, \ldots R_r\}$ are the relations to be joined as specified in a query and all of them are not fragmented. One of them, say $R_f$, will be chosen to be partitioned into d fragments, for some integer d. Then, the fragments will be assigned to a set of d sites. The other relations, if not present at each of the d sites, will be replicated at those sites. The answer is the union of the joins of the fragments with the other realtions at the d sites. The problem is to decide (i) the relation to be partitioned i.e. $R_f$ (ii)

0190-3918/86/0000/1021 $01.00 © 1986 IEEE

the number of fragments the relation is to be partitioned i.e. d (iii) the size of each of the d fragments (iv) the sites where the fragments are to be assigned (v) the copy of the partitioned relation to be used, if multiple copies exist, such that the response time (in terms of both local processing cost and communication cost) is minimized.

The following notations are used with respect to the given query Q.

AS(Q): Accessed Sites; the set of sites containing at least a copy of a relation referenced by Q.

NAS(Q): Non-Accessed Sites; the set of sites containing no relations referenced by Q.

$CS(R_f)$: The set of sites each containing a copy of the relation $R_f$ to be partitioned.

As in [YGCC, YGZT], the cost of joining relations $R_1,...R_n$ is given by $h(R_1) + ... + h(R_n)$, where

$$h(X) = \begin{cases} f(X) & \text{if there exists a fast access path(e.g. index) for the joining operation involving X} \\ n(X) & \text{otherwise,} \end{cases}$$

with $f(X) << n(X)$.

This is a rough approximation, with the implicit assumption that the join is restrictive.

$W(R_f,p)$: The weight of site p. This includes the cost to transmit required data into the site from other sites and the processing cost at the site but not including the costs associated with relation $R_f$, which is chosen to be partitioned. The weight

$$= \sum_{D_{ij} \text{ in } p, i \neq f} h(D_{ij})/Sp(p) + \sum_{D_{ij} \text{ not in } p, i \neq f} [t(D_{ij})/Tspeed + n(D_{ij})/Sp(p)]$$

where $D_{ij}$ is a copy of relation i at site j and Tspeed is the communication speed of network, and Sp(p) is the processing speed of site p; t() is the cost function for data transfer. The first term represents the local processing cost for those data already at site p, taking into consideration the processing speed of the site. The second term gives the local processing cost and the data trasmission cost for the data to be transferred into site p.

d-partition: A relation is partitioned into d fragments.

$par(R_f)$: The cost function to partition $R_f$. This is assumed to depend only on the size of the relation $R_f$.

$PS(R_f,d)$: The set of the processing sites each of which is assigned one fragment of $R_f$, if the partition is a d-partition, i.e., $|PS(R_f,d)| = d$.

$PT(PS(R_f,d),s)$: A d-partition of $R_f$ by using the copy of $R_f$ at site s (if multiple copies of the relation exist) and the processing sites $PS(R_f,d)$.

$F(R_f,d,p)$: The size of the fragment that will be assigned to site p for a d-partition of $R_f$.

$Assign(R_f,d,p,s)$: The cost to assign and to process a fragment of size $F(R_f,d,p)$ at site p, $p \in PS(R_f,d)$ by using the copy of $R_f$ at site s for partition.

$$= \begin{cases} t(F(R_f,d,p))/Tspeed + n(F(R_f,d,p))/Sp(p) & \text{if } p \neq s \\ n(F(R_f,d,p))/Sp(p) & \text{if } p=s. \end{cases}$$

It is assumed that after the partitioning process, fast access paths, if exist earlier, will be lost. Thus, the cost function for not having a fast access path, n(), is used.

$cost(R_f,d,p,s)$: The total ( processing and communication ) cost at site p when the copy of $R_f$ at site s is chosen to be partitioned into d fragments, and the fragment of size $F(R_f,d,p)$ is assigned to site p.

$= W(R_f,p) + Assign(R_f,d,p,s) + par(R_f)/Sp(s)$.

Note that since each processing site has to wait for the completion of the partitioning of $R_f$, $par(R_f)/Sp(s)$ is incurred at each processing site.

All cost functions t(), h(), f() and par() are monotonically increasing functions i.e. if the relation/fragment is larger, a higher cost will be incurred for local processing and/or data transfer.

$Res(R_f,d,s)$: The response time obtained at d-partition when the copy of $R_f$ at site s is chosen to be partitioned into d fragments and the processing sites are $PS(R_f,d)$.

$$= \max_{p \in PS(R_f,d)} \{ cost(R_f,d,p,s) \}$$

We are interested in minimizing $Res(R_f,d,s)$.

## 3. Partition strategy

### 3.1 Determine the optimal processing sites

Given a relation and its copy to be partitioned, we want to determine (1) the processing sites (and therefore the number of partitions) and (2) how the relation is to be partitioned and assigned to the processing sites.

Proposition 1 below shows that an optimal way to assign fragments to processing sites is in such a way that each processing site will have the same total cost. Thus, it remains to determine the processing sites. We will show in Propositions 3 and 4 that (i) if a site is not used as a processing site, then those sites with weights higher than or equal to that of the site should not be used as processing sites and (ii) if a site is used as a processing site, then those sites with weights smaller than or equal to that of the site should be used as processing sites. Based on results (i) and (ii), all sites are arranged in ascending order of weight. Consider site t. If site t is not a processing site, then sites (t+1) to the last site need not be considered; otherwise, site 1 to site t and possibly the next few sites will be processing sites.

Proposition 1: Let $Res(R_f,d,s)$ and $Res_1(R_f,d,s)$ be the response times obtained by the d-partitions $PT(PS(R_f,d),s)$ and $PT_1(PS(R_f,d),s)$, respectively. If the d-partition $PT(PS(R_f,d),s)$ makes $cost(R_f,d,p,s) = cost(R_f,d,j,s)$ for every pair p,j $\notin PS(R_f,d)$ then $Res(R_f,d,s) \leq Res_1(R_f,d,s)$.

Definition: S is an optimal set of processing sites for the copy of relation $R_f$ at site t if the copy is partitioned into fragments and assigned for processing at each of the sites in S to yield the optimal response time. Each site s in S is an optimal processing site.

Lemma 2: Let $Res(R_f,d,s)$ be the response time obtained by d-partition $PT(PS(R_f,d),s)$.
If $W(R_f,j) + par(R_f)/Sp(s) < Res(R_f,d,s)$, j not in $PS(R_f,d)$, then there exists a (d+1)-partition, $PT(PS(R_f,d+1),s)$, such that $Res(R_f,d+1,s) < Res(R_f,d,s)$, where $Res(R_f,d+1,s)$ is the response time obtained by including site j as a processing site.

Proposition 3: If site p is an optimal processing site and site j satisfies $W(R_f,j) \leq W(R_f,p)$ then site j is also an optimal processing site.

Proposition 4: If site p is not an optimal processing site and site j satisfies $W(R_f,j) \geq W(R_f,p)$ then site j is also not an optimal processing site.

Suppose $R_f$ is the relation to be partitioned. After the sites are arranged in ascending order of weights, the best solution is obtained by assigning the fragments of $R_f$ using Proposition 1 to the first d sites, for some d. We now seek to determine d.

One simple-minded way is to compute the response time for a given d by assigning the fragments of $R_f$ to the first d sites using Proposition 1. Then d is increased by 1 and the process is repeated until an increase in the number of sites yields an increase in the response time or the total number of sites, m, is reached. For a given d, finding the response time for the first d sites takes O(d) time. Since the process may be repeated up to m times, the time complexity is $O(m^2)$.

A more efficient process is as follows. We first consider the middle site, the m/2-th site. If this is not an optimal processing site ( determined by Proposition 5), then it is sufficient to consider the first (m/2 - 1) sites. We then repeat the process by checking the m/4-th site. If the m/2-th site is an optimal processing site, then the 3m/4-th site will be examined. In other words, a binary search is performed on the set of sites. The process of determining whether the i-th site is an optimal processing site will be shown to take at most O(i) time. Since the binary search process is an O(log m) process, the time complexity for determining the optimal number of sites is at most O(m log m). It remains to determine whether a given site is an optimal processing site.

Suppose the given site is the i-th site. Even if this given site is assigned a fragment of size zero (i.e. the site is not a processing site), the time incurred at this site is $T= W(R_f,i) + par(R_f)/Sp(s)$ ( the copy of $R_f$ at site s is partitioned). Suppose each of the preceding (i-1) sites is assigned some part of $R_f$ (the parts of $R_f$ assigned to the sites need not be disjoint) such that its response time is T. The next proposition states that site i is not an optimal processing site if and only if the sum of the sizes of the fragments of $R_f$ assigned to the first (i-1) sites is greater than or equal to the size of $R_f$.

Proposition 5: Suppose size(j) is the size of the part of $R_f$ assigned to site j such that the total cost of site j, $cost(R_f,i-1,j,s) = W(R_f,i) + par(R_f)/Sp(s)$ for each site $1 \leq j \leq i-1$. Then site i is not an optimal processing site iff

$$size = \sum_{j=1}^{i-1} size(j) \geq size(R_f) \qquad (1)$$

where $size(R_f)$ is the size of relation $R_f$.

The process of determining the last processing site is given as follows.

```
BINSEARCH(low,high,result)
/* The relation to be partitioned is $R_f$; the copy
of $R_f$ to be partitioned is at site s. The optimal
set of processing sites is 1 to result. */
    If ( low > high ) then result = high
    else {
         MID = ( low + high )/2 ; MID1 = MID - 1
         For i := 1 to MID1
         {  Assign part of $R_f$ to site i such that
            $cost(R_f,MID1,i,s)$
            $= W(R_f,MID) + par(R_f)/Sp(s)$ }
         If $\sum_{i=1}^{MID1} size(i) \geq size(R_f)$
         then BINSEARCH(MID+1,high,result)
                 /* search right half */
         else BINSEARCH(low,MID-1,result)
                 /* search left half */
    }
```

### 3.2 Determine the copy of the relation to be partitioned

When there are more than one copy of the relation to be partitioned, we need to determine which copy should be used to obtain the best response time. Suppose we use the copy $CO_u$ at the site u that has the fastest processing speed among the sites that have a copy of the relation. Let the set of the optimal processing sites and the optimal response time for this copy be $PS_u$ and $OP_u$ respectively. Proposition 7 below states that any other copy which is not in one of the optimal processing sites, $PS_u$, can not yield a better response time than $OP_u$ and should not be chosen for partitioning.

Suppose there is a copy $CO_v$ at site v which is within $PS_u$. If the set of the optimal processing sites obtained for $CO_v$ is not a subset of $PS_u$ then the response time obtained by using $CO_v$ can not be less than $OP_u$. This is shown in Lemma 6. Thus, we do not need to consider any site outside $PS_u$ as a processing site for copy $CO_v$.

Lemma 6: Let $Res(R_f,d,u)$ and $Res(R_f,d',v)$ be the optimal response times obtained by the optimal partitions $PT(PS(R_f,d),u)$ and $PT(PS(R_f,d'),v)$, respectively, by using the copies $CO_u$ and $CO_v$ of $R_f$ at sites u and v, respectively.

If $Sp(u) \geq Sp(v)$ and $PS(R_f,d') \not\subseteq PS(R_f,d)$ then $Res(R_f,d',v) > Res(R_f,d,u)$.

Proposition 7: Let $Res(R_f,d,u)$ and $Res(R_f,d',v)$ be the optimal response times obtained by the optimal partitions $PT(PS(R_f,d),u)$ and $PT(PS(R_f,d'),v)$, respectively, by using the copies $CO_u$ and $CO_v$ of $R_f$ at sites u and v, respectively.

If $Sp(u) \geq Sp(v)$ and $v \notin PS(R_f,d)$
then $Res(R_f,d,u) \leq Res(R_f,d',v)$.

When there are more than one copy of the relation to be partitioned, one method is to first use the copy at the site that has the fastest processing speed among the sites that have a copy of the relation, then discard some unnecessary copies by applying Proposition 7. The remaining copies are processed in descending order of processing speed of their residing sites. For each such copy, the processing sites will be restricted to be the intersection of the processing sites of the previous copies since, by Lemma 6, no copy can yield a better response time by using any site outside the processing sites of a previous copy. We then compare all such cases and the copy yielding the least response time is chosen. Suppose instead we choose the copy $CO_u$ at the site u that has the fastest processing speed among the sites that contain a copy of the relation to be partitioned, and obtain the response time for this copy. Let the size of the fragment assigned to site j, where a copy $CO_j$ of the relation exists, be $F_j$. (If no copy of the relation exists in a processing site of $CO_u$, then, by Proposition 7, the optimal solution for the relation is obtained.) If we choose $CO_j$ to be partitioned, we incur $par(R_f)/Sp(j) - par(R_f)/Sp(u)$ additional time at each processing site, but we save transmission cost of $t(F_j)/Tspeed$ for site j. If the copy $CO_j$ is chosen to be partitioned, we can reduce the response time by at most $t(F_j)/Tspeed - ( par(R_f)/Sp(j) - par(R_f)/Sp(u) )$. In fast local area networks, the transmission cost is supposed to be small in comparision with processing cost. Thus, the copy at the site with the fastest processing speed should be a good choice.

### 3.3 Discard of certain non-accessed sites

The following result (Proposition 9) says that if a site j is an non-accessed site and the weight of this site for partitioning relation $R_f$ is greater than or equal to the optimal response time obtained by partitioning $R_f$, then this site should not be considered as one of the processing sites for any partitioned relation $R_r$, where $|R_r| \leq |R_f|$, since it will result in higher response time. Thus, if we order the relations in descending order of size, a non-accessed site discarded in the processing of a relation is automatically discarded when a later relation is processed. Suppose site j is discarded. Any non-accessed site whose weight is greater than or equal to site j with respect to relation $R_f$ satisfies the same condition as site j. Thus, it can also be discarded.

Lemma 8: If $j \notin NAS(Q)$ and $|R_f| \geq |R_r|$
then $W(R_f,j) \leq W(R_r,j)$.

Proposition 9: Let $Res(R_f,d,u)$ and $Res(R_r,d',v)$ be the optimal response times obtained by partitioning relations $R_f$ and $R_r$, respectively. Let $PS(R_r,d')$ be the set of the optimal processing sites for partitioning relation $R_r$.
If $j \notin NAS(Q)$, $j \in PS(R_r,d')$, $|R_f| \geq |R_r|$ and $W(R_f,j) \geq Res(R_f,d,u)$
then $Res(R_r,d',v) \geq Res(R_f,d,u)$

### 3.4 An optimal algorithm

We now give an algorithm to find an optimal partition strategy.
Let R(Q) be the set of relations referenced by query Q.
The set of sites $S = AS(Q) \cup NAS(Q)$ i.e. the union of the accessed and the non-accessed sites of Q.
Among the non-accessed sites in NAS(Q), let s be the site having the fastest processing speed.

ALGORITHM PARTITION

```
(1) Estimate the total time if the query is pro-
    cessed in a single site t, $t \notin AS(Q) \cup \{s\}$.
    Set Bound = the best estimated response time
    obtained.
(2) Arrange the relations in R(Q) in descending
    order of size. Let the arranged relations be
    $R_i$, $1 \leq i \leq n$.
(3) For i = 1 to n /* from the largest relation to
    the smallest */
  3.1 From the remaining non-accessed sites, dis-
      card those sites p with
      $W(R_i,p) \geq Bound$.   /* Once a non-accessed
                     site is discarded for a re-
```

```
                    lation, it is discarded for
                    all smaller relations by
                    Proposition 9 */
3.2 Arrange all remaining sites p in ascending
    order of weight $W(R_i,p)$
3.3 Discard those sites p with weight
    $W(R_i,p) + par(R_i)/Sp(u) \geq Bound$
    where u is the site having the fastest pro-
    cessing speed among the sites that contain a
    copy of $R_i$.
            /* Unlike 3.1 this discard is for
            the relation $R_i$ only */
3.4 Use binary search to determine the optimal
    processing sites for the copy of $R_i$ at site
    u.
    low = 1; high= the number of sites remained
    after step 3.3.
    BINSEARCH(low,high,result)
3.5 Compute response time Res using the process-
    ing sites 1 to result.
3.6 Order the remaining copies of $R_i$ that reside
    in a site j between 1 and result in descend-
    ing order of processing speed of their
    residing sites. (Let $k_i'$ be the number of
    these remaining copies). Let the arranged
    copies be $CO_t$, $1 \leq t \leq k_i'$. $result_0$ = result.
    For t=1 to $k_i'$
    { low = 1; high = $result_{t-1}$
      If( $1 \leq site(CO_t) \leq high$) ) /* By Proposi-
                 tion 7, if $site(CO_t)$, the site
                 where $CO_t$ resides, is beyond
                 high, it can not yield a
                 response time better than $res_{t-1}$
                 */
        { BINSEARCH(low, high, $result_t$)
          Compute the response time $res_t$ for the
          processing sites 1 to $result_t$.
          res = MIN { res, $res_t$ }
          }
      }
3.7 Bound = MIN { Bound, Res }.          []
```

### 3.5 Given the relation $R_f$,and its copy at site s, to be partitioned ~~and the optimal processing sites~~, determine the sizes of the fragments to be assigned to the sites.

By Proposition 1, the optimal assignment is to make each processing site have the same total cost. Thus, for each optimal processing site i,

$W(R_f,i) + par(R_f)/Sp(s) + assign(R_f,d,i,s) = c$

where c is the total cost (and hence the response time) to be determined and $F(R_f,d,i)$ is the fragment of $R_f$ to be assigned to site i.

$F(R_f,d,i)$

$= assign^{-1}( c - W(R_f,i) - par(R_f)/Sp(s))$ (2)

where the assign function is in terms of the transmission cost function t() and the join processing function n().

Since $\sum_i F(r_f,d,i) = |R_f|$,

we can solve for c by substituting (2) into it and therefore $F(R_f,d,i)$ can be solved. We can solve Equation (2) for $F(R_f,d,i)$ as a function of c in constant time. We need to repeat this for d fragments. Thus, c can be solved in O(d) if the relation is partitioned into d fragments and the sizes of fragments can also be computed in O(d).

## 4. Time complexity

In the algorithm PARTITION, it takes $O(N_d)$ to obtain the best response time for Step (1)[YGZT], where $N_d$ is the total number of the copies of the relations. At Step (2), it takes O(r log r) to arrange the r relations. We know that the higher the processing speed of a non-accessed site the smaller the weight of the site. Thus, we can pre-arrange all sites in ascending order of weight ( or descending order of processing speed) as if they are non-accessed sites. For a given site, check if the site is non-accessed or not and if it is, determine whether its weight is greater than or equal to the Bound. A binary search of sites can be employed here, since the sites are in ascending order of weight. Thus, the non-accessed sites with weight ≥ Bound can be determined in O(log m) in Step 3.1, where m is the number of sites. For step 3.2, it takes $O(|AS(Q)| \log |AS(Q)|)$ to order the accessed sites and then takes $O(|AS(Q)|+|NAS(Q)|)$ to merge the non-accessed and the accessed sites since the non-accessed sites are arranged in ascending order of weight. At Step 3.3, binary search can be used to discard sites it takes O(log m'), where m' is the total number of the remaining non-accessed and accessed sites. It takes at most O(m' log m') for the BINSEARCH algorithm for Step 3.4. At step 3.5, it takes at most O(m'). Thus, the time complexity for Steps 3.1-3.5 is O(m log m). Suppose there are $k_i$ copies of relation $R_i$. At Step 3.6, Steps 3.1 to 3.5 is repeated at most $k_i$ times with time $O(k_i m \log m)$. We will repeat this process for every relation. Thus, it needs $O(N_d m \log m + r \log r)$ for the algorithm PARTITION.

## 5. Special situation

Suppose both the transmission cost function and the join cost function are linear i.e. $n(X) = a_1 X$ and $t(X) = a_2 X$ for some constants $a_1$ and $a_2$. Then

$$assign(R_f,d,j,s) = \begin{cases} a_1F(R_f,d,j)/Sp(j) + a_2F(R_f,d,j)/Tspeed & \text{if } j \neq s \\ a_1F(R_f,d,j)/Sp(j) & \text{if } j = s. \end{cases}$$

where s is the site where the copy of $R_f$ is to be partitioned. We can rewrite it as

$assign(R_f,d,j,s) = b_{js} F(R_f,d,j)$ where

$$b_{js} = \begin{cases} a_1/Sp(j) + a_2/Tspeed & \text{if } j \neq s \\ a_1/Sp(j) & \text{if } j = s. \end{cases}$$

If we make use of this special property for the algorithm BINSEARCH, the complexity of this algorithm can be reduced to O(m) instead of O(m log m).

In algorithm BINSEARCH, in order to determine whether site (d+1) is a processing site using Proposition 5, we will set $cost_1(R_f,d,j,s) = W(R_f,d+1) + par(R_f)/Sp(s)$ and compute $F_1(R_f,d,j)$ for every site j, $1 \le j \le d$. If we substitute the assign function into $cost_1(R_f,d,j,s)$, we have

$$
\begin{aligned}
cost_1(R_f,d,j,s) \\
&= W(R_f,j) + par(R_f)/Sp(s) + b_{js} F_1(R_f,d,j) \\
&= W(R_f,d+1) + par(r_f)/Sp(s)
\end{aligned}
$$

If we solve for the size of the fragment, we have $F_1(R_f,d,j) = (W(R_f,d+1) - W(R_f,j))/b_{js}$ for $1 \le j \le d$.

The summation of the sizes of the fragments is

$$
\begin{aligned}
R(d) &= \sum_{j=1}^{d} F_1(R_f,d,j) \\
&= \sum_{j=1}^{d} (W(R_f,d+1) - W(R_f,j))/b_{js}.
\end{aligned}
$$

After obtaining R(d), we will continue to search the right half or the left half.

Case 1: Search the right half

In this case, we will determine whether (d'+1)-th site should be an optimal processing site, where d'>d. We need to compute

$$
\begin{aligned}
R(d') &= \sum_{j=1}^{d'} F_1(R_f,d',j) \\
&= \sum_{j=1}^{d'} (W(R_f,d'+1) - W(R_f,j))/b_{js} \\
&= \sum_{j=1}^{d} (W(R_f,d'+1) - W(R_f,j))/b_{js} \\
&\quad + \sum_{j=d+1}^{d'} (W(R_f,d'+1) - W(R_f,j))/b_{js} \\
&= \sum_{j=1}^{d} (W(R_f,d'+1) - W(R_f,d+1))/b_{js} \\
&\quad + \sum_{j=1}^{d} (W(R_f,d+1) - W(R_f,j))/b_{js} \\
&\quad + \sum_{j=d+1}^{d'} (W(R_f,d'+1) - W(R_f,j))/b_{js} \\
&= (W(R_f,d'+1) - W(R_f,d+1)) \sum_{j=1}^{d} 1/b_{js} + R(d) \\
&\quad + \sum_{j=d+1}^{d'} (W(R_f,d'+1) - W(R_f,j))/b_{js}
\end{aligned}
$$

If $1/b_{js}$, $1 \le j \le d$, has been accumulated, the first term can be done at constant time. What remains to be computed is the size of the fragment that will be assigned to site j, $d+1 \le j \le d'$, and their summation. (note that $F_1(R_f,d',j) = W(R_f,d'+1) - W(R_f,j)$ ) It needs only (d'-d) steps instead of d' steps.

Case 2: Search the left half

In this case, we will determine whether (d"+1)-th site should be an optimal processing site, where d" < d. We need to compute

$$
\begin{aligned}
R(d") &= \sum_{j=1}^{d"} F_1(R_f,d",j) \\
&= \sum_{j=1}^{d"} (W(R_f,d"+1) - W(R_f,j))/b_{js} \\
&= \sum_{j=1}^{d} (W(R_f,d"+1) - W(R_f,j) \\
&\qquad + W(R_f,d+1) - W(R_f,d+1))/b_{js} \\
&\quad - \sum_{j=d"+1}^{d} (W(R_f,d"+1) - W(R_f,j))/b_{js} \\
&= \sum_{j=1}^{d} (W(R_f,d+1) - W(R_f,j))/b_{js} \\
&\quad = ( W(R_f,d+1) - W(R_f,d"+1)) \sum_{j=1}^{d} 1/b_{js} \\
&\quad + \sum_{j=d"+1}^{d} (W(R_f,j) - W(R_f,d"+1))/b_{js} \\
&= R(d) - ( W(R_f,d+1) - W(R_f,d"+1)) \sum_{j=1}^{d} 1/b_{js} \\
&\quad + \sum_{j=d"+1}^{d} (W(R_f,j) - W(R_f,d"+1))/b_{js}
\end{aligned}
$$

Again, if R(d) is obtained and $1/b_{js}$, $1 \le j \le d$, is accumulated, then R(d") can be computed in (d-d") steps.

Suppose there are m sites. In binary search, we start at the m/2-th site; this takes m/2 steps to compute R(m/2); then the 3m/4-th site is checked if the right half is searched or the m/4-th site if the left half is searched. But no matter which half is searched, according to the above argument, it takes only m/4 steps to compute R(3m/4) or R(m/4). Thus, it will take m/2, then m/4, m/8 steps and so forth for the sequence of searches. Since the binary search process terminates in (log m) steps,and

$$\sum_{i=1}^{\log m} m/2^i = m-1$$

the algorithm BINSEARCH takes O(m) instead of O(m log m) time.

Suppose not only the cost functions n() and t() are linear, but all sites have the same processing speed. Then, the time complexity is further reduced.

When all sites have the same processing speed, those non-accessed sites will have the same weight associated with the relation to be partitioned. Therefore, by Propositions 3 and 4, if a non-accessed site should (not) be an optimal processing site, then all non-accessed sites should (not) be optimal processing sites. Thus, we only need to use those accessed sites and one non-accessed site to determine the optimal processing sites in algorithm BINSEARCH. The complexity of the algorithm BINSEARCH becomes O(|AS(Q)|+1).

Furthermore, we do not need to repeat the search for the optimal processing sites for every copy of the relation to be partitioned. The copy at the site which has the smallest weight among those sites having a copy of the relation to be partitioned, will yield the best response time. This will be shown in Proposition 12.

Lemma 10: If $a_1 > a_2 > 0$ and $x_1 \geq x_2 > 0$ then $a_2 x_1 + a_1 x_2 \leq a_1 x_1 + a_2 x_2$

Proof: $a_2 x_1 + a_1 x_2 - a_1 x_1 - a_2 x_2$
$= (a_2 - a_1) (x_1 - x_2)$
$\leq 0$ []

Lemma 11: If $a_1 > a_2 > 0$ and $x_1 \geq x_2 > 0$ then $x_1/a_1 + x_2/a_2 \leq x_1/a_2 + x_2/a_1$.

Proof: $x_1/a_1 + x_2/a_2$
$= (a_2 x_1 + a_1 x_2)/(a_1 a_2)$
$\leq (a_1 x_1 + a_2 x_2)/(a_1 a_2)$ (Lemma 10)
$= x_1/a_2 + x_2/a_1$ []

Proposition 12: Let t be the site having the smallest weight among all sites containing copies of the relation, $R_f$, to be partitioned. Let $Res(R_f,p_t,t)$ and $Res(R_f,p_v,v)$ be the response time for using the copy at site t and for using a different copy at site v, respectively.
If all sites have the same processing speed, then $Res(R_f,p_t,t) \leq Res(R_f,p_v,v)$.

Proof:
Case 1: $p_v > p_t$
By Lemma 6, $Res(R_f,p_v,v) > Res(R_f,p_t,t)$.
Case 2: $p_v \leq p_t$
Suppose $Res(R_f,p_t,t) > Res(R_f,p_v,v)$. Let $F_{jt}$ be the size of the fragment assigned to a processing site j, $1 \leq j \leq p_t$, by partitioning the copy at site t. We know that $F_{jt} = ( Res(R_f,p_t,t) - W(R_f,j) - par(R_f)/Sp(t) )/b_{jt}$. Since all sites have the same processing speed, $b_{jt} = b_{jv}$, $j \neq t$ and $j \neq v$. Since $b_{jt} = b_{jv}$ for $j \neq t$ and $j \neq v$, we have that $F_{jv} < F_{jt}$ for $j \neq t$ and $j \neq v$ because $Res(R_f,p_v,v) < Res(R_f,p_t,t)$ and $Sp(t) = Sp(v)$. Since all sites have the same processing speed, $b_{tv} = b_{vt}$, $b_{vv} = b_{tt}$ and $b_{tt} < b_{vt}$. We can have $F_{tv} + F_{vv} < F_{tt} + F_{vt}$

Thus,
$$\sum_{j=1}^{p_v} F_{jv} < \sum_{j=1}^{p_v} F_{jt} \leq \sum_{j=1}^{p_t} F_{jt} = |R_f|,$$
a contradiction that the copy of $R_f$ at site v is partitioned. Thus, $Res(R_f,p_v,v)$ can not be smaller than $Res(R_f,p_t,t)$.
[]

By Proposition 12, if we use the copy of the partitioned relation at the site with the smallest weight to determine the optimal processing sites, the optimal response time of partitioning the relation is obtained. This takes only $O(|AS(Q)|)$. It takes $O(|AS(Q)| \log |AS(Q)|)$ to arrange the accessed sites in ascending order of weight. Thus, it takes $O(r |AS(Q)| \log |AS(Q)|)$ at Step 3 of the algorithm PARTITION if there are r relations. Therefore, the complexity of the algorithm is reduced to $O(r |AS(Q)| \log |AS(Q)| + r \log r)$.

Since the number of relations referenced by a query and the number of accessed sites are usually very small, the algorithm will run very fast. In situation where the join cost function is difficult to estimate accurately, a linear function may serve as a first order approximation. The processing speed of a site may depend on many factors, such as the number of users at a given time, the query type, the job mix etc. In the absence of accurate strategies, the assumption that all sites have the same processing speed is applicable.

## 6. Conclusion

In a fast local network, it is preferable to use a fragment and replicate strategy to process queries. However, if no relation referenced by a query is fragmented, it is necessary to decide which relation is to be partitioned into fragments, which copy of the relation should be used, how the relation is to be partitioned and where the fragments are to be sent for processing. An optimal algorithm in time $O(N_d m \log m + r \log r)$ has been given to provide answers to the above questions. Under special situations that all sites have the same processing speed and the cost functions for data transmission and local processing cost are linear, the time complexity reduces to $O(r |AS(Q)| \log |AS(Q)| + r \log r)$.

# A COMPILER-ASSISTED CACHE COHERENCE SOLUTION FOR MULTIPROCESSORS

*Alexander V. Veidenbaum*

Center for Supercomputing Research and Development
University of Illinois at Urbana-Champaign
Urbana, Illinois, 61801

**Abstract** -- The existing solutions to multiprocessor cache coherence problem are not suitable, in our opinion, for systems with a large number of processors. We propose a new solution in which a compiler generates cache management instructions. Conditions necessary for cache coherence violation are defined. The structure of a program and its dependence graph are used to detect when these conditions become true, and the instructions to enforce coherence are generated. No communication between processors is required at run-time to enforce coherence. The correctness of the solution is proved.

## Introduction

Several multiprocessor architectures have been built or are being built that can truly be called large-scale ([4], [5], [14], [2]). They can have several hundred processors sharing memory and all working on solving a single problem. Such multiprocessors are characterized by a long memory access time making the use of cache memories very important. However, a cache coherence problem makes the use of caches difficult. In this paper we discuss the proposed solutions to the cache coherence problem and why they may not be suitable for a large-scale multiprocessor. We propose a different solution that relies on a compiler to manage the caches. We define conditions necessary for a data incoherence to occur. A restructuring compiler, such as Parafrase [9], can be used to detect when such conditions arise and to generate cache management instructions to enforce coherence.

## Existing solutions to the cache coherence problem

Let us examine the proposed solutions to the cache coherence problem (see [18]) for use on large-scale multiprocessors. The solutions can be divided into the following groups:

(1) Solutions based on a single shared resource.
These include a central directory scheme of [15] and a shared cache scheme of [17].
A large number of processors can not access the shared resource without severe performance degradation. That's why these solutions are not extendable to large-scale multiprocessors.

(2) Bus-based solutions.
An example of such a solution is that of Goodman [6].
These solutions are also using a shared resource, the bus, and could have been considered in the first group. We put them in a separate group because they seem to us capable of supporting a larger number of processors then the solutions in the first group, but not hundreds of processors on a single bus.

(3) Cacheability attribute processed during virtual address translation.
This scheme was used in C.mmp [3]. Again a central resource, shared page tables, can be identified in this solution. The overhead of changing the cacheabilty attribute seems large to us for a truly extendable solution.

In addition, most modern processors contain a translation buffer (TLB) acting as a cache for page table entries. When a cache attribute needs to be changed all of the TLBs need to be updated. Therefore, we may have solved the data cache coherence problem, but we have created a TLB coherence problem.

A variant of this solution has been proposed which allows the cacheability of read-only data. In this case the attribute is never changed during the execution of a program. This solution is restrictive and may not allow a large number of references to be cached.

## Multiprocessor architecture

The architecture we are interested in is a shared-memory multiprocessor. It consists of a global shared memory, a global interconnection network, and proces-

sors with private caches. The only way of exchanging data between processors is through the shared memory. The block diagram of this architecture is given in Figure 1.

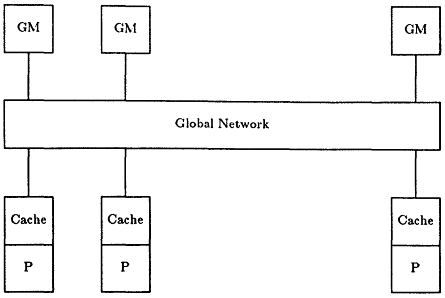

Figure 1. Multiprocessor architecture.

### Interconnection network

We assume the interconnection network to be of the shuffle-exchange type. The network has a unique path from any input to any output port. The order of accesses by a given processor to a given memory location is preserved by the network.

### Cache organization

We assume that a cache is a physical address cache, using the "Write-through" policy, and having a block size of one. We also assume that on context switch the system ensures the correctness of cache contents. Other details of cache organization will be presented in the following sections.

## Definitions

The following notation is used in this paper:

(1) $S_i$ - statement i of a program,

(2) $P_j$ - processor j of a multiprocessor,

(3) $C_j$ - private cache of processor $P_j$,

(4) M[X] - the contents of a memory location of a variable X,

(5) $C_j[X]$ - the value of X contained in the cache of processor $P_j$,

(6) $X^s$ - a store of X,

(7) $X^f$ - a fetch of X,

(8) $X^a$ - an access to X, i.e either a fetch or a store, In some cases we may qualify the access type by a processor that performed the access as follows: $X^{a(P_j)}$.

(9) $(Y)^*$ - zero or more repetitions of Y.

### Data dependencies

The definitions of this section follow those of [8] and [16] which should be consulted for any additional information on dependence analysis.
For each statement $S_i$ we define two sets, IN and OUT.

-- $IN(S_i)$ is a set of variables the statement uses.

-- $OUT(S_i)$ is a set of variables the statement generates.

The following types of dependencies are defined between two statements $S_i$ and $S_j$ if there is a flow of control path from $S_i$ to $S_j$ and $S_i$ precedes $S_j$ on that path.

-- $S_j$ is data flow dependent on $S_i$ if the set $IN(S_j) \cap OUT(S_i)$ is not empty.

-- $S_j$ is data antidependent on $S_i$ if the set $IN(S_i) \cap OUT(S_j)$ is not empty.

-- $S_j$ is output dependent on $S_i$ if the set $OUT(S_j) \cap OUT(S_i)$ is not empty.

-- $S_j$ is control dependent on a conditional statement $S_i$ if its execution depends on the execution of $S_i$ and the path chosen after that.

If the two statements are both enclosed by DO loops a dependence may exist on some but not all iterations of the enclosing loops. Also, a dependence may exist between $S_i$ executed in one iteration and $S_j$ executed in another iteration of a loop. Such a dependence is called a cross-iteration dependence. The data dependence information can be represented by a graph on the statements of a program, called a data dependence graph.

### Loop types

A program can have any of the following four loop types:

(1) A DOALL loop - a loop which does not have any cross-iteration deoendencies [11].

(2) An R(N,1) loop - a loop solving a first-order linear recurrence [8].

(3) A DOACROSS loop - a loop that has a dependence graph cycle but can be executed in a pipelined fashion [13].

(4) A serial loop - a loop with a dependence graph cycle where pipelined execution is not possible.

The type of a loop is determined by the dependence graph of statements nested in it. The first three types of loops can be executed on multiple processors to achieve performance improvement.

## A memory reference sequence

A memory reference sequence **X** for a memory location of a variable X is an ordered sequence of accesses generated by a program as observed at the memory:

$$\mathbf{X} = X^{s} \left( (X^{f})^{*} \, (X^{s})^{*} \right)^{*}$$

Any access $X^{a}$ generated by a program can be identified by a sequence number i giving the position of $X^{a}$ in **X**. We use a subscript i to indicate the sequence number, $X^{a}_{i}$. Let us assume that the sequence number is know a priori for any access.

For a serial program the sequence is unique for a given set of input data. For a deterministic parallel program the sequence is unique except for possible permutations in any of the fetch subsequences.

The model of computation we use assumes that the following two conditions are satisfied at any time T when a processor generates $X^{a}_{i}$ :

A1. $M[X] = X^{s}_{j}$, where $j < i$ and $\forall$ k, $j < k < i$: $X_{k}^{a}$ was a fetch,

A2. If $X^{a}_{i}$ is a store then $\forall$ j, $j < i$: $X^{a}_{j}$ has been performed.

In other words, the value in the shared memory is always current. All the stores preceding the current access have been completed but none of the following stores have been completed. This is necessary to keep things "simple" in the system where the only way of communicating between processors is through shared memory. These conditions a equivalent to enforcing the data dependence constraints between the statements. We assume that the ordering is enforced through the use of synchronization primitives.

## Cache incoherence

We define an incoherence as a condition when:

1. a processor $P_{j}$ performs a memory fetch $X_{i}^{f}$

and

2. $M[X] \neq C_{j}[X]$ at such time.

An incoherence cannot occur if $X_{i}$ is a store. Note that we require a processor to try to fetch X, otherwise the fact that the memory and the cache have different values is not an error.

Using the notion of the reference sequence let us define the necessary conditions for the cache incoherence to occur.

### Lemma 1

The two conditions necessary for a cache incoherence to occur at processor $P_{j}$ issuing $X^{f}_{i}$ are:

C1. $C_{j}[X] = X_{l}^{a(P_j)}$, where $l < i$ and $X_{l}^{a}$ was the last access to X by $P_{j}$.

C2. $\exists$ k, $l < k < i$: $M[X] = X_{k}^{s(P_m)}$, where $j \neq m$. (If more then one such stores took place let $X_{k}^{s}$ be the one with largest sequence number.)

That is, a value of X is present in the cache of $P_{j}$ (C1), and a new value has been stored in the shared memory by another processor since the last access by $P_{j}$ (C2).

### Proof

(1) The first condition must be true, for if it is not true the value is fetched out of GM and is therefore correct.

(2) Let us assume that an incoherence occurred on $X_{i}^{f(P_j)}$, i.e. $M[X] \neq C_{j}[X]$ at that time, but C2 is not true. Let us also assume that this is the first time any of the conditions {A1, A2, C1, C2} we specified are not satisfied.
C2 being false means:

$$M[X] = X_{k}^{s(P_m)},$$
$$\text{where } k \geq i \text{ or } k \leq l \text{ or } j = m.$$

If $j = m$ then the value in the cache is that stored by processor j. Since it was the last store before $X_{i}^{f}$ we have $M[X] = C_{j}[X]$, which is not true. Therefore $j \neq m$.
If $k > i$ then condition A2 has not been satisfied when the store of $X^{s}_{k}$ occurred since not all the preceding accesses have been made. We assumed that this was the first time any of the conditions were false, but found that A2 must have been false earlier. Therefore, $k \leq i$.
k cannot be equal to i since $X_{k}$ is a store and $X_{i}$ is a fetch.
k cannot be equal to l since this will imply $j = m$ which we have shown is false.
For the case of $k < l$ we have two possibilities: $X_{l}$ is a store or $X_{l}$ is a fetch. If $X_{l}$ is a store then $M[X] = C_{j}[X]$ when $X_{i}$ is issued since no other processors store into X after $X_{l}$ and neither does $P_{j}$. If $X_{l}$ is a fetch we again have $M[X] = C_{j}[X]$. Since the contents of memory and the cache are not equal, k cannot be less then l.
It follows then that C2 is a necessary condition for the incoherence to occur.□

### Corollary

Cache incoherence cannot occur on a variable that is assigned only once during program execution.

The proof follows from the fact that the conditions C1 and C2 of Lemma 1 cannot be true at the same time.

### Detecting the necessary conditions

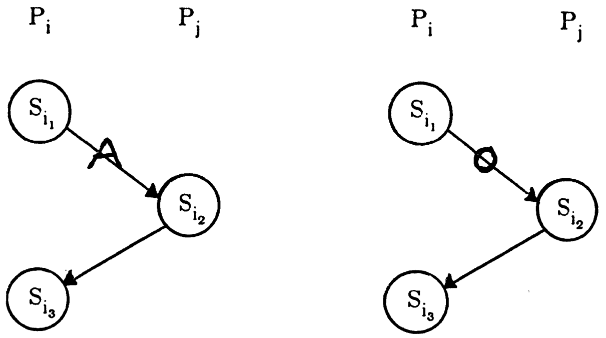
Our goal is to have the restructuring compiler detect the conditions of Lemma 1 and generate the cache management instructions. The power of restructuring compilers is in the ability to perform the data dependence analysis. Therefore, let us express the conditions necessary for cache incoherence to occur in terms of data dependencies. It follows from Lemma 1 that:

(1) The value of X has to be in the cache of processor $P_j$. This implies that a statement $S_{i_1}$ was executed by $P_j$ such that X belongs to $IN(S_{i_1})$ or X belongs to $OUT(S_{i_1})$.

(2) A different processor has computed a new value of X. This implies that a statement $S_{i_2}$ was executed by $P_k$ such that X belongs to $OUT(S_{i_2})$, $k \neq j$.

(3) Finally, an incoherence can only occur if $P_j$ is fetching X. This implies a statement $S_{i_3}$ is executed by $P_j$ such that that X belongs to $IN(S_{i_3})$.

From the above, $S_{i_2}$ depends on statement $S_{i_1}$, and statement $S_{i_3}$ depends on statement $S_{i_2}$. One of the following two dependence graphs are possible:



In addition to the above dependence structure, it is necessary that $S_{i_2}$ be executed on a different processor. How can we detect that? We propose to use the loop type information for this purpose. (If other types of parallelism are being exploited they can be taken care of in a similar fashion.) Recall that only three of the four types of loops we are dealing with can be executed on multiple processors. Let us concentrate on DOALL and DOACROSS loops. We assume that one or more consecutive iterations of such a loop are assigned to a processor. By definition, any dependence between two statements inside a DOALL loop is not across iterations, but there are cross-iteration dependences in DOACROSS. It follows that a statement $S_i$ in a DOALL dependent on a statement $S_j$ in the same loop is executed on the same processor as $S_j$. In a DOACROSS loop, two statements with a cross-iteration dependence are executed on different processors, while statements with a dependence on the same iteration are executed on the same processor.

Using the above we first construct a simplified algorithm using only the loop type information. We then extend it to consider the dependence structure and the flow of control.

### A cache management algorithm

Let us assume that the following instructions are available for cache management:

Flush. This instructions invalidates the entire contents of a cache.

Cache_on. This instruction causes all global memory references to be routed through the cache.

Cache_off. This instruction causes all global memory references to by-pass the cache and go directly to memory.

In addition, the cache state, on or off, must be part of the processor state and has to be saved/restored on context switch. Processes are created in the cache-off state.

The algorithms uses loop types for its analysis as follows:

(1) A DOALL loop does not have any dependencies between statements executed on different processors. Therefore condition C2 of Lemma 1 is false, and any shared memory access in such a loop can be cached.

(2) A serial loop is executed by a single processor, and hence condition C2 of Lemma cannot be true.

(3) A DOACROSS or an R(N,1) loops do have cross-iteration dependencies. Therefore condition C2 can be true. Initially, let us just turn caches off in such loops.

The algorithm is shown in Figure 2. The algorithm turns cacheing on and off, depending on the type of loop a program enters. (Note that cache management instructions inserted in parallel loops are executed once by every participating processor.) Conditions for incoherence are checked at loop boundaries. In addition, procedure and function calls which may have parallel loops in called routines are considered. The algorithm does not really consider individual dependencies or look for the dependence structure satisfying conditions of Lemma 1. It states that within certain loop types (or nests of this type) the conditions cannot be satisfied or cacheing is not allowed.

The algorithm is simple enough to be executed either at compile time or at run time. At compile time we know which loops can be executed on multiple processors, but whether they will be executed as such depends on run-time processor allocation. At run time we know which loops get multiple processors. For example, if a DOACROSS is serialized we can turn the cacheing on during the whole time the loop is executed.

```
cache_state := on
insert Cache_on, Flush
For every statement in a program do
        case(statement type)
          of(DO)
               case(DO type)
                 of(DOALL)
                      insert Cache_on, Flush after
                              the DO statement
                      push(cache_state)
                      cache_state := on
                 of(serial)
                      if cache_state = off
                      then   insert Cache_on, Flush before
                                      the DO statement
                      fi
                      push(cache_state)
                      cache_state := on
                 of((DOACROSS, R(N,1))
                      insert Cache_off after the DO statement
                      push(cache_state)
                      cache_state := off
               endcase
          of(DOEND)
               do_type := type of DO for which this is DOEND
               old_cstate := cache_state
               cache_state := pop()
               if cache_state=on AND old_cstate=off
               then   insert Cache_on after DOEND
               fi
               if       cache_state=on
                 AND
                      do_type={DOALL,DOACROSS,R(N,1)}
               then   insert Flush after DOEND
               fi
          of(CALL)
               insert Cache_off before the CALL statement
               if cache_state = on
               then   insert Cache_on, Flush after
                              the CALL statement
               fi
        endcase
enddo
```

Figure 2. The cache management algorithm

## Correctness proof

We will prove the correctness of the algorithm by showing that the conditions necessary for an incoherence to occur are not satisfied in programs processed by the algorithm. The conditions necessary for an incoherence on a variable X to occur when executing a statement $S_i$ are:

CC1: Statement $S_i$ depends on statement $S_j$ through a variable X.

CC2: $S_i$ is executed by processor $P_l$ and $S_j$ is executed by processor $P_m$, $l \neq m$.

CC3: X is in the cache $C_l$ prior to the execution of $S_i$ and $C_l[X] \neq X^{s(P_m)}$.

A general loop structure enclosing statements i and j is shown in Figure 3. Note that a statement not in any loop can be represented by a statement enclosed in a serial loop with one iteration. Therefore some of the loops shown in Figure 3 can be removed to obtain simpler cases.

```
DO a
      .
      .
      DO b
            .
            .
            DO c
                  .
                  .
                  Sj
                  .
                  .
            DOEND c
            .
            .
      DOEND b
      .
      .
      DO d
            .
            .
            DO e
                  .
                  .
                  Si
                  .
                  .
            DOEND e
            .
            .
      DOEND d
      .
      .
DOEND a
```

Figure 3. Program structure

We have to show that for every path in the control flow graph of our program between $S_j$ and $S_i$ one of the conditions above is false for any $S_i$. A note about loops with GOTOs exiting the loop: we assume such loops have a single exit path regardless of how the loop was exited. This is usually required for correct synchronization, while it also simplifies the analysis of control flow between loops in our proof.

Let us consider the innermost loop $DO_e$ enclosing $S_i$. Three cases are possible:

(1) $DO_e$ is a DOACROSS or an R(N,1) loop.
In this case a Cache_off instruction is issued by every processor executing the iterations of the $DO_e$.

Therefore, X will be fetched from memory when $S_i$ is executed. This is equivalent to CC3 being false.

(2) $DO_e$ is a DOALL loop.
In this case a Flush instruction is issued by every processor executing iterations of $DO_e$. Therefore CC3 is false.

(3) $DO_e$ is a serial loop.
Consider all the loops enclosing $S_i$ between $DO_e$ and $DO_d$. Let us skip all loops e, ..., k+1 that are serial to $DO_k$, $k \leq d$, such that:

A. $DO_k$ is a DOACROSS.
In this case $S_i$ is enclosed by a nested set of serial loops $DO_e$ through $DO_{k+1}$. The nested set is executed on one processor and a Flush instruction is executed before the $DO_{k+1}$ according to the Algorithm 1. Therefore CC3 is false.

B. $DO_k$ is a DOALL.
In this case a Flush instruction is executed by every processor executing iterations of $DO_k$. Since all of the loops $DO_{k+1}$ through $DO_e$ are serial, every processor executing $S_i$ has executed a Flush instruction. Therefore CC3 is false.

C. Otherwise $DO_k$ is a serial, i.e. all of the loops $DO_d$ through $DO_e$ are serial.
Now let us consider the loop type of $DO_a$:

$\alpha$ $DO_a$ is a DOACROSS.
In this case a Flush instruction is executed before $DO_d$ according to Algorithm 1. Since $S_i$ is executed by the same processor, CC3 is false.

$\beta$. $DO_a$ is a DOALL or a serial loop.
In this case we have to consider the loops enclosing $S_j$.

I) $DO_b$ through $DO_c$ are all serial.
In this case both loop nests $DO_b$ through $DO_c$ and $DO_d$ through $DO_e$ are serial. Since they are nested in a DOALL or a serial loop they will be executed on the same processor. Hence condition CC2 cannot be true for statements $S_i$ and $S_j$.

II) Otherwise consider the outermost loop $DO_k$, $b \leq k \leq c$, that is not serial, i.e. it is a DOALL, a DOACROSS, or an R(N,1).
In this case a Flush instruction is executed after $DOEND_k$ by the same processor that is to execute $S_i$. Therefore CC3 is false.

Finally, let us consider CALL statements. Suppose $S_j$ is a subroutine or function CALL. In this case a called routine may have loops in it enclosing the statement actually generating X. In addition, the called routine may not have any cache management instruction in it (that is why we turn cacheing off before a call). However, in all but one of the cases considered in the proof a Flush or Cache_off instruction is performed by a processor that executes $S_i$. Therefore, CC3 is false when $S_i$ is executed regardless of the type of statement of $S_j$.

The one case that does not have the cache flushed is C.$\beta$II. In that case $S_i$ and $S_j$ are executed by the same processor, and there is no Flush on any path between the two statements. The algorithm inserts a Flush instruction after a CALL statement taking care of this case.□

### Improving the cache management algorithm

In this section we describe the extensions of the cache management algorithm. The first one allows cacheing to be used in DOACROSS loops. The second and third attempt to reduce the number of cache flushes by doing a more detailed dependence and flow analysis.

(1) Cacheing of data inside DOACROSS loops.
A DOACROSS loop is executed by assigning successive iterations to different processors (mod the number of processors available). The cross-iteration dependencies that exist in a DOACROSS are thus between statements executed by different processors. Synchronization primitives have to be used between these processors to ensure that dependencies are satisfied (say, the classical P and V primitives).
A straight-forward solution is to issue a Flush instruction after the V by each processor executing a statement depending on a statement executed by another processor. Since the shared memory has the current value after the V instruction and the cache does not have anything, the value will be fetched out of global memory. Otherwise the DOACROSS loops can be treated the same way as the DOALL loops by the cache management algorithm.
A more interesting solution is possible for architectures that support memory access combined with synchronization, such as [7] or [5]. In this case we can identify exactly which word requires synchronization and invalidate just one word, not the entire cache. Cache controller design has to be modified to allow invalidation of individual words, preferably as part of a synchronized fetch. The correct value is fetched from memory and can be put in the cache. Any subsequent unsynchronized fetch will use the value out of the cache.

The processor performing a synchronized store does not have to do anything special, just write the data through to shared memory.

The last solution requires a synchronized data access for every variable on which a cross-iteration dependence exists. Any attempt to minimize the number of synchronization primitives, as proposed by [12], or use of implied synchronization may result in an incorrect execution of a program.

(2) The simplified algorithm we presented does not really look for the dependence structure implied by the Lemma 1 conditions. Specifically, it does not check the existence of a statement bringing a variable into a cache prior to the execution of the two statements with a dependence on two different processors. An incoherence cannot occur if such a statement does not exist. In such a case it is not necessary to invalidate the contents of a cache.

Consider a DOACROSS loop with cacheing enabled. Assume each processor executing this loop performed a Flush instruction just after it entered the loop. Let us know consider a statement $S_i$ that uses a variable X generated in another iteration of the DOACROSS. If we examine all the flow of control paths from the first statement in a loop to $S_i$ and determine there are no generations or uses of X on any of them then we do not have to invalidate X in the cache before $S_i$ (a single assignment condition). If the above is true for all the cross-iteration dependencies in the loop we do not need a Flush instruction in this DOACROOS.

This technique can be extended to analyze the whole program to avoid Flushing after every parallel loop.

(3) The algorithm uses data dependence information indirectly, through loop types. A beginning and end of a parallel loop are synchronization points it detects and uses to issue cache management instructions. This synchronizes all dependencies from statements in such loops to statements outside of such loops. However, this synchronization point may be located much earlier than the statement using the data. Another synchronization point may exist later in the program that takes care of an earlier one. For example, consider the program segment in Figure 4. If no statement in DOALL$_b$ has dependence arcs to statements in DOALL$_c$ or any code between the two loops, and the flow of control always goes through DOALL$_c$ after passing through DOALL$_b$, a Flush is not necessary after DOALL$_b$.

The correctness proof can be easily extended to include the algorithm improvements shown in this section.

```
DO a
      .
      .
      DOALL b
      .
      DOEND b
      .
      .
      DOALL c
      .
      DOEND c
DOEND a
```

Figure 4. Program example.

## Conclusions

We have presented a solution to the cache coherence problem in which a restructuring compiler generates cache management instructions. An algorithm to do that is presented and its correctness proved. In this solution each processor manages its own cache without any additional communication with other processors. The cache management instructions are very simple, affect only the processor issuing them and have a small fixed cost. Finally, the total number of such instructions issued by any processor is a function of loop bounds and loop structure of a program, not of the number of processors used or the number of stores in the program. That is why we believe the solution is scalable to multiprocessors of any size.

ABSTRACT — This paper presents a heuristic algorithm for allocating the tasks in a task force to a set of execution sites in a locally distributed computer system. The algorithm dynamically allocates tasks on arrival with the objectives of balancing the load of the system and of minimizing the communications costs for the task force to the extent possible within the constraints imposed by load balancing. Results from experimenting with the algorithm on pipelined task forces arising from distributed database queries indicate that it finds the optimal allocation in most cases, and also that load-balanced task allocation effectively improves system performance.

## 1. INTRODUCTION

Task allocation and load balancing are major issues associated with the design of distributed computing systems. When a task or set of tasks are to be executed in a distributed system, they must be properly allocated to sites in the system. The problem of selecting appropriate sites is known as the *task allocation* problem, and a number of solution methods have been developed for this problem [2,4,10,12,13]. A common trait of these task allocation schemes is that they operate using static information. That is, they ignore an important dynamic characteristic of distributed computer systems: the probability of one or more sites being idle while tasks are waiting at other sites can be remarkably high [6]. *Load balancing* aims to reduce this probability via *task migration*, which is the process of transferring tasks from one site to another (idle or less heavily loaded) site to either begin or continue execution there. In the class of task migration schemes known as sender-initiated schemes [3,6], tasks are migrated upon arrival in the system by the site at which they arrive. This is similar in some ways to more traditional task allocation schemes, but the allocation decision is made dynamically and the load status of the system is considered. To distinguish this dynamic, load-based approach to task allocation from static approaches, we refer to it as *load-balanced task allocation*.

In this paper we present a heuristic algorithm for solving an instance of the load-balanced task allocation problem. The particular problem that we consider here is unique as compared to most previous load balancing work, as we address the problem of selecting execution sites for an *entire distributed program* consisting of a number of tasks which are to be executed concurrently and which communicate with one another. Such distributed programs are known as *task forces* [5]. The particular class of task force that motivated this study is distributed database queries. In distributed relational database systems, queries are usually decomposed into sequences of *data moves* and *subqueries*. The subqueries may be executed concurrently at different sites in the system in a pipelined fashion to achieve good performance [7,8]. Note that the problem of allocating subqueries to sites in a locally distributed database system in a load-balanced fashion is a variant of the load-balanced task allocation problem.

The load-balanced task allocation problem addressed in this paper differs from previous work on task allocation in several ways. First, and most importantly, load-balanced task allocation is a dynamic problem. It takes a task force and the current load status of the system as inputs, and its main objective is to achieve a load-balanced system dynamically through proper task allocation. Second, given load balancing as the primary objective, the communications cost for executing the task force is minimized as a secondary objective. Third, each task in the task force is assumed to have a *feasible assignment set* that specifies the sites to which the task may be allocated. This constraint arises in our application (distributed query processing) because each relation is stored at only a subset of the sites in the system. Finally, since load-balanced task allocation is dynamic in nature and must be accomplished quickly at runtime, we require a solution method that is capable of solving the problem quickly.

The remainder of this paper presents our heuristic algorithm and summarizes the results of its evaluation. Section 2 defines the load-balanced task allocation problem more precisely, and Section 3 describes the details of our algorithm. In Section 4, we present some performance evaluation results plus two enhancements to the algorithm. Finally, Section 5 outlines our plans for future work.

## 2. THE LOAD-BALANCED TASK ALLOCATION PROBLEM

In many research efforts, the load of a processing site $s_i$ is represented by the number of tasks currently being served or awaiting service at that site, $N(s_i)$ [6,11]. That is, $LD(s_i) = N(s_i)$. In order to quantitatively measure the degree of "balancedness" of a system, we extend Livny's definition of the *load unbalance factor* [6], $UBF$, to be the variance of the system's load distribution:

$$UBF = \frac{\sum_{j=1}^{n}(LD(s_j) - \overline{LD})^2}{n} = \frac{\sum_{j=1}^{n}(N(s_j) - \bar{N})^2}{n}$$

$N(s_j)$ is the number of tasks at site $s_j$ and $\bar{N}$ is the average number of tasks per site after all query units are allocated. Using this definition, the load-balanced task allocation problem for a locally distributed system with $n$ sites, $\{s_1, ..., s_n\}$, can now be expressed as follows:

**Given:**

(1) A number of tasks $\{t_1, ..., t_m\}$, to be executed concurrently as a task force.

(2) A feasible assignment set $S_i = \{s_{i_1}, ..., s_{i_k}\}$ for each task $t_i$ $(1 \le i \le m)$.

(3) An *initial load vector* specifying the intial load at each site $s_j$, $1 \le j \le n$, as given by $LD(s_j)$.

**Find:** An allocation of tasks to processing sites such that:

(1) The unbalance factor under this allocation is minimized.

(2) The total communications cost, measured as the sum of the total data transfers between communicating tasks that are allocated to different sites, is also minimized to the extent possible without increasing the unbalanced factor of the allocation.

In the following discussion, we assume that the $m$ tasks are executed in a pipelined fashion because of our application [1,9]. In this case, communication only occurs between pairs of adjacent tasks in the pipeline, so the total communications cost can be roughly approximated by the number of nonlocal task pairs (i.e., pairs of adjacent subtasks $t_i$ and $t_{i+1}$ that are allocated to different sites). However, this assumption does not affect the generality of our algorithm, and only relatively minor modifications are required in order to apply the algorithm to concurrent task forces with more general communication patterns.

## 3. A HEURISTIC APPROACH

The fact that task allocation is to be performed at runtime implies that the allocation algorithm should introduce as little overhead as possible. Heuristic methods requiring less computational effort while providing near-optimality are therefore preferable to exhaustive (optimal) solution methods. In this section, we present a heuristic algorithm for solving the load-balanced task allocation problem as defined in the previous section.

### 3.1. Task Allocation Heuristics

Three main heuristics are employed by the algorithm — a heuristic to control the order in which tasks are considered for allocation, a heuristic to avoid considering sites with particularly heavy loads, and a heuristic to help ensure that a good allocation site is selected for each task.

**Heuristic 1: Order of Allocation.** The notion of the *degree of freedom* of a task is used in our algorithm to determine the order in which tasks are allocated to sites. This is an important consideration, as our algorithm avoids backtracking or reconsidering previous allocation decisions. The algorithm uses two freedom-related metrics associated with each task: (1) *static freedom* — the number of sites where the task can be allocated (i.e., the cardinality of its feasible assignment set). A task with a higher static freedom value will be relatively more flexible than one with a lower value because there are more site choices available. (2) *dynamic freedom* — the sum of the current load of the sites in the task's feasible assignment set.

Using these freedom measures, tasks are allocated by our heuristic algorithm one by one in order of their degree of freedom. That is, tasks with fewer site choices are allocated earlier, and the degree of static freedom is the primary consideration. In the event of a tie, the task with the largest dynamic freedom measure is chosen, as its candidate sites are more heavily loaded.

**Heuristic 2: Elimination of Full Sites.** A site with a current load which is larger than the expected post-allocation average load is considered to be full. A site that becomes full will not be assigned any further tasks (except if it is the only site in the feasible assignment set for a given task). Thus, whenever a site is full, whether due to its initial load or to the assignment of a new task to the site, it is deleted from the feasible assignment set of each task that also has some other site in its feasible assignment set.

**Heuristic 3: Site Selection Criteria.** After determining the task to be considered next, four metrics are used to select a site for the task from its feasible assignment set. These are:

(1) The *current load* of a candidate site: This is the total number of tasks currently assigned to the site, including those tasks in the initial load of the site.

(2) The *potential load* of a candidate site: This is the number of unassigned tasks that have the site in their feasible assignment set.

(3) The *benefit* of a possible assignment: This is the communications cost that can be avoided by this assignment. In our case, since communications occur only between adjacent tasks in the pipeline, the benefit of assigning task $t_i$ to site $s_j$ is the number of adjacent tasks (e.g., $t_{i-1}$ or $t_{i+1}$) that have already been allocated to the site (either 0, 1, or 2).

(4) The *potential benefit* of a possible assignment: This measures the communications cost that might be eliminated by this assignment. In our case, this is the number of unassigned tasks which have the site in their feasible assignment set and which would form a consecutive sequence of tasks including the task being allocated if they too were assigned to the site.

Since load balancing is the main objective, an attempt is first made to allocate task $t_i$ to the site with the minimum current load among its feasible assignment sites. In the event of a tie, the benefit of assigning $t_i$ to each site with the minimum load is calculated, and the site with the maximum benefit is selected. In case of another tie, the site with the minimum potential load is chosen, with maximum potential benefit being used if there are several sites with the same minimum potential load.

### 3.2. The Basic Load-Balanced Task Allocation Algorithm

The algorithm's input includes a *feasible assignment set* for each task plus an *initial load vector* that specifies the number of existing tasks at each site when the new tasks are to be allocated. The originating site and result site for the task force are also specified as input so that the communications costs for initiating tasks at remote sites and for returning results to the result site (assuming that a user is awaiting results at that site) will be considered by the allocation algorithm. These are handled using two dummy tasks, $t_0$ and $t_{m+1}$, which are assumed not to introduce any real load at their sites, but whose communications costs play a role in influencing allocation decisions. The basic load-balanced task allocation algorithm can now be described as follows:

(1) Allocate dummy task $t_0$ to the task force's site of origin, and allocate dummy task $t_{m+1}$ to the result site for the task force.

(2) Compute the static and dynamic freedom metrics for each task $t_i$, $1 \le i \le m$.

(3) Select the next task to be allocated as the one with the least assignment flexibility using the degree of freedom metrics.

(4) Select an allocation site $s_j$ for this task ($t_i$) by choosing the site from its feasible assignment set with the least current load, considering the benefit, potential load, and potential benefit metrics in turn as necessary (to break any ties).

(5) Increment the load of site $s_j$, and recompute the freedom metrics of any unallocated tasks that have $s_j$ in their feasible assignment set. (If $s_j$'s load now exceeds the expected average, simply delete $s_j$ from their feasible assignment sets.)

(6) If any unassigned tasks remain, go to step (3).

**EXAMPLE:** Consider a task force consisting of 5 tasks, and suppose that there are 8 sites in the system. Assume that the originating and result sites for the task force are both $s_3$, that the initial system load vector is {4, 1, 1, 2, 2, 0, 1, 1}, and that the feasible assignment sets for the tasks are:

| | | | |
|---|---|---|---|
| $t_1$: | $\{s_1, s_2, s_5, s_7\}$ | $t_2$: | $\{s_2, s_4, s_5\}$ |
| $t_3$: | $\{s_3, s_5, s_7, s_8\}$ | $t_4$: | $\{s_1, s_6\}$ |
| $t_5$: | $\{s_3, s_4, s_5, s_6, s_7\}$ | | |

Our algorithm would then operate as follows:

i. The total initial load is 12 and the expected average load after allocation (rounded up) is 3. Site $s_1$ is therefore full initially, so it is deleted from the feasible assignment sets of $t_1$ and $t_4$.

ii. The static degrees of freedom for the tasks are {1, 3, 3, 4, 1, 5, 1}. The dummy tasks $t_0$ and $t_6$ are allocated to $s_3$ first.

iii. $t_4$ is allocated to $s_6$, the only site in its feasible assignment set.

iv. Both $t_1$ and $t_2$ have the same static degree of freedom value (of 3). Since $t_2$ has less dynamic freedom, it is allocated next.

v. $t_2$ is allocated to site $s_2$ because $s_2$ is the site with the minimum load (of 1) in its feasible assignment set.

vi. $t_1$ is now allocated to site $s_7$ for the same reason as in v.

vii. Since $t_3$ is next in increasing order of static freedom, it is considered next. It is allocated to site $s_8$, which has the smallest potential load.

viii. Finally, $t_5$ is allocated to site $s_6$, which has the largest benefit among the sites in $t_5$'s feasible assignment set.

ix. The final task assignment is:

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| task | ($t_0$) | $t_1$ | $t_2$ | $t_3$ | $t_4$ | $t_5$ | ($t_6$) |
| execution site | ($s_3$) | $s_7$ | $s_2$ | $s_8$ | $s_6$ | $s_6$ | ($s_3$) |

After assignment, the load vector is {4, 2, 1, 2, 2, 2, 2, 2}. The *UBF* for this assignment is 0.61, and the total communications cost is 5. It turns out that this is actually an optimal allocation under the problem definition.

## 4. PERFORMANCE AND ENHANCEMENTS

The heuristic algorithm described in the last section is a greedy algorithm in the sense that tasks are assigned one by one, without lookahead or backtracking. In order to evaluate the quality of the allocations generated by our algorithm, we conducted a study in which we compared its allocation decisions to those of an exhaustive search method which always finds the optimal allocation [9]. This study led to the design of two enhancements for the basic algorithm. The algorithm was also used in a simulation study to investigate the usefulness of load-balanced task allocation for distributed database systems [1,9]. We briefly summarize all of these results here.

### 4.1. Optimality of the Algorithm

Three groups of tests were conducted to investigate the optimality of the heuristic algorithm [9]. The first group of tests studied the general behavior of the algorithm, varying the number of tasks and the number of sites in the system. In the second group of tests, the initial "unbalancedness" of the system's load was varied. In the last group of tests, the tasks' feasible assignment set sizes were varied.

The results of these tests showed that, in most cases, the heuristic algorithm finds the optimal allocation. The percentage of optimal allocations generated was always at least 75%, and typically higher, for runs in the first group of tests. About 95% of the allocations obtained in this group were optimal if the unbalance factor alone was considered, which is encouraging since load balancing is the main objective. Also, more than 80% of the allocations had the same (or lower) communications costs as the optimal allocation. As the numbers of sites and tasks were increased, however, the number of optimal allocations found by the heuristic algorithm decreased. The explanation for this is that larger numbers of sites and tasks increase the number of possible allocations, so the probability of selecting an optimal allocation using a greedy algorithm decreases. It is then more likely that a near-optimal allocation will be chosen instead of the true optimum. This was especially clear in a case where each task was capable of being executed at any site, where our heuristically obtained allocations frequently resulted in higher communications costs.

### 4.2. Enhancing the Basic Algorithm

The results of these tests motivated the design of two enhancements to further reduce communications costs, improving the overall optimality of the resulting allocation of tasks to sites.

*Enhancement 1.* Enhancement 1 is applied to each task individually. If a task $t_i$ has been assigned to site $s_j$, its feasible assignment set is searched to find another site $s_k$ so that, if $t_i$ is instead assigned to $s_k$, the unbalance factor of the system is not affected but the communications cost decreases.

*Enhancement 2.* Enhancement 2 tries to group as many tasks together at the same site as possible without affecting the *UBF*. It looks at each pair of adjacent tasks $(t_i, t_{i+1})$, where $t_i$ and $t_{i+1}$ have been allocated to two different sites $s_i$ and $s_k$, and it tries to find a third task $t_j (j > i+1)$ which was also allocated to site $s_i$ (i.e., to the same site as $t_i$); it considers the possibility of reversing the choice of sites for $t_{i+1}$ and $t_j$ without affecting the *UBF* but eliminating the communications cost between $t_i$ and $t_{i+1}$.

The tests described earlier were repeated with Enhancements 1 and 2 employed, and the results indicated that they indeed improve the algorithm [9]. Enhancement 2 was especially helpful for the previously troublesome case where every task is able to run at any site; the optimal allocation was always found in this case using the algorithm with Enhancement 2.

### 4.3. Execution Time and Algorithm Complexity

The execution time and complexity of the heuristic algorithm are also important concerns. Tests were run using an unoptimized version of the algorithm, and its execution time was indeed found to be fairly small [9]. For instance, with 3-5 tasks in a task force and 8 sites in the system, its execution time on a VAX 11/780 was in the 15-40 millisecond range. In our database application [1,9], query task forces are typically small like this, and the time required to initiate a compiled query will easily dominate such task allocation times. As the numbers of tasks and sites were increased, the execution time for our heuristic algorithm was observed to be basically linear in $mn$, whereas the elapsed time for an exhaustive search was seen to rise dramatically. This agrees with a complexity analysis of the basic algorithm which determined its cost to be $O(max(mn, m^2 \log_2 m))$ for $m$ tasks with a total of $n$ candidate execution sites.

### 4.4. An Example Application

As mentioned in the Section 1, the load-balanced task allocation algorithm presented here was motivated by the load balancing problem for locally distributed database systems. We have designed and evaluated a load-balanced approach to query processing for locally distributed database systems, and this work is reported in [1,9]. In particular, a simulation study was conducted to address the impact of using our load-balanced query allocation algorithm. The results of this study indicate that load-balanced task allocation provides better performance than either static or random task allocation strategies, improving the response time and waiting time for queries, and even improving overall system throughput in many cases. Waiting time reductions of 50% or more were typical under moderate CPU loads, and throughput improvements in some cases reached 10-30%.

## 5. CONCLUSIONS AND FUTURE WORK

This paper presented a new algorithm for allocating task forces to sites in a locally distributed computer system. The algorithm is novel in that it takes the current system load into account, using load balancing as the primary objective driving the task allocation procedure, although communications costs are also considered (as a secondary objective).

Because the algorithms and ideas presented in this paper resulted from work on load balancing for distributed database systems, our discussions of task forces and our algorithm descriptions have assumed a linear, pipelined task force structure. The ideas discussed here are applicable to more general task force topologies, however. Future work is needed to evaluate the optimality of the plans generated via our heuristic algorithm (and also the complexity of the algorithm) for other task force topologies. It would also be interesting to study the performance improvements provided for various task force topologies using our approach to dynamic task allocation. Finally, we have not addressed the question of how the necessary load information is to be exchanged among the sites, making the integration of our ideas with an appropriate load information exchange policy a problem for future work as well.

### *ABSTRACT*

We consider the problem of uniformly distributing the load of a parallel program over a multiprocessor system. We describe and analyze four strategies for load balancing. The performance of each of these strategies is compared on a set of problems whose structure permits the use of all four strategies.

The four strategies are (1) the optimal static assignment algorithm which is guaranteed to yield the best static solution, (2) the static binary dissection method which is very fast but sub-optimal (3) the greedy algorithm, a static fully polynomial time approximation scheme, which estimates the optimal solution to arbitrary accuracy and (4) the predictive dynamic load balancing heuristic which uses information on the precedence relationships within the program and outperforms any of the static methods.

It is also shown that the overhead incurred by the dynamic heuristic (4) is reduced considerably if it is started off with a static assignment provided by either (1), (2) or (3).

## 1. Introduction

Efficient utilization of parallel computer systems requires that the task or job being executed be partitioned over the system in an optimal or near-optimal fashion. In the general partitioning problem, one is given a multicomputer system with a specific interconnection pattern as well as a parallel task or job composed of modules that communicate with each other in a specified pattern. One is required to assign the modules to the processors in such a way that the total execution time of the job is minimized.

An assignment is said to be *static* if modules stay on the processors to which they are assigned for the lifetime of the program. A *dynamic* assignment, on the other hand, moves modules between processors from time to time whenever this leads to improved efficiency.

Given an arbitrarily interconnected multicomputer system and an arbitrarily interconnected parallel task, the problem of finding the optimal static partition is very difficult and can be shown to be computationally equivalent to the notoriously intractable NP-Complete problems [1]. However, many practical problems have special structure that permits the optimal solution to be found very efficiently.

In this paper we will consider four methods of balancing load. The first three produce static mappings of modules to processors. These static methods are: (1) the calculation of the optimal static load balance, (2) a suboptimal but very inexpensive static load balancing method, and (3) a fully polynomial time approximation scheme; the solution of which can be made to approach the optimal load balance. A dynamic load balancing method is also considered - this method allows the mapping of modules to processors to vary. These methods for balancing load are suitable for distinct but overlapping varieties of problems. These problems can arise, among other places, in signal processing and image analysis, in the solution of systems of linear equations using point or block iterative methods, in problems of adaptive mesh refinements, as well as in time driven discrete event simulation. We describe our experience with four different algorithms that we have used to solve a problem for which all these methods are applicable.

The first method finds the optimal static assignment using the bottleneck path algorithm described in [2]. This algorithm captures the execution costs of the modules or processes of the task as edge weights in an *assignment graph.* A minimum bottleneck path in this graph then yields the optimal assignment. This algorithm has moderate complexity and is guaranteed to yield the optimal static assignment.

The second method that we evaluate is the binary dissection algorithm which is derived from the work of Berger and Bokhari [3],[4]. This algorithm is very fast but does not always yield the optimal static solution.

The third scheme that we consider is based on a widely used *greedy method* described in [5], which when combined with a binary search yields an approximate solution to the static partitioning problem.

Finally we evaluate the predictive dynamic load balancing method developed by Saltz[6]. This is a dynamic algorithm in that modules are reassigned form time to time during the course of execution of the parallel program. This heuristic takes the precedence relationships of the subtasks into account when deciding whether and when to relocate modules. This additional information and the capability to relocate dynamically permits this algorithm to usually allow for higher processor utilizations than the optimal static algorithm. Each of the load balancing strategies incurs an overhead. The overheads of the static algorithms are incurred prior to the execution of the program and consists of the calculations required to decide on the assignment of modules to processors. In contrast, the overhead of the dynamic load balancing problem is incurred throughout the execution of the program.

The following section discusses in detail the problem addressed in this research. Sections 3, 4, and 5 describe the optimal static, binary dissection and greedy static load balancing schemes, along with an

analysis of the costs of performing the calculations necessary. A proof is presented demonstrating that the greedy algorithm produces an approximate solution to the static partitioning problem which can be made to converge to the optimal solution. Section 6 contains a description of the dynamic algorithm along with descriptions of data structures required for the efficient execution of this method. Section 7 compares the performance of these four algorithms. The factors influencing the run time overhead of the dynamic load balancing method are explored. An investigation is made of the performance and overheads that result from initially balancing load using the various static load balancing methods, and then dynamically balancing load.

## 2. Formulation of Problem

The methods of load balancing discussed here are applicable to distinct but overlapping sets of problems. The following is a description of a class of problems for which all of the load balancing methods presented here are applicable. We consider the partitioning on a multiprocessor system of problems which are composed of $m$ computational modules, numbered 1 to $m$ with a chain like pattern of inter-module data dependencies, such that module $i$ is connected only to modules $i + 1$ and $i - 1$. The computation is divided into steps, and each module requires data from neighboring modules at step $s$–1, to begin the computations required for step $s$.

When the relevant domain is partitioned into strips, explicit schemes for solving time dependent partial differential equations [7], problems in discrete event simulation [8], time driven discrete event simulation [a] , as well as Jacobi and block Jacobi iterative methods [6], [9] used to solve a discretized partial differential equation can exhibit this pattern of data dependence. Pipelined algorithms in signal processing and image analysis [2] can also take this form. A similar but slightly more complex pattern of data dependence occurs in red black and multicolor SOR [10].

The importance of good load balancing strategies is accentuated when the work involved in solving a problem separates naturally into a number of subunits that is relatively small compared to the number of processors utilized, and when partitioning any one of these subunits across several processors is inconvenient or expensive.

Consider the simulation of physical processes, either by means of solving a partial differential equation or by means of a discrete event simulation. The computations relating to a particular spatial strip may be assigned to a specific process which handles all computations describing events occurring in that region. Interactions between strips are local, each strip is coupled only to its immediate neighbors. It should be noted that in adaptive methods for the explicit solution of time dependent partial differential equations [11], block iterative methods, and discrete event simulation, the subunits of computation into which the problems naturally separate may each involve substantial amounts of computation.

In signal processing, a fixed sequence of operations or transforms is applied to a long series of inputs. For example, each arriving packet of data may have to be Fourier transformed, multiplied by a fixed frequency, filtered, clipped and inverse transformed. This type of application has a chain like structure and lends itself naturally to pipelining[12]. We will index successive arriving data packets or inputs by a positive integer i. Module 1 processes i and sends the results to module 2. Each module $j$, $2 \leq j \leq m$–1, receives the modified packet $i$ from module $j - 1$, further processes it and sends it off to module $j + 1$. We will say that module j is computing step $s = i + j$, when it is working on calculations pertaining to packet $i = s - j$. When module $j$ advances from step $s$ to $s + 1$, the module processes the modified packet $i - j$.

From the above, we see that in order to advance to step $s$, module $j$ must obtain information from module $j - 1$ at step $s - 1$. While module $j - 1$ does not require information from module $j$, it is useful to impose the condition that module $j - 1$ must be no more than one step ahead of module $j$. By doing this, we ensure that no more than one modified data packet need be stored per module.

The static load balancing methods yield a mapping of modules to processors. The time required to complete a problem is determined by the processor with the heaviest load. With the dynamic load balancing method, each module may proceed at a rate constrained only by the local availability of computational resources and its data dependence on other modules. Load balancing is performed in a way that is explicitly designed to prevent processor inactivity due to a lack of data availability.

The performance of the static and dynamic load balancing methods are compared through a variety of simulations. The performance of the dynamic load balancing method may be expected to depend to some extent on the initial balance of load at the time dynamic load balancing is initiated. One would expect the performance of the dynamic load balancing method to be favorably influenced by the use of static load balancing to improve the initial load balance.

The performance of each load balancing strategy discussed here is compared on a set of problems whose structure permits the use of all four strategies. Dynamic load balancing becomes particularly desirable in problems in which the time needed for a process to complete one step is difficult to determine before the problem is mapped onto a machine, or when the time required to complete a step changes during the problem's execution.

In the case of discrete event simulations, the time required by a process to complete a step is difficult to determine a-priori, and both the cases of discrete event simulations and methods that solve time dependent partial differential equations using an adaptive grid as part of an explicit timestepping scheme, the activity in a given region may vary during the course of the solution of the problem.

## 3. The Optimal Static Algorithm

In this section we discuss briefly Bokhari's algorithm for optimally partitioning a chain structured parallel or pipelined program over a chain of processors [2]. We assume that a chain structured program is made up of $m$ modules numbered $1..m$ and has an intercommunication pattern such that module $i$ can communicate only with modules $i$+1 and $i$–1 as shown in Fig. 1. Similarly, we assume that the multiprocessor of size $n<m$ also has a chain like architecture. We work under the constraint that each processor has a contiguous subchain of program modules assigned to it. Thus the partitions of the chains have to be such that modules $i$ and $i$+1 are assigned to the same or adjacent processors. This is known as the *contiguity* constraint. The optimal partitioning would then be the assignment of subchains of program modules to processors that minimizes the load on the most heavily loaded processor.

The above problem is solved by first drawing a layered graph (Fig. 2) in which every layer corresponds to a processor and the label on each node corresponds to a subchain of modules. Every layer in this graph contains all subchains of modules i.e. all pairs $<i,j>$ such that $1 \leq i \leq j \leq m$. A node labeled $<i,j>$ is connected to all nodes $<j+1,q>$ in the layer below it for all $j$ except 1 and $m$. All nodes $<1,i>$ in the first layer are connected to the starting node $s$ while all nodes $<i,m>$ in every layer are connected to the terminating node $t$. Any path connecting nodes $s$ and $t$ corresponds to an assignment of modules to processors. For example the thick edges in Fig. 2 corresponds to the assignment of Fig. 1.

Weights can now be added to the edges of this layered graph as follows. In layer $k$, each edge emanating downwards from node $<i,j>$ is weighted with the time required for processor $k$ to process nodes $i$ through $j$ and this accounts for the total computation time on processor $k$. It is clear now that there is a path in this graph corresponding to every possible contiguous subchain assignment and the weight of the heaviest edge in a path corresponds to the time required by the most heavily loaded processor to finish. Thus to find the optimal assignment, we have to find the path in the layered graph in which the heaviest edge has minimum weight – the bottleneck path.

The bottleneck path can be found by using the following labeling procedure. Initially all nodes are given labels $L(i) = \infty$ except in the first layer, in which all nodes are labeled zero. Then starting at the top and working downwards we examine each edge $e$ emanating downwards from a layer. If this edge connects node $a$ (above) to node $b$ (below) then replace $L(b)$ by $min(L(b),max(W(e),L(a))$ where $W(e)$ is the weight

[a] D. Nicol and J. Saltz, "A Statistical Methodology for the Control of Dynamic Load Balancing," to be published as an ICASE Report.

associated with edge $e$. Once the graph has been labeled, we then find the edge incident on node $t$ which has maximum weight. Suppose the edge joining node $<i,m>$ of layer $k$ with node $t$ has maximum weight, then it means that the bottleneck path would contain the node $<i,m>$ of layer $k$ and thus modules $i$ through $m$ would be assigned to processor $k$. The rest of the bottleneck path can be found in the same manner by working upwards from layer $k$ to the top.

The number of nodes per layer in the layered graph is $O(m^2)$ and thus the total number of nodes in the graph is $O(m^2n)$. The number of edges emanating from a node is at the most $m$, thus the total number of edges would be $O(m^3n)$. As the labeling algorithm looks at each edge once, therefore the space as well as time required by this algorithm is $O(m^3n)$.

## 4. The Binary Dissection Method

The binary dissection approach to the solution of the basic partitioning problem addressed in this paper is very efficient in terms of run time and gives solutions that are very close to optimal. This algorithm is a one dimensional version of the two dimensional partitioning strategy developed by Berger and Bokhari [3],[4]. The two dimensional binary dissection method gives a heuristic for partitioning a two dimensional grid of modules, and [3] , [4] give methods for mapping this partitioning onto a variety of architectures.

The algorithm proceeds as follows. The given chain of $m$ modules is split up into two halves such that the difference of the sums of execution costs in each half is minimum. The two halves are then recursively subdivided as many times as desired. Clearly, the number of pieces into which the chain can be partitioned must be exactly $2^k$ where the integer $k$ represents the depth of partitioning.

Thus this algorithm is useful for problems in which the number of processors is a power of 2. The time required by this algorithm is $O(m\log n)$ for a problem with $m$ modules and $n$ processors since there can be no more than $\log n$ levels of partitioning with each level requiring at most one access to each module weight.

At first sight this algorithm may seem capable of yielding the optimal solution. This is not always so, as the example in Fig. 3 demonstrates. In the next paragraph we will find an upper bound on the difference between the optimal solution and the solution yielded by the binary dissection method.

Let $W_T$ represent the sum of the weights of all $m$ modules. A lower bound on the weight of the heaviest subchain $W_{OPT}$ in the optimal partition will be $W_T/n$ under the special case when all the $n$ processors are uniformly loaded. Let us designate the weight of the heaviest module by $w_{\max}$ and the weight of the heaviest subchain assigned to a processor using the techniques of binary dissection by $W_{MAX}$. Then whenever a chain is divided into two parts, the maximum difference between the two halves will be bounded by $w_{\max}$. Thus if $n$=2 then $W_{MAX} \leq W_T/2 + w_{\max}/2$. Similarly if there are $n$ processors then an upper bound on $W_{MAX}$ will be:

$$W_{MAX} \leq W_T/n + w_{\max}(\frac{1}{2}+\frac{1}{4}+...+\frac{1}{n})$$

$$\leq W_T/n + w_{\max}(n-1)/n$$

Thus the maximum difference between $W_{MAX}$ and $W_{OPT}$ will be given by the following equation under the assumption that $m>n$.

$$W_{MAX} - W_{OPT} \leq w_{\max}(n-1)/n \qquad (1)$$

## 5. The Greedy Algorithm

The Greedy algorithm yields an approximate solution to the optimal partition of a chain structured parallel or pipelined program over a chain of processors. This algorithm is based on a greedy method, which is a widely used technique and is applied to a variety of problems [5]. Sahni [1] has devised a polynomial time approximation scheme to solve the knapsack problem using a greedy method while Kernighan uses a similar approach [13] for finding optimal sequential partitions of graphs. Utilizing this method one can devise an algorithm which works in stages and at each stage a decision is made regarding whether or not the next input be included in the partially constructed solution. If the inclusion of the next input will result in an infeasible solution then this is not added to the partial solution. Greedy methods may not necessarily provide optimal answers. For example consider the binpacking problem: Given a finite set $W=\{w_1,w_2,...,w_m\}$ of $m$ different weights, find a partition of $W$ into $n$ disjoint subsets $W_1,W_2,...,W_n$, such that $n$ is minimum and the sum of the weights in each subset $W_i$ is no more than a fixed constant. The First Fit algorithm for the above problem is essentially a greedy method in the sense that it tries to place each weight in the lowest indexed subset as far as possible, but this does not result in the optimal solution [1]. If however we put an extra condition on the problem that weights $w_i$ and $w_{i+1}$ are to be placed in either the same subset or subsets $W_j$ and $W_{j+1}$ respectively then the same greedy approach will be able to find the optimal solution.

The greedy algorithm is based on the function *PROBE* (described below) and takes advantage of the fact that the weight assigned to the most heavily loaded processor in the optimal partition lies somewhere between $W_T/n$ and $W_T/n + w_{\max}$ as discussed in the previous section. The algorithm selects a trial weight $w$ in the above range and then uses the function *PROBE*. The function *PROBE(w)* returns *true* if it is possible to partition the chain of modules into subchains such that the weight of each subchain is less than or equal to $w$, and *false* otherwise. The partition that results from a successful attempt to partition the chain so that the weight of each subchain is no more than w is called the *greedy partition(w)*

```
function PROBE(Processors[1..n], Modules[1..m], w):boolean;

begin
  $i$ = 1; $j$ = 1; $p$ = 1;
  while $p \leq n$ do
    begin
      repeat
        $j$=$j$+1;
      until weight of subchain Modules[$i..j$] > $w$ or $j$=$m$;
      If $j$ = $m$ (all modules have been assigned) then return(true);
      Assign the subchain Modules[$i..j-1$] to processor $p$;
      $i$ = $j$; $p$ = $p$+1;
    end;
  return(false);
end.
```

The greedy algorithm then makes a binary search in the range $W_T/n$, $W_T/n+w_{\max}$ using the above function to find the partition for which the weight of the heaviest subchain is minimum. For each trial weight $w$ the function *PROBE* has to look at each module only once. If the above range is resolved to an accuracy of $\varepsilon$ then the greedy algorithm will find a *greedy partition*($\hat{w}$) in time proportional to $O(m\log_2(w_{\max}/\varepsilon))$ with the assurance that $W_{OPT}\leq\hat{w}\leq W_{OPT}+\varepsilon$ where as before, $W_{OPT}$ is the weight of the heaviest subchain in the optimal assignment. It is important to note that the order of the greedy algorithm is proportional to $\log(w_{\max}/\varepsilon)$ unlike other *fully polynomial time approximation schemes* in which the time complexity is polynomial in $1/\varepsilon$ as described in [1].

In the following paragraphs we will prove that if there exists an assignment with the weight of its heaviest subchain equal to $w$ then the procedure PROBE will always find that or an equivalent assignment assuming that subchains with no modules in them (empty subchains) are allowed.

*Definition:* The *weight of a partition* is the weight of its heaviest subchain.

*Notation:*

$\pi_{w,n}$ a partition with weight $w$ and $n$ subchains.

$\gamma_{w,n}$ a greedy partition with weight $w$ and $n$ subchains.

$\mu_{w,n,k}$ a mixed partition with weight $w$ and $n$ subchains in which the partition up to the first $k$ subchains is greedy and the remaining partition may or may not be greedy.

Observe that $\mu_{w,n,0}$=$\pi_{w,n}$ and $\mu_{w,n,n}$=$\gamma_{w,n}$.

Claim 1: $\mu_{w,n,k}$ can always be transformed into $\mu_{w,n,k+1}$

Proof: Move the right hand partition of subchain $k+1$ to the right until any further movement would cause the weight of subchain $k+1$ to exceed $w$ or exhaust the modules.

1. If this is possible without disturbing the right hand partition of subchain $k+2$ then $\mu_{w,n,k}$ been transformed into $\mu_{w,n,k+1}$ and the claim is correct.
2. If during the course of this movement the r.h. partition of subchain $k+1$ coincides with the r.h. partition of subchain $k+2$, this means that subchain $k+2$ is now empty (which is permitted). Continue movement of both partitions together, combining with any further partitions that may be encountered. When the threshold point is reached, $\mu_{w,n,k}$ been transformed into $\mu_{w,n,k+1}$, one or more subchains to the right of $k+1$ are empty but the claim is still correct. □

Claim 2: If there exists a $\pi_{w,n}$ then there must also exist a $\gamma_{w,n}$.

Proof: Recall that $\pi_{w,n}=\mu_{w,n,0}$.

By repeatedly applying transformation (1) above we can transform: $\pi_{w,n}=\mu_{w,n,0}\rightarrow\mu_{w,n,1}\rightarrow\cdots\rightarrow\mu_{w,n,k}\rightarrow\cdots\rightarrow\mu_{w,n,n}=\gamma_{w,n}$ □

Result: If there exists an assignment of weight $w$ then the procedure PROBE will find that or an assignment of equal weight.

## 6. The Predictive Dynamic Load Balancing Method

We assume that a computation is composed of a fixed number of computational processes or modules. The computation is divided into steps, and each module requires data from a set of other modules at step $s-1$ to begin the computations required for step $s$. Each module may proceed at a rate constrained only by the time required for the processor to perform the computations required by the module, the local availability of computational resources and data dependence on other modules. Hence at a given point in time, the system may contain modules advanced to a variety of different step numbers. In the predictive dynamic load balancing method, the data dependencies between step $s-1$ and $s$ are arbitrary, although in the section following this only chain structured data dependencies will be considered.

At any given point in the computations, the data dependency requirements place limitations on the number of steps a module may advance. As stated before, in order to advance to step $s$, a module requires data from step $s-1$ from a specific set of associated modules. The *largest step reachable* by each module is the largest step number to which a module may be advanced while maintaining the required data dependency relationships. Load balancing is performed in a way that is explicitly designed to prevent processor inactivity due to a lack of data availability.

The *potential work* of a processor is defined as the amount of time that will be required to advance all modules in a processor as many steps as possible given the data currently available from other processors. The *parallel efficiency* of a processor may be defined as the percentage of time a processor spends performing the computations required by the modules assigned to it. Transfers of modules between processors impact parallel efficiencies in a machine dependent way. The communication time required to transfer a module from one processor to another along with the degree to which that communication can be masked with computation are essential factors in this dependency.

In the predictive dynamic load balancing method to be discussed here, load is shifted between processors in a way that attempts to equalize the potential work in each processor. When the potential work of a processor falls below a predetermined threshold, load balancing is considered. A module is shifted from a neighboring processor when the neighboring processor has stored an amount of potential work greater than or equal to the threshold plus a pre-determined safety factor. If more than one neighboring processor fits this criterion, the processor with the largest potential work contributes a module. In the chain structured one dimensional problem considered here, there is only one module that a given processor can contribute at a given point in the computations. In general, the choice of the module to be contributed may not be straightforward [6].

The ability to efficiently calculate the potential work in a processor is central to the usefulness of this method. Simple and inexpensive methods for calculating potential work will now be described. The potential work stored in a processor may have to be calculated from scratch in some situations. When the computations involved in solving a problem are initiated or when modules are shifted in or out of a processor after load balancing, one must take into account both the pattern of data dependencies within a processor and the availability of data from other processors in order to calculate potential work. Given a processor which has assigned to it a value for potential work, a simpler set of computations can be performed to update the value of potential work in response to the receipt of a new datum from another processor.

It is useful at this point to describe in more detail the interaction between step numbers achievable by the modules assigned to a processor and the external data available to the processor. A linked data structure representing an undirected graph DEPEND, with weighted vertices is defined for each processor P. The I *internal vertices* represent the modules in P while the B *boundary vertices* represent modules in other processors directly coupled to modules in P. Let $z_i$ $1 \le i \le B$ represent boundary vertices and let $v_i$ $1 \le i \le I$ represent vertices within the processor. The *weight* $w_i$ of each vertex $v_i$ represents the largest step reachable by each module, given the currently available boundary information. The weight $q_i$ of each of the vertices $z_i$, represents the step of the largest available boundary variable data for the module.

The largest step reachable by a vertex $v_i$ in the processor given currently available boundary data is determined by adding one to the minimum of: (1) the largest steps reachable by all internal vertices $v_j$ linked to $v$ and (2) the step number of the latest available boundary data for the boundary vertices $z_l$ linked to $v$. The weight assigned to $v_i$ may be written as

$$w_i=\min_{j,l}(w_j,q_l)+1 \tag{2}$$

where $v_j$ and $z_l$ are linked to $v_i$.

Denote the current step number of $v_i$ as $s_i$ and the time required to advance $v_i$ one step $t_i$. The potential work associated with P at a given point in the computations may be written as

$$\sum_i (w_i-s_i)t_i \tag{3}$$

where the sum is over all $i$ corresponding to $v_i$ in P. For each boundary vertex $z_i$ the graph DEPEND may be divided into equivalence classes based on the minimum number of edges that have to be traversed to get to $z_i$. We define $r_{k,j}$ as the equivalence class of $z_k$ to which $v_j$ belongs. Note that each internal vertex belongs to B different equivalence classes, one corresponding to each boundary vertex $z_k$, $1 \le k \le B$. The proposition below states a sort of superposition principle that holds for the determination of the maximum achievable step for internal vertices in response to constraints arising from boundary vertices.

Proposition: The weight of $v_i$ is given by

$$w_i = \min_{1 \le k \le B}(q_k+r_{k,i}) \tag{4}$$

Proof: The proof is carried out by substituting the postulated solution into (2). Fix attention on an internal vertex $v_i$. Corresponding to each $r_{k,i}$ where $r_{k,i} \ge 2$ there must be an internal vertex $v_j$ linked to $v_i$ with $r_{k,j}=r_{k,i}-1$. If there were not, it would not be possible to find a shortest path from $v_i$ to $z_k$ consisting of $r_{k,i}$ edges. Moreover, there cannot be an internal vertex $v_j$ connected to $v_i$ with $r_{k,j}<r_{k,i}-1$, if there were, then $v_i$ would have a shortest path to $z_k$ consisting of fewer than $r_{k,i}$ edges. Corresponding to each $r_{k,i}$ where $r_{k,i}=1$ there is a direct edge from $v_i$ to $z_k$.

Now substituting (4) for each $w_j$ into (2) yields

$$w_i=\min_{j,l}[\min_{1 \le k \le B}(q_k+r_{k,j}),q_l]+1 \tag{5}$$

for all j,l such that $v_j$ and $z_l$ are linked to $v_i$. Equation 5 may be rewritten as

$$w_i = \min_{1 \le k \le B} \ [\min_{j,l}((q_k + r_{k,j}), q_l)] + 1$$

For each k, there exists an internal vertex $v_j$ with $r_{k,j} = r_{k,i} - 1$ connected to $v_i$ and there cannot be a vertex $v_j$ where $r_{k,j} < r_{k,i} - 1$. Hence from (5) we obtain (6)

$$w_i = \min_{1 \le k \le B, l} [q_k + (r_{k,i} - 1), q_l] + 1 \qquad (6)$$

For boundary vertices $z_l$ to which $v_i$ is directly connected, $r_{l,i} = 1$. Since all quantities involved are positive in sign, we obtain from (6) the equation (4) for $v_i$ as desired. □

We are now in a position to calculate the potential work from scratch, given values of $s_i$ and $t_i$ corresponding to all vertices $v_i$ in P. For each $v_i$ in P one may calculate $w_i$ from (4) in O(B) operations per vertex. Since there are I vertices the calculation of potential work from scratch requires O(IB) operations.

If a processor has a value of potential work assigned to it the potential work may be updated in response to the receipt of a boundary datum. One finds the weights for each vertex $v_i$ in P in the following way. By equation (4) incrementing the weight of a single boundary vertex can either leave the weight of interior vertices unchanged or increase the weight by one unit. Moreover, only interior vertices currently constrained by the incremented boundary vertex will have their weights incremented.

In response to an increment in a boundary vertex $z_k$, the weights in equivalence classes may be adjusted in order of increasing equivalence class number with only one pass necessary. Assume that $z_k$ has had its weight incremented from $q_k - 1$ to $q_k$. Before $z_k$ was incremented, the constraint on the weight of vertices in equivalence class $r_k = n$ was $q_k - 1 + n$. The constraint on the weight of vertices in equivalence class $r_k = n - 1$ after $z_k$ is incremented is $q_k + (n-1)$. The adjusting of equivalence class $r_k = n$ will have no effect on the adjustment of equivalence class $r_k = n - 1$.

If a vertex in equivalence class $r_k = n$ has a weight of less than $q_k + n - 1$ before being considered for readjustment, it is not being constrained by $z_k$. Incrementing $z_k$'s weight will consequently not affect the vertex. Since the only vertices which can possibly have their weights incremented have weights $q_k + n - 1$, the order in which vertices in an equivalence class are considered is unimportant.

Updating DEPEND may proceed as follows. The weight of the vertex in DEPEND representing $z_k$ is first incremented. In a breadth first manner beginning with the vertex representing $z_k$, DEPEND is searched for vertices whose weights must be incremented. When a vertex $v$ is found that does not require a weight increment, the search does not continue to examine other vertices linked to $v$.

In the model problem, the time and space requirements of this updating algorithm algorithm are $O(nm)$ and $O(m)$ where $n$ is the number of modules in the problem and m is the number of steps over which advancement is to proceed.

## 7. Comparison of Results

We have compared the performance of both the static load balancing methods and the predictive dynamic method through a variety of simulations. Note that with minimal computational effort, on a set of weights consisting of single precision floating point numbers, the greedy approximation scheme produces a balance identical to the optimal load balance. Thus, the performance obtained through the use of the optimal method and the greedy approximation scheme were identical, and in this section we shall simply refer to the performance of the optimal load balancing method.

Static and dynamic methods can be combined; a static load balancing may be performed before beginning work on a problem, and a dynamic load balancing policy may be utilized once work on the problem has begun. It is found that the initial use of static load balancing policies can enhance the performance of the dynamic policy when compared to the performance obtained through the initial assignment of an equal number of contiguous modules to each processor. Furthermore, both the optimal and the binary dissection static load balancing methods yield rather comparable performance when used with the dynamic predictive load balancing method. Used without a dynamic load balancing method, the optimal load balance was found to be notably superior to binary dissection, while there was hardly any difference between the optimal load balance and the greedy load balance on the test problems described here.

It is important to note that the performance measured in the case of the dynamic load balancing method is average processor utilization, the overhead required to move modules from one processor to another is accounted for through counting the average number of module shifts per step per processor. The time required for these shifts is an architecture dependent variable.

We consider a system with 16 processors and a fixed number of modules. In each trial, random deviates representing the weights of modules are drawn from a truncated normal distribution. For each set of random deviates, both the optimal static load balance and the binary dissection balance are calculated and the performance is tabulated. Simulations utilizing the predictive dynamic policy are also run using the same set of random deviates. These simulations utilize both static policies and the assignment of a fixed number of modules to each processor as starting conditions. Performance is measured by calculating the average percentage of time processors are occupied advancing modules over the course of the simulations. Performance results are averaged over 50 trials differing only in the values of the random deviates generated.

In Fig. 4 and Fig. 5 the performance obtained through the use of the static and dynamic policies is depicted. In these figures, the performance of the policies is plotted against the variance of the truncated normal distributions from which the module weights were drawn. In the experiments depicted in the above figures, the weights for the modules were drawn from truncated normal distributions with variances of 0.5, 1.0 and 2.0 and mean 1, and the problem was assumed to run for 200 steps. In Fig. 4 during each trial 64 modules were assigned to the system while in Fig. 5 96 modules were assigned to the system. In both of these cases, for all variances tested, the dynamic load balancing method outperformed both static load balancing methods. Note however, that this measure of performance does not take into account the machine dependent cost of shifting modules between processors, a cost that will be studied in more detail below. The binary dissection static method was in all cases noticeably inferior to the optimal static load balance. The use of a static load balancing method initially had a relatively minor positive impact on performance in the experiments with 96 modules, and no discernible impact at all in experiments with 64 modules. The performance impact of the initial use of a static load balancing method is quite dependent on the number of steps required to solve a problem. It will be seen later that for problems that continue for a relatively small number of steps, the initial use of a static load balancing method can markedly improve performance.

In the dynamic load balancing method, the moving of modules from one processor to another will exact a cost that will depend on the details of the machines' interprocessor communication network. We can calculate an approximate expression that estimates the overhead that results from the module transfers required by the predictive dynamic method. Let $\gamma$ be the ratio between the average cost of transferring a module and the average computation cost $C$ of advancing a module one step. Letting P represent the number of processors in the system, t be the average module transfers per step per processor, and recall that m is defined as the number of modules in the problem. The average time spent computing per processor per step is $\frac{Cm}{P}$, and the average time spent transferring modules per processor per step is $\gamma Ct$. Under the pessimistic assumption that no communication can be masked by computation, the ratio of the time spent transferring modules to the time spent in computation is $\frac{\gamma sp}{m}$.

In Fig. 6 and Fig. 7 the average number of modules that must be moved from one processor to a neighbor per step of the computation is plotted against performance for a range of values of the dynamic method's safety factor. The average processor utilization obtained through the use of optimal static load balancing and through the use of binary dissection static load balancing are depicted in these figures for the sake of comparison, these involve no module shifts. In each of the two figures, the use of static load balancing does play a notable role in increasing performance and decreasing the frequency with which modules have to be shifted. On each curve in Fig. 6 and Fig. 7 both the cost and performance were strictly decreasing functions of the safety factor used. As the safety factor increases, modules are moved increasingly frequently and the performance and the overhead cost both increase. If the time required to transfer a module is equal to the time required to advance a module one step, the ratio of the time spent in computation to the time transferring modules in Fig. 6 and Fig. 7 is simply the average number of module shifts per step per processor divided by six. This ratio ranged from 0.005 to .0045 in the plots depicted in Figures 6 and 7.

The number of steps advanced are varied and the performance and the overhead in modules moved per step are depicted for the dynamic load balancing method in Fig. 8 and Fig. 9 respectively. In both figures, the effects of using the two static load balancing methods as well as using no load balancing at the beginning of the computation are compared. In all cases, the performance increases with the number of steps advanced.

For problems that do not require a large number of steps, the performance obtained by starting out with a static load balancing method is superior to that arising from the dynamic load balancing method without initial static load balancing. Perhaps somewhat counter-intuitively, initially balancing load with binary dissection leads to better performance than initially performing an optimal balance for problems requiring over 10 steps. The optimal static load balance is not necessarily the initial load distribution that best allows the dynamic load balancing method to move modules so that processor idleness is avoided. As the number of steps increases, the performance differences obtained through the use of different initial load distributions becomes less marked.

The initial use of static load balancing also leads to marked reduction in module transfer overhead as depicted in Fig. 9. In this figure the overhead per step generally increases with the number of steps. For problems with very large numbers of steps, the overheads for the initial load distributions all approach a single value. When no initial static load balancing is used in a problem that is advanced a small number of steps, both low performance and relatively high costs in number of modules transferred are incurred. It is noted that in Figure 9, when of initial static load balancing was not used, the number of modules transferred reaches a local maximum for problems of 10 steps, and then declines briefly before resuming its long term increase. This phenomena has been observed in a number of similar experiments, its cause is unclear.

The performance obtained through the use of binary dissection as a static load balancing method was notably poorer than that produced by the optimal balance. We have observed in these and other experiments that initial static load balancing used along with the predictive dynamic load balancing method improves performance and reduces the frequency with which modules must be moved. The choice of method used to initially balance load does not appear to have a marked impact on performance or cost.

## 8. Conclusions

The experimental results presented here revealed that the predictive dynamic load balancing method led to processor utilizations that were consistently above those obtained by the optimal static load balancing method, when the delays caused by the overhead of transferring modules are negligable. As one would expect, the optimal static load balancing method, in turn, consistently out performed the binary dissection method.

The initial partitioning of load at the point dynamic load balancing was initiated proved to have a marked effect on the performance of the dynamic load balancing algorithm. All three static load balancing methods used in conjunction with the dynamic load balancing method lead to a substantial improvement in performance and a decrease in module transfer overhead when compared to a uniform initialization of modules to processors. The magnitude of these effects depended on the number of steps the problem is advanced, being most pronounced when a problem is finished after relatively few steps. It is interesting to note that the binary dissection algorithm appeared under some circumstances to consistently lead to results that were superior to optimal load balancing when used in conjunction with dynamic load balancing.

One of the principal costs of the predictive dynamic load balancing method is expected to be the machine dependent cost of transferring the computational modules between processors. The effect of initial load distribution on this cost was examined and it was found that the frequency with which modules were transferred between processors was markedly reduced when either form of static load balancing was initially employed.

The initial distribution of load in a multiprocessor system is clearly an important determinant of the performance gains achievable by the dynamic load balancing policy; this initial distribution also has a strong influence on the overhead costs of the dynamic policy.

The four load balancing methods discussed in this paper each have their own distinct advantages and disadvantages. Finding an optimal static load balancing is in general an NP-Complete problem unless special structure is present to permit a low order polynomial solution. For the test problems that we have considered, the greedy algorithm was an order of magnitude faster than the optimal load balancing algorithm and it provided results as good as the optimal solutions. The binary dissection method and the predictive dynamic load balancing algorithms are both quite useful in situations in which low order polynomial solutions to the optimal static load balancing problem do not appear to be available.

**Abstract**

High level tasking constructs and rendezvous mechanism are employed to experiment with parallel processing of program components on nodes of a local network. In contrast to instruction level synchronization requirements of SIMD machines, our study centers around *interaction point* level synchronization in a distributed MIMD machine. Program decomposition issues are discussed and a strategy for allocation of tasks to optimum number of processing stations together with experimental performance results are presented.

## 1. Introduction

Local area networks have generally been used for connecting a number of computing modules within a limited geographical space. The primary objective has been to enable users on different hosts to communicate and share access to expensive peripheral devices and remote disc files. There has also been much work on distributed processing aspects of local networks, with emphasis on intertask communication primitives and remote call implementation [1,2,3]. In this paper we address parallel processing potentials of local area networks.

Parallel processing within a local network is attractive for two main reasons. First, it enables utilization of the spare processing capacity of the increasingly powerful personal workstations by distributing the computational intensive jobs among them. Secondly, a fast local network can be used as an inexpensive way of connecting processors in a stand-alone multiprocessor computer. The basic issues of parallel processing in a local network include: the choice of the programming language, suitable granularity of parallelism, and especially program partitioning and assignment strategies.

In the following sections we will discuss the above issues and present the results of our experiments with task level parallelism. The experiments were carried out to measure effects of the frequency of *interaction points* (rendezvous) between constituent tasks modules, as well as the number of processing stations employed, on the execution time of a given job. Finally we present a heuristic method which can be used to estimate the optimum number of workstations which should be used for parallel execution of components of a given job.

## 2. System Support Components

Since parallelism at task level was our main objective, a high-level language with concurrent tasking facilities was the logical choice. The programming language used in this project is Martlet [4] which is a Pascal derivative with concurrent tasking facilities added on. The details of Martlet and its implementation have been given in references [5,6]. Briefly, a Martlet program generally consists of a number of cooperating tasks which communicate using the Entry_Call Accept rendezvous mechanism similar to Ada [7]. The compiled tasks are assigned to the processing stations by means of a system generation program called *SETUP* which creates the final core images for the processing stations. The criteria for allocation of tasks to processing stations will be discussed in the section dealing with program decomposition. Martlet has proven very suitable for distributed and parallel programming applications and was ported to a network of PC/XTs for this project [8]. An example of a Martlet program is given in the Appendix I.

The target network consists of a number of workstations (PC/XT/AT's) connected by 10 Mbps Ethernet [9] as shown in Figure 1. Martlet's run-time support system consists of a distributed multitasking kernel and an interpreter with copy of each in every station of the local network. The station kernel is responsible for managing the processor and the tasks

*This research was funded by the Natural Sciences and Engineering Research Council of Canada (NSERC).

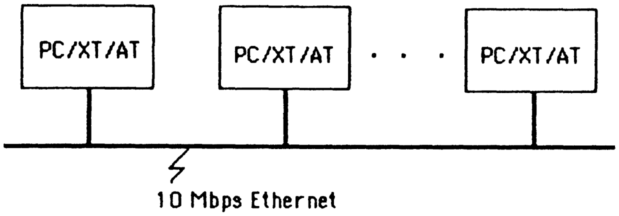

**Figure 1 The Local Network Configuration**

in the station. Interstation communication between tasks is handled transparently by pseudo transport level tasks which are created at system SETUP time.

## 3. Program Decomposition

The problem of decomposing a large program into concurrently executable sub-tasks has been studied for some time [10,11]. Partitioning (i.e. division of a program into procedures, modules, and tasks) together with assignment which deals with allocation of these units to the available processing units, are the two most important issues in distributed and parallel processing systems. In a network or distributed environment, the actual placement of the computational objects has substantial effect on the overall performance of the system. This is mainly because of additional communication delays when communicating tasks are located in different stations of a local network [3].

Minimizing interprocessor communications as well as load balancing are the two main criteria for allocating tasks to the available processors in a system. Exact partitioning of a set of communicating tasks into a distributed multiple processor system is an np-complete problem. However, heuristic algorithms have been developed for optimum allocation of computational objects in a distributed system. These algorithms generally define a graphical model of the communications structure of the tasks, then use a heuristic approach to 'cut' the graph into distinct components such that the sum of the weights (representing the frequency of communications) of the edges in the resulting edgecut is a minimum [12].

However, we have to be cautious when trying to apply the above allocation algorithms in a local network because these algorithms assume: (1) the cost of in-station communications between tasks to be zero and (2) the cost per inter-station communication to be the same for all configurations. Our experimental results show that both of these assumptions are far from being acceptable when using high level intertask communication constructs in a broadcast type local network. To achieve higher execution speed we must distribute the load among additional stations. The question is how many stations should be employed before the benefits of additional processing power are offset by the increased communication delays. We try to answer this question in the next section.

## 4. The Task Allocation Method

Here, we are concerned with the class of problems which can be implemented using task level parallelism. Of particular interest are ***synchronized algorithms*** where parallel tasks must exchange data and synchronize their operations at some ***interaction points.*** As an example, a number of producer tasks may perform many iterations of a simple function and then communicate the results to a consumer task at specific points within the computation. Therefore we are dealing with a MIMD environment where operations are synchronized after some intervals; this is in contrast to a SIMD environment where instruction level synchronization of the processing units is necessary.

We now present the heuristic allocation strategy which was developed for the class of problems which can be translated into a set of producers-consumer tasks as stated above. The strategy is based on the simple guideline that the actual processing speed-up due to an additional workstation should be at least equal to or greater than the corresponding communication overhead which must be handled by the new station. To find the formula for estimating the optimum number of stations we define:

Ts = Total execution time for a job when all component tasks are assigned to a single station.

Tr = Average delay overhead of a network rendezvous (message exchange).

n = Total Number of Rendezvous during the execution of the entire job.

N = Maximum number of stations to be used for a given job.

Assuming balanced load distribution, then for an additional station to have a positive effect we should have:

$$\frac{Ts-nTr}{N-1} - \frac{Ts-nTr}{N} \geq \frac{nTr}{N}$$

Therefore:

$$N \leq \frac{Ts}{nTr}$$

Ts can easily be obtained from the single station execution of a job in the class of problem concerned. Even Tr can also be estimated from communications delay overheads when all tasks are run in a single station (see Figure 3). Once N is estimated from the formula, the component tasks are divided evenly among N stations. Figures 2(a) and 2(b) support the validity of such a strategy as discussed above.

## 5. Experiments and Results

The experiments were conducted for configurations which ranged from a single station to 9 stations in the local network. The entire job consists of one consumer and eight instances of a function (producer) task as given in Appendix I. Each producer performs an identical amount of computation and returns a single result to the consumer. The consumer then computes the sum of eight results. Each function is a simple iterative loop from 1 to 100. At run-time, each function is given a parameter called Force = 1..200 telling the function how many 1..100 iterations it should perform before returning a value. The entire system is given a parameter called WORK = 1..10, telling the system how many times the consumer should calculate the sum. WORK determines the number of rendezvous during the test. Figures 2(a) and 2(b) show the speed-up in execution time as the number of stations is increased. The total workload and the number of rendezvous are used as parameters.

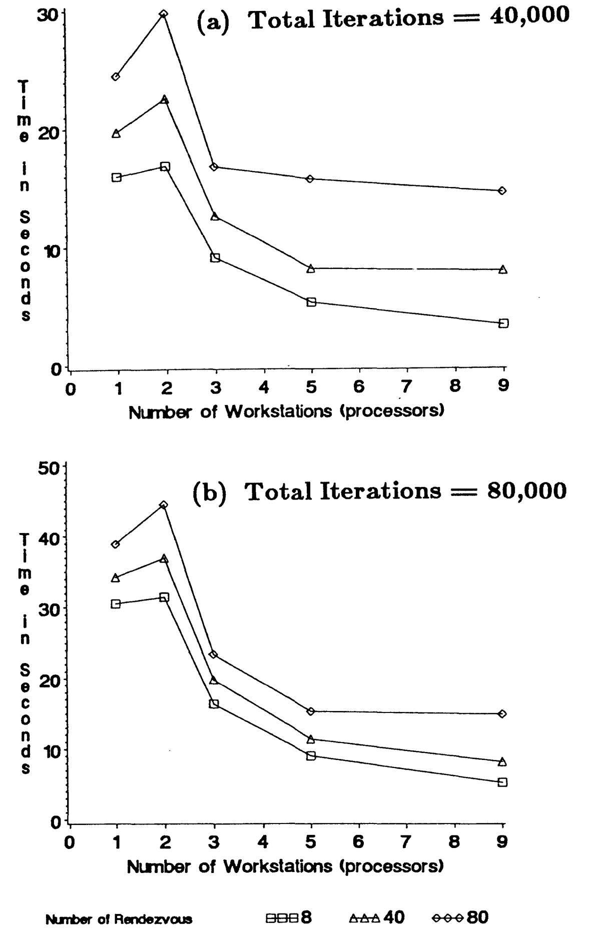

**Figure 2 Execution Time vs No. of Workstations**

Figure 3 gives the variation in rendezvous delay overhead as a function of the number of stations taking part in execution of the job. We should point out here that due to the interpretative nature of the run-time system the execution and delay figures are larger than normally encountered in non-interpretive systems. However, this does not effect the relative nature of our comparisons.

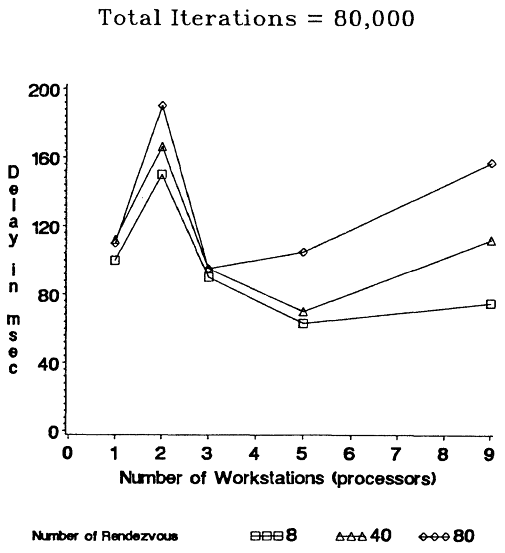

**Figure 3 Variations in Rendezvous Delay**

Table I shows the maximum number of stations which should be employed for different workloads and frequency of rendezvous as calculated using our proposed allocation method. These numbers are in close agreement with the actual number of stations at which execution speed-up levels off, as shown in Figures 2(a) and 2(b).

**Table I Optimum No. of Workstations for a Given Job**

| No. of Iterations | Execution time on a single Station(Ts) | No. of Rendezvous (n) | Optimum No. of workstations using N = Ts/nTr and load balancing |
|---|---|---|---|
| 40,000 | 20.5 (sec) | 40 | 5 |
| 40,000 | 24.5 | 80 | 3 |
| 80,000 | 34.8 | 40 | 9 |
| 80,000 | 39.2 | 80 | 5 |

## 6. Conclusions

We have shown that a particular class of problems which require *interaction point* level synchronization similar to the given test problem, are suitable for parallel processing on stations of a local network. We have also presented a heuristic method which uses the data from a single station execution of a set of cooperating tasks to estimate the optimum number of stations that should be used for their parallel execution.

Further work includes finding methods by which a general computation intensive problem can be decomposed into a set of producers-consumer tasks which can then be handled by the method described in this paper.
