## ABSTRACT

The use of optical techniques has been widely recognized as a solution for overcoming the fundamental problems in data communications. It is potentially feasible to build large optical crossbar networks that do not suffer from many of the limitations of their electronic counterparts. In this paper we discuss several optical matrix-vector implementations of crossbar networks and present a comparative study of these designs. These designs employ acousto-, electro-, or magneto-optic spatial light modulators for achieving the generalized crossbar functions. Some new optical systems suitable for implementation of crossbar networks are also described. They can also be used to construct multistage networks of larger size.

## 1. INTRODUCTION

Any multiprocessor system that uses several processors must be designed to allow efficient communication among processors and memory units, as this data communication contributes significantly to the overall performance of the system. An ideal interconnection network for this purpose is a high speed, high bandwidth crossbar network. A crossbar network will allow any processor to communicate with other processors or memories with simple control and small delay. Even though crossbars are ideal networks for multiprocessors, they are generally used in only relatively small systems, as the cost of large crossbars is prohibitively expensive with the VLSI technology. There have been several crossbar designs reported for up to several hundred inputs and outputs [BURG 83, DENN 82, BROO 84].

For large crossbar implementations other types of technology may offer a viable alternative. The use of optical techniques has been widely recognized as a solution to overcoming the fundamental problems in data communications [SAWC 84]. The parallel nature of optics and free-space propagation, together with their relative freedom from interference make them ideal for parallel communications. There exists many different optical devices which provide switching capability. It was shown in [SAWC 85] that any implementation of matrix-vector multiplier in optics results in an optical crossbar network.

Suppose that $N$ serial data input lines (each one-bit wide) are to be connected to a set of $N$ serial data output lines (each one-bit wide). We can think of the data bits on each line flowing synchronously, although, for some of the techniques we describe, this synchronism is not necessary. We can represent the data on the input lines at some instant of time by the column vector $\vec{b}$ of length $N$. The data on the output line of the interconnection network (which we refer to as a switch) is represented by the column vector $\vec{c}$ of length $N$, and both these vectors have only binary elements. The state of the switch is described by the $N \times N$ matrix $A$ whose elements are also 0's and 1's. Matrix $A$ is a generalized permutation matrix; an entry of 1 in row $i$ and column $j$ of $A$ means that input $j$ is connected to output line $i$.

Once the physical connection described by the matrix $A$ is made, the data transfer could be synchronous or asynchronous [SAWC 85]. This idea can be generalized for the interconnection of $N$ parallel input lines (each $M$ bits wide) to $N$ parallel output lines (each $M$ bits wide). Thus, systems capable of performing matrix-vector or matrix-matrix multiplications with binary entries may be suitable for use as a crossbar interconnection network. In this paper, several different optical implementation of crossbar networks are presented and the tradeoffs in their performance are discussed.

## 2. OPTICAL MATRIX-VECTOR SYSTEMS

There are many techniques available for matrix-vector or matrix-matrix multiplication using optics. In some of these systems, the physical switch may be analog and passive (a switchable reflective or transmissive element); thus bit synchronism is not required and the data bandwidth is limited only by the optical sources and detectors used (currently available sources and detectors can operate at > 1 Gb/s). In other systems, the matrix-vector multiplication is implemented by active electro-optical or acousto-optical components, implying the detection and regeneration of optical signals. In such systems the switch itself may limit the data bandwidth. In the remainder of this section we will discuss some of the optical systems we have studied for crossbar implementations.

### 2.1 $N^2$-Parallel Matrix-Vector Inner Product Processor

In this system, $N$ input lines drive an array of $N$ light emitting diodes (LEDs) or laser diodes with a binary signal, so that a binary 1 is represented by light of a fixed intensity, and a binary 0 is represented by a lower (or zero) intensity. An optical system to the right of the input vector spreads the light from each input source into a vertical column that illuminates the crossbar mask [SAWC 85]. Following the crossbar mask, the next set of optics collects the light transmitted by each row of the mask, and sums the mask output onto a vertical array of $N$ photodetectors corresponding to the $N$ output lines. Thus the system performs a parallel matrix-vector multiplication. Since it is a passive interconnection, once the mask is set, the data can flow through synchro-

* This research is supported by the DARPA/ARO Contract No. DAAG29-84-K-0066.

nously or asynchronously, can be analog or digital, and has a bandwidth limited only by the sources and detectors.

### 2.2 Systolic and Engagement Architectures

Systolic and engagement architectures have the advantage of providing for rapid reconfiguration of the network, i.e., they can be reconfigured at the bit rate of the data (neglecting any overhead in calculating the needed states of the crossbar matrix elements). In these systems, though, the input data must be configured appropriately for the matrix multiplication to proceed; this will require electronics at the input that can buffer the signals and send them into the switch in the appropriate sequence and at appropriate times. In some cases, only minimal buffering is required, e.g. when the data is originally time-division multiplexed bit by bit. More details on systolic architectures can be found in [SAWC 85].

An engagement architecture for matrix multiplication is shown in Fig. 2.1. The matrix elements of $A$ enter into a 2-D source array or a multichannel AO cell, skewed and formatted as shown. The data, or elements of $B$, enter a second, crossed multichannel AO cell from the top and propagate downwards. A 2-D stationary integrating detector array then accumulates the results and outputs them in parallel. Systolic architectures are similar to engagement architectures but use shift-and-add detectors instead of time-integrating detectors and data enters in a different way.

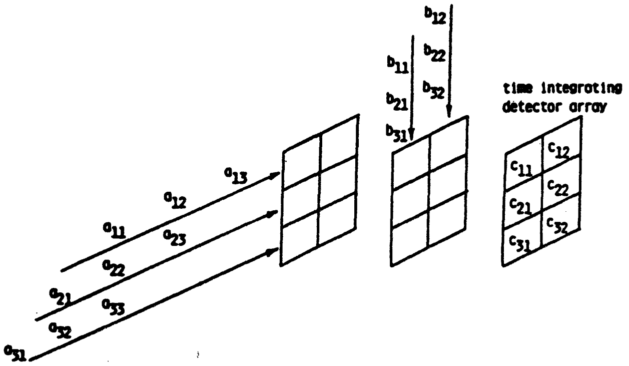

Fig. 2.1. Engagement architecture for matrix multiplication.

Compared to the inner product architecture above, systolic architectures yield crossbars that are more light efficient, have shorter reconfiguration times, but have lower bandwidth. For an $N$-parallel system, with sufficiently fast input and output devices, the AO cell will generally limit the bandwidth of each individual line to $\nu_0/2N$, where $\nu_0 \approx 1$ Gb/s. A number of these 1-D elements in the $N$-parallel multiplier can be placed in parallel however, permitting each line to be $M$ bits wide, thereby increasing the effective bandwidth by a factor of $M$ ($M \approx 100$ with current devices). If $M = N$, then the system is an $N^2$-parallel systolic matrix-vector multiplier. Because a new matrix is essentially read in for each new bit or word, the system can be reconfigured rapidly.

An $N$-parallel engagement matrix multiplier requires $N(3N-2)$ clock cycles to complete one matrix-matrix operation or one arbitrary switching operation on $N$ $N$-bit wide lines, approximately the same as the ($N$-parallel) systolic case. An $N^2$-parallel engagement arrangement, such as the RUBIC (Rapid Unbiased Bipolar Incoherent Calculator) cube [BOCK 84], takes $(3N-2)$ clock cycles. The input data formatting requirements are similar to the systolic case, but interleaved 0's are not required. The $N$-parallel case uses time multiplexing again. We can think of the width of each functional input line as being equal to the word length so that an $M$-bit wide line can transfer one word at an instant of time. In the $N^2$-parallel engagement system, there are $N$ physical input lines, and the switch operates on word slices: it is word serial and bit parallel except for a unit time shift from one physical line to the next. In other words, the first line has the first bit of each word, sequentially in time, etc. In the systolic case above, the physical lines are actually serial over diagonals of matrix $B$ rather than strictly bit-serial or word-serial. The detectors here are 1-D or 2-D time integrating detector arrays. As with systolic systems, reconfiguration is rapid but updating of the state of the switches is needed even when the state does not change from one multiply to the next.

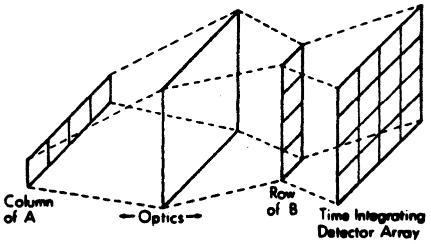

Fig. 2.2. $N^2$-parallel outer product processor.

### 2.3 $N^2$-Parallel Outer Product Processor

An $N^2$-parallel outer product processor such as that shown in Fig. 2.2 performs $C = AB$ by taking outer products of column $i$ of $A$ and row $i$ of $B$, and summing the results over $i$. It can perform a matrix-matrix operation in $N$ clock cycles. The requirement of a 2-D detector array will limit the bandwidth to much lower values; removing the data electronically from the detector array slows the system down. The data input is a row of B at a time, or bit parallel, word-serial. The detector is a 2-D array of stationary, time-integrating detectors. Since the $A$ matrix is read in for each matrix multiplication, reconfiguration is rapid, although the state of the switches needs to be updated for each matrix multiply.

### 2.4 $N^2$-Parallel Inner Product AO Deflector

While the above systems may be useful in many applications, they all share a common fault. Since the matrix $A$ is mostly 0's, most of the scalar multiplications performed by the above systems are multiplies by 0. This translates into either wasted time (thereby lowering the bandwidth) or wasted light (lowered light efficiency). One of the new architectures we have devised eliminates these problems which is the inner product AO deflector and is very similar to the system described in Section 2.1 except for the deflector. It is also a passive system and utilizes a simple 1-D detector array.

The input data to the crossbar enters through a 1-D array of sources. Each source is then transferred to the corresponding cell (or channel) of a multichannel AO device, used as a deflector. There is a separate channel for each data-input line, or each column of $A$. Rather than reading in the elements of $A$ into the AO device ($N$ elements into each channel), one single number is input into each channel, and the signal is frequency-modulated according to the amount of deflection desired for the corresponding input line. Broadcasting can be achieved, to a limited extent, by superimposing multiple frequencies onto the same channel of the AO cell, or by time multiplexing the different frequencies in the cell. Each channel of the AO cell in this system has just one signal on it; it is not divided into multiple (moving) resolution elements. Each channel then deflects the signal the appropriate amount in the y dimension, and the light is then focused down in the x dimension, yielding a one dimensional output array.

### 2.5 $N^2$-Parallel Inner Product/Engagement Processor

Another new type of matrix-matrix processor architecture that could be used as an optical crossbar is shown in Fig. 2.3. The system is a combination of an $N^2$-parallel inner product processor and an $N^2$-parallel engagement architecture. The $b$ 's to be multiplied in the system enter a parallel array of AO cells as shown, although the data for each row enters simultaneously instead of being staggered as in the $N^2$-parallel engagement processor. The input data also arrives in a time-staggered form and controls the illumination of LED's or laser diodes as shown. A set of optics similar to that in the $N^2$-parallel inner product processor spreads the light across the multichannel Bragg cell, and the final result accumulates on a time-integrating detector array. The results emerge in a time-offset fashion from a row of the detector array as shown. This system requires ($3N$−2) clock cycles to complete a matrix-matrix multiplication and requires a digital synchronous data format. Broadcast operation is possible with this system, and the overall light efficiency can be as high as $1/N$.

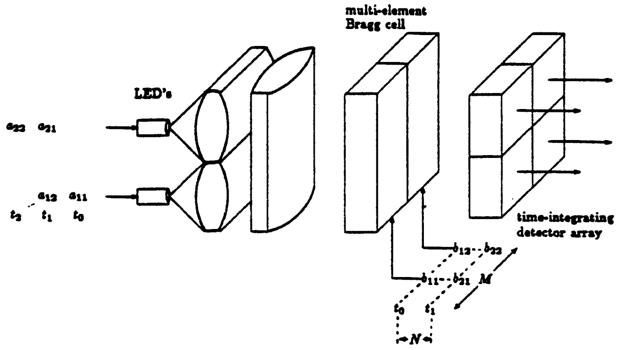

Fig. 2.3. $N^2$-parallel inner product/engagement processor.

## 3. PERFORMANCE COMPARISON

The optical systems introduced in the previous section differ widely among themselves in many characteristics which are of importance when used for interconnection. For example, some of the systems provide a bandwidth that is essentially independent of the size of the system, while for others, it is an inverse function of the system-size. In this section, we compare the different systems based on some parameters of interest in crossbar implementation.

*1. Number of Lines N:* Optical systems can implement moderately large crossbars (100×100 to 500×500) with relative ease.

*2. Bandwidth:* For passive optical networks, the bandwidth of each line is limited by sources and detectors, which can easily operate at 1 Gb/s rates or higher. Sources (laser diodes) and detectors are available at 20 GHz and 40 ps, respectively. 1-D arrays are presently limited to lower values; current detector arrays with parallel outputs operate at approximately 50 Mb/s. Higher bandwidths could be achieved by first coupling to fibers and routing the fibers to detectors; still higher bandwidths might be possible by avoiding conversion to electronics altogether. In contrast, electronic systems typically operate at 10 Mb/s for each line.

*3. Reconfiguration Time:* Reconfiguration of optical networks is limited to approximately 1 $\mu$s for moderate or large networks with current or near-future technology; in fact, most 2-D switch arrays have a frame time of 1 ms or greater. Acousto-optic devices have faster response times, but the electronic input (to each cell) is serial and limited to a few GHz; and the signal cannot be changed as it propagates down the cell. Most of the acousto-optic architectures permit fast reconfiguration at the expense of bandwidth.

*4. Broadcast Capability:* In electronic implementations, the provision of broadcasting involves higher control complexity, a larger number of pins, and/or slower operation. In some optical systems, the addition of broadcast capability involves only very minor increases in complexity.

*5. Data Format:* The switching process as well as the transfer of data can be performed either synchronously or asynchronously. Synchronous operation requires strobing or capture of data at precise instants of time in the system.

*6. Type of detector:* There are three major types of optical detectors, namely, real-time, shift/add, and time-integrating detectors. The inner-product processors need a vector array of detectors with separate channels and a real-time output. The data-bandwidths of these systems is generally limited by the response characteristics of the detector array. In some of these systems (e.g. those with real time detectors), the output may be directly coupled to a light guide or fiber; in this case the detectors, if any, are physically located some distance from the optical switching array. The engagement and outer-product systems with full $N^2$ parallelism require $N \times N$ time-integrating detectors which can be operated synchronously with the data. 2-D $N \times N$ detector arrays have either $N$ output lines or 1 output line. Thus the necessity of multiplexing at least $N$ detector signals onto each electronic output line creates a bottleneck and limits the bandwidth of the overall system. The systolic architectures require a shift/add detector array to perform the summation. $N \times N$ shift/add arrays necessarily have at most $N$ output lines; this and the use of electronics to perform the shift and add limits the detector speed, in turn lowering the overall bandwidth of the system.

Table 3.1 summarizes the above considerations for the six basic optical matrix-vector crossbar architectures given in Section 2.

## 4. CONCLUSIONS AND FUTURE WORK

In this paper, we described several possible optical systems for implementation of crossbar networks and studied the tradeoffs involved. Advantages of these systems include large amount of inherent parallelism, high data-bandwidth, small size and power requirements, and freedom from mutual interference of signals. We have found that moderately large crossbars (64×64 to 512×512) may be feasible using current or near-future optical technology. It is feasible to build optical crossbars that have a higher bandwidth and more data lines than electronic systems, although their reconfiguration speeds are much slower. The main difficulties that need to be surmounted are the slow reconfiguration, means for efficient conversion of electronic signals to optical signals and vice-

| Method of implementation | Number of lines | Bandwidth (BW) | Reconfiguration time | Broadcast | Data format | Type of detector |
|---|---|---|---|---|---|---|
| $N^2$-parallel inner product | $> 256$ | 1 Gb/s (passive) | $(N)1\ \mu$S | yes | async | real time $N \times 1$ element |
| $N^2$-parallel systolic | $> 100$ | 10 Mb/s* | $N$/BW | yes | sync | $N \times N$ shift/add |
| $N^2$-parallel engagement | $> 100$ | 10 Mb/s* - 100 Mb/s | $N$/BW | yes | sync | $N \times N$ time-integrating |
| $N^2$-parallel outer product | $>256$ | 10 Mb/s* - 1 Gb/s | max ($N$/BW, $N \cdot 10$ nS) | yes | sync | $N \times N$ time-integrating |
| $N^2$-parallel inner product AO deflector | $> 100$ | 1 Gb/s (passive) | 1 $\mu$S | limited | async | real time $N \times 1$ element |
| $N^2$-parallel inner product/ engagement | $>100$ | 10 Mb/s* - 100 Mb/s | $N$/BW | yes | sync | $N \times N$ time-integrating |

Table 3.1. Comparison of optical crossbar capabilities.

* Limited by output (detector array) electronics. Higher numbers (when given) apply when fibers guide light to discrete detectors or other optical components.

versa, and techniques for control.

An intriguing and powerful possibility is to use these crossbars as building blocks to make larger networks. In order to make use of this important possibility, means of cascading these optical crossbars need to be devised. This involves studying the input and output formats of the data in the different optical systems for compatibility. The light efficiency of the crossbar must also be factored in, as it determines how often detection and regeneration of the optical signals is needed. Methods of physically coupling the output of one system to the input of the next must be devised, and additionally the signals may need to be sent to multiple crossbars in different locations. Of course, one way of doing this would be to use electrical lines to connect up the optical crossbars; but it is preferable to keep as much of the overall system optical as possible, in order to maximize the advantages that the optics provides, such as high bandwidth and large number of lines. All-optical amplifiers have been demonstrated [KOBA 84], [DAGE 86a]. While there are practical problems to be solved to build 1-D arrays of optical amplifiers, it can, in principle, be done [DAGE 86b]. Optical cascading of crossbars can be done with fibers or holograms. It has been shown [JENK 84] that holograms can be quite powerful for interconnecting optical gates. Even the capability of connecting a small number (4 or 5) of sizable crossbars together could yield a system that is substantially more powerful than a single crossbar.

# Distributed Recovery in Applicative Systems

Frank C.H. Lin [*]
ESL, Inc.
Sunnyvale, California 95051

Robert M. Keller[*]
Quintus Computer Systems, Inc.
Mountain View, California 94041

**Abstract:** Applicative systems are promising candidates for achieving high performance computing through aggregation of processors. This paper studies the fault recovery problems in a class of applicative systems. The concept of *functional checkpointing* is proposed as the nucleus of a distributed recovery mechanism. This entails incrementally building a resilient structure as the evaluation of an applicative program proceeds. A simple rollback algorithm is suggested to regenerate the corrupted structure by redoing the most effective functional checkpoints. Another algorithm, which attempts to recover intermediate results, is also presented. The parent of a faulty task reproduces a functional twin of the failed task. The regenerated task inherits all offspring of the faulty task so that partial results can be salvaged.

**Keywords**: fault tolerance, error recovery, distributed systems, applicative systems, data flow architecture, functional language.

## 1. Introduction

An important feature of a multiprocessor system, including applicative multiprocessing systems, is the ability to sustain partial system failures. By an*applicative system* in this paper, we mean a partitioned-memory system such as Rediflow [8, 9, 18] which coherently executes *applicative*, or *functional*, programs.

The evaluation of an applicative program generates an implicit call tree. The result of the root task is the answer of the program. Every task in the call tree represents a partial result which is used by its parent task to compute other partial results. Because the semantics of applicative of languages has no notion of destructive modification, a parent task is capable of regenerating all of its child tasks based upon the argument and function information.

Many fault-tolerance techniques for general multiprocessor systems have been proposed [1]. Some of these schemes can be adapted to applicative systems. However, applicative systems possess some interesting characteristics, e.g., *determinacy*, that merit distinct fault recovery considerations [6, 7, 14].

In this paper, fault tolerance issues in a class of applicative systems are studied. We assume that any task can be executed by any processor and that tasks are dynamically assigned to execution processors at run time. A single processor failure is also assumed. A processor is assumed to be either faulty or fault-free. A faulty processor must voluntarily declare itself faulty, or otherwise be identified as faulty by other processors.

It is further assumed that if a processor fails, it will no longer transmit any valid messages. This assumption can be enforced by commanding a faulty node to keep silent and not to respond to any inquiry. Alternatively, a faulty node may answer an inquiry with an invalid message. Several techniques are available for a processor to determine node malfunctioning. Parity checking on the system bus or resident memory, illegal instruction trap, protection violation, or a subsystem breakdown may trigger the CPU reporting a processor failure. Duplication of processors within a node, called "passive node diagnosis" [12], is also a common technique for building self-checking nodes.

It is assumed that a processor makes its best effort to communicate with a destination node. If the destination cannot be reached due to a network problem, the unreachable node is considered faulty. Problems with the interconnection network may be detected via coding or timeout mechanisms.

Our approach exploits the determinacy property of applicative programs. A distributed checkpointing scheme, *functional checkpointing*, is proposed in the next section. As the evaluation of an applicative program proceeds, a distributed resilient evaluation structure is incrementally established across the network of processors. Any single processor breakdown is salvaged by the implicit redundant path of the robust structure. A simple rollback recovery algorithm, which basically discards all partial results, is discussed in section 3. In section 4, another recovery algorithm, *splice recovery*, is proposed to salvage as many intermediate results as possible. Tasks which are equivalent to those trapped inside the faulty processor are generated to replace the failed tasks. Partial results produced by the failed tasks are inherited by the recovery tasks.

## 2. Functional Checkpoints

Checkpointing is familiar in the fault-tolerant computing literature [1]. In a uniprocessor system, checkpointing is normally performed by storing machine state on nonvolatile devices periodically. Such a periodical checkpointing technique has been extended to multiprocessor systems [3, 5, 7, 15]. The basic idea is to virtually stop all computational operations while periodic global checkpointing takes place.

[*] Work reported herein was supported by a grant from the IBM Corporation, while both authors were at the University of Utah.

Periodic global checkpointing may not serve the best interests of fault tolerant applicative systems. For example, nonvolatile storage for storing system states may not be necessary, if recovery of a faulty processor is accomplished outside the node. Checkpoint information may be stored on one or more peer processors. Furthermore, periodic global synchronization among a large number of processors is potentially inefficient [2].

We propose a distributed checkpointing strategy for applicative systems. The approach attempts to exploit the determinacy property of applicative programs.

By a *functional* checkpoint, we mean a recovery point for a function application in an applicative system. A partial state of the system is stored so that recovery of the function is possible. The partial system state used in a functional checkpoint is related to a *single* function only. Normally, a functional checkpoint does not have enough information to recover an entire node, not to mention recovering a system. The sole purpose of the partial state is just to back up a function application.

The idea of functional checkpointing is to disseminate the responsibilities of recovering a faulty node to processors which have immediate relationship with the faulty node. Complete recovery is done by collective efforts from various associated processors to retrieve the corrupted tasks.

### 2.1 Determinacy

*Determinacy*, or *referential transparency*, is the characteristic of applicative programs which makes them attractive for distributed execution. A program is called determinate if an identical answer always results from any function invocation for given arguments. In other words, a functional program is free from side effects.

Determinacy suggests that an appropriate time for a functional checkpoint is when a parent task spawns a child function. A task packet is formed for the new function and then waits for execution. The packet contains *all* necessary information, either directly or indirectly accessible, to activate the child task. Furthermore, determinacy insures that different activations of the same task packet will always yield the same result. Thus, even if a task is aborted during computation, a new invocation will not be contaminated by its predecessors.

### 2.2 Checkpoint Properties

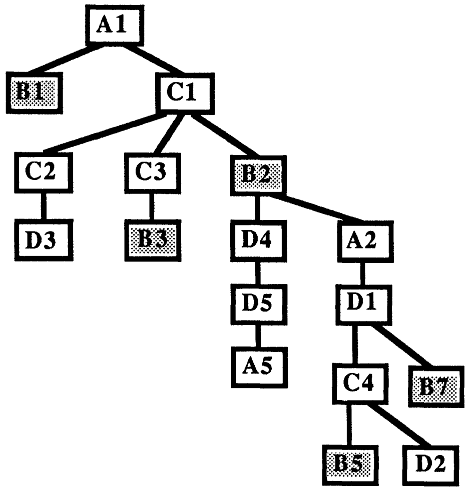
Periodic checkpointing is a synchronous operation whereas functional checkpointing is **asynchronous**. Each processor holds the privilege and responsibility of checkpointing its offspring tasks. A processor may opt to arrange the checkpoints in a partial order such that more efficient recovery can be implemented (section 3). Checkpoint coordination between processors is not necessary.

Functional checkpointing can be implemented **implicitly**. As a child task is spawned to a new node, the parent task may retain a copy of the task packet. This retained copy is all that the parent needs to regenerate the child task, should the node evaluating the child task fail. Therefore, functional checkpointing can be fully embedded in the evaluation process.

## 3. Rollback Recovery

Using functional checkpointing as a framework, a simple rollback recovery mechanism can be devised. An applicative call tree is mapped onto a set of processors. Each processor may have an arbitrary number of tasks. When a processor fails, the call tree may be broken into pieces. However, the piece that contains the root task is always capable of regenerating all severed pieces.

Suppose that an applicative program has been spawned into the call tree as shown in Figure 1. For ease of discussion, tasks Ai (i = 1, 2) are mapped onto processor A, tasks Bi are executed in processor B, etc. Suppose that processor B fails. Then tasks Bi are destroyed. The call tree is thus fragmented into three pieces: {A1,C1,C2,C3,D3}, {A2,D1,D2,C4}, and {D4,D5,A5}.



| A | B | C | D |
|---|---|---|---|
| --- | A2 | ----- | A5 |
| B1 | --- | B2,B3,B5 | B7 |
| C1 | --- | ----- | C4 |
| D1 | D4 | D2,D3 | --- |

Figure 1: A call tree mapped onto processors A,B,C, and D, and corresponding distribution of checkpoints

Assuming the check point of an application is kept on the processor of its parent. Processor A contains the functional checkpoint for B1, processor C contains checkpoints for B2, B3 and B5, and processor D contains checkpoints for B7. To recover from the failure of B, the system needs to command processor A to respawn B1, and command processor C to regenerate B2 and B3. Task B2 will in turn generate new tasks which are equivalent to D4 and A2. Since an applicative program has no side effects, it does not require any *undo* operation, and hence there is no *domino effect* [13].

Note that task C4 holds the checkpointing data for B5. Processor C may regenerate B5 when B fails. However, the recovery of B5 is not fruitful because antecedent task A2 cannot report its result to B2. Reactivation of B5 only increases the system overhead. Therefore, an efficient way to salvage a group of genealogical dependents is to redo only the most ancient ancestor and ignore the rest.

### 3.1 Level Stamps

Genealogical dependencies among tasks can be monitored by a simple level numbering scheme. Assume that the root task carries a null level number, a task at level one will bear a unique one digit identification. Tasks in subsequent levels are stamped by appending one more digit to the number of their parents. The term "digit" is used here generically and is not limited to a specific radix representation.

Since each task is associated with a unique level stamp, it is obvious that ancestor-descendant relationships can be observed by comparing stamps. Note that a level stamp is not a time stamp. Its uniqueness is guaranteed by the program structure. Stamping of tasks can be fully asynchronous.

### 3.2 Recovery Scheme

Each processor maintains a table of linked lists. The Nth entry of the table contains all topmost checkpoints from the host processor to processor N. Referring to FIgure 1, for example, when processor C spawns task B2 to processor B, C compares the level stamp of B2 with all checkpoints in entry B. If B2 is a descendant of an existing functional checkpoint, C does nothing. Otherwise, processor C makes a checkpoint for B2 in entry B.

When processor C identifies the failure of processor B, C simply reissues all the checkpointed tasks found in entry B of the table. By doing so, processor C fulfills its responsibility of recovering B. Other processors take similar actions to recover their descendant tasks being trapped in B. The complete recovery of a faulty processor is a collective effort from processors which have checkpointed applications on the failed processor.

During task evaluations, a processor is required to abort a task if new arguments of the task cannot be obtained due to failures of other processors. A task is also aborted if the result of the task cannot be forwarded to the parent task. The aborted tasks and their descendants may be recollected during garbage collection operations.

### 3.3 Dynamic Allocation and Recovery

The possibility of discarding intermediate results without extensive undo operations is a property of applicative programs. However, the ability to recover by simply reissuing checkpointed tasks depends on the availability of a dynamic allocation strategy, such as the *gradient model* approach [10].

Recovering tasks in a static allocation environment requires manipulations of some linkage information. For example, tasks being allocated to a failed processor have to be reassigned to other processors. Descendants of the reassigned task have to modify their return addresses accordingly. Furthermore, the balanced state derived from the static allocation method may not be maintained easily after a processor fails.

Dynamic allocation does not distinguish between tasks generated for recovery and original tasks. All tasks are treated equally during load-balancing activities. The parent-child linking information is dynamically produced. Hence, there is no need to update these linkages when the task is reassigned.

### 3.4 Orphan Tasks

Rollback recovery inevitably leaves a few orphan tasks after some recovery has taken place, e.g., task D4 in Figure 1 becomes an orphan when processor B fails. The problem is that a task might not know whether it is an orphan without expenditure of a considerable amount of system resources.

Returns from orphan tasks are theoretically harmless since they are forwarded to a faulty processor and no side-effect can be induced. However, the partial results produced by orphan tasks are in fact correct answers of their associated functions. Failure of a node does not contaminate these incomplete answers; it just breaks the linkage among them. These partial results are usable if the regenerated parent task knows where to retrieve them, or if the orphan tasks know the new address to which to forward their answers. The desire to salvage partial results motivates the design of the following recovery scheme.

## 4. Splice Recovery

Applicative systems facilitate evaluation of a functional program by dynamically unfolding the underlying structure of the algorithm and disseminating parallel tasks to many processing nodes. At any instant, task distribution in a system represents a snapshot of the program structure. Generation of a task creates a new substructure and establishes a linkage between the parent and children. Return packets from a child task normally eliminate the children that are no longer needed.

The simple rollback scheme cuts off the branch or branches originating from a faulty node and regrows new branches. The method basically abandons all intermediate results computed by the orphan tasks. This section suggests a different approach, *splice recovery* , which attempts to retrieve all possible intermediate results.

### 4.1 Resilient Evaluation Structure

The splice approach is to continuously establish a *resilient evaluation* structure during program computations. A resilient structure is one containing redundant information which allows a system to rebuild the original structure after a failure has been identified. By rebuilding the structure, the system may salvage many partial results.

We have seen that when a processor fails, an applicative call tree may break into several pieces. The idea of splice recovery is to provide necessary bridging information such that broken pieces can be put together again. When a parent discovers the failure of a child task, the parent task generates a twin task of the faulty child. This twin task **inherits** all offspring of the faulty task with the help of the grandparent pointer.

A grandparent pointer of a task is a pointer from the task to its ancestor in the grandparent *processor*. For example, the grandparent pointer of task B3 in Figure 1 points to task A1, and task D4 has a grandparent pointer to C1 (Figure 2).

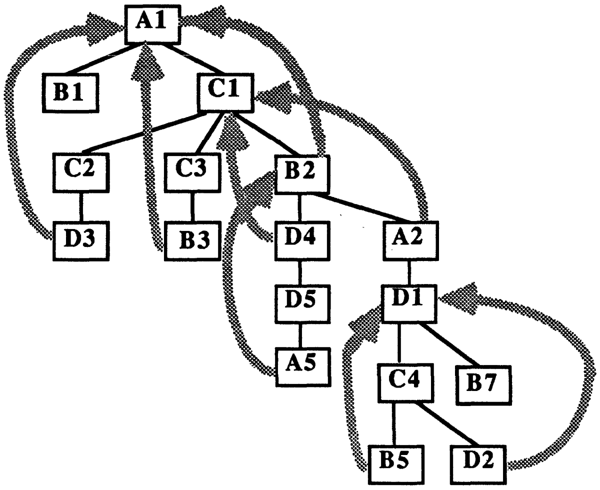


Figure 2: Grandparent pointers

Assuming as before that processor B fails, processor C may start recouping the loss of B2 as soon as C realizes that node B is dead. A twin task of B2, say B2', is created by the parent C1 to inherit tasks D4 and A2 (Figure 3). A full emulation of task B2 would require task B2' to possess physical binding information between B2 and D4, and between B2 and A2. Unfortunately, this information must be embedded not only inside the faulty node, but also within every descendant processor. Changing the return addresses of every descendant task at various sites could be very tedious.

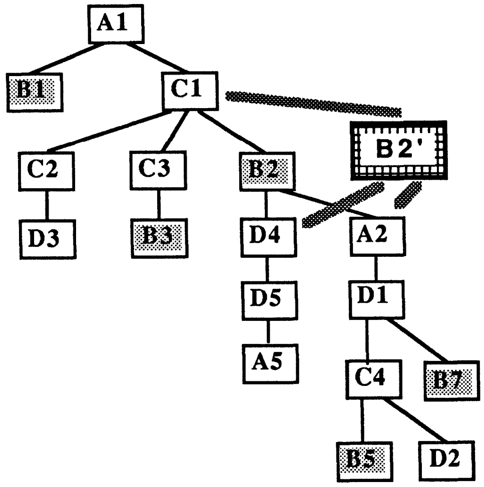

Figure 3: Task B2 is inherited by task B2'

Instead of fully emulating a faulty task, we opt to make B2' inherit descendant tasks of B2. Suppose that when D4 tries to return the evaluated answer to parent B2, it detects that node B is dead. The algorithm commands D4 to forward the result to grandparent C1. Processor C receives these unexpected partial answers from grandchildren and asserts that the parent of these grandchildren is faulty. Then, processor C forms the recovery task B2' by duplicating the task packet of B2.

If processor C has already reproduced B2' when the return from D4 arrives, task A simply forwards what it has received to step-child B2'. The role of a grandparent node in this recovery scheme is two-fold: it reproduces the dead task and it transports the orphan results to their step-parent when these returns become available. Having the grandparent relay partial results eliminates the problem of updating return addresses in every orphan task.

A recovered task, like any other, starts executing its function code as soon as it is committed to a physical processor. When it encounters a function call, it forms a task packet and spawns the child. However, offspring of a recovered task may or may not have been demanded by the preceding faulty task. Let P represent a faulty task, and C a child task of P. Let P' be the recovery task for P. C' is generated by P' and is the equivalent of C, as suggested in Figure 4.

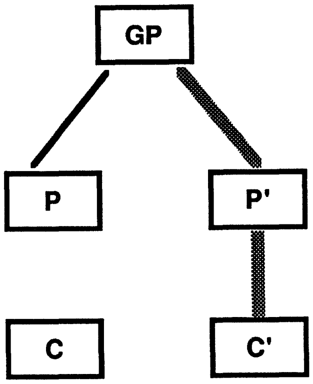

Figure 4: Tasks in splice recovery model

The relationship between child task C and its clone C' has the following possibilities: (Figure 5)

(1) C has never been invoked;
(2) C will never complete;
(3) C completes before P dies;
(4) C completes after P dies, but before P' is invoked;
(5) C completes after P' is invoked, but before C' is invoked;
(6) C completes after C' is invoked;
(7) C completes after C' has completed;
(8) C completes after P' has completed.

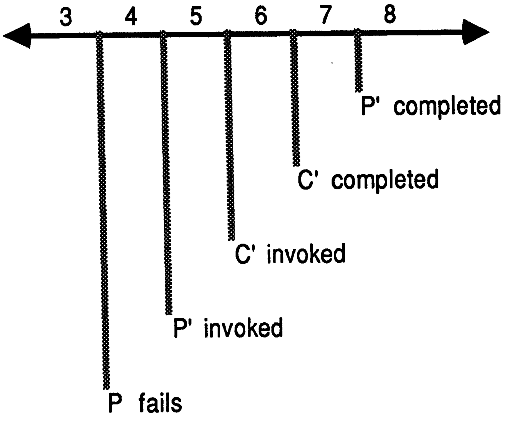

Figure 5: All possible orderings with respect to completion of C

**Case 1 or 2:** C has never been invoked or C will never complete. In either case, no result of C is produced. Task C is practically nonexistent and will be garbage collected. Only C' may produce an answer.

**Case 3:** C completes before P dies. Task C may have already finished the computation and returned the answer back to parent P before P breaks down. The result of task C is stored inside the parent P. When P fails, the system loses all partial results which have been saved in P. The recovery task P' must recalculate C by activating task C'.

**Case 4 and 5:** an old result comes before the new invocation. Task C finishes computation after the parent P dies. C sends its result to the grandparent task which transfers the result to the step-parent P'.

The difference between cases 4 and 5 is that in case 4, the grandparent has to reproduce P' first. When child task C' is executed by task P', P' will not spawn C' because the answer is already there. There is still only one result C' in the system.

**Case 6:** C completes after C' is invoked. Suppose that P' has already spawned C' when the result from C arrives at P'. Theoretically, the result from C and the would-be answer from C' are identical. Therefore, parent P' takes the answer from C and proceeds with the execution. The addition of C' may produce a duplicate answer to P'. Since they are identical, the second copy is simply ignored.

**Case 7:** C completes after C' has completed. This is the reciprocal situation of case 6. Note that due to the asynchrony nature of task evaluations, late invocation of an identical task may yield a result faster than the earlier invocation.

**Case 8:** old result arrives after everything is completed. The processor which contained P' may no longer recognize the arrived answer. The result is discarded.

**4.2 Protocol for Splice Recovery** The main idea of the splice recovery method is to build a resilient structure along with a program evaluation. The redundant information must be in place long before a recovery is initiated. This section describes the usage of these redundancies from the view of a single processor.

```
LOOP
  CASE received packet OF
  forward result:
      Interpret the level stamp.
      CASE level stamp OF
        child: Place data at the location indicated by the
               level stamp. If a task can be continued,
               resume the task.
         grandchild: Create a step-parent for the grandchild
                     if there isn't one already.
                     Transfer the result to its step-parent.
        others: Ignore the packet
      ENDCASE

  fetch data: If the location has been evaluated, forward the
              data. Otherwise, DEMAND_IT.

  task packet: Execute the task. DO each instruction
       If an unevaluated function encountered,
       DEMAND_IT.
       If cannot proceed, suspend the task.
      UNTIL completion. Send the result to the parent.
      If the parent is dead,
            notify the grandparent and
            send the result to the grandparent.

  error-detection: Find the topmost offspring of all
        branches, respawn all of these apply tasks.
        Establish transport mechanism for relaying
        partial results.
  ENDCASE
ENDLOOP.
```

The routine *DEMAND_IT* is the fundamental evaluating process of an applicative program. We elaborate the algorithm in the following form.

```
DEMAND_IT:
        Create a task packet.
        Level-stamp the task packet
        Attach parent and grandparent identifications
           to the task.
        Queue the task packet to load balancing manager.
        Functional checkpoint the packet.
End DEMAND_IT.
```

As a rule of thumb, if a processor receives a packet and cannot find a proper rule to handle it, the processor simply ignores the received message. Note that the overhead of splice recovery protocol is small. By using the level stamps as tags for a program structure, the apparent overhead for establishing a resilient structure is a physical identification of grandparent node which may be just an integer.

### 4.3 Correctness of the Recovery Scheme

The successful evaluation of an applicative program is signaled by the completion of the root task. A necessary condition for completing the root evaluation is to satisfactorily compute all immediate descendants of the root. This observation, when applied recursively, implies that all tasks must be evaluated correctly.

In order to guarantee a task can be evaluated, the task has to be generated in the first place. This means that every task is flawlessly reproducible even if some processor may fail during the evaluation. *Reproducibility* of tasks is the main criterion for a resilient applicative system.

#### 4.3.1 Reproducibility

If the failed processor contains the root of a task tree, the regeneration of the root does not come naturally with recovery schemes. The user must restart the program, or a preevaluation functional checkpoint needs to be implemented.

One simple method to generate a preevaluation checkpoint is to create a super-root which acts as the parent processor of all user programs. When a user program is initiated, the super-root checkpoints the program so that a duplicate copy of the program can be found in the system should the root fail.

With this modification, every task in an applicative program has a parent. A parent task is capable of generating and regenerating any immediate child task as long as the parent is informed by some error detecting mechanism. This satisfies the reproducibility requirement of a correct recovery algorithm.

### 4.3.2 Residue Effects

Without loss of generality, evaluation of an applicative tree can be typified by scrutinizing the spawning process of a three-task sequence. Figure 6 shows the state transition diagram of spawning and reduction of task G. Task G spawns task P which subsequently spawns C. Note that states b and d are transient. The existence of transient states is a result of the dynamic load balancing method.

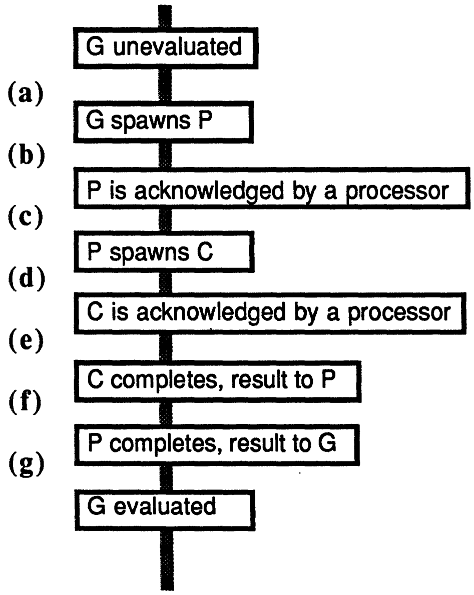

Figure 6: State transition diagram for evaluating G

The pointers being produced and reduced among tasks of each state are depicted in Figure 7. The pointer from P to its grandparent and the pointers to P from its grandchildren are omitted for clarity. Assume that task P fails during the evaluation of G, residue effects may affect any one of the related tasks at any stage of the state transition. A residue-free fault tolerant measure must assure that tasks G and C are not affected by the failure of P from state a through state g.

The failure of P obviously has no effect in state a. In state b, failure of the processor which absorbs P means that parent task G will not receive a positive acknowledge from task P. As a result, processor G times out and reissues a new task P. The system acts as if the first invocation of P did not take place.

In state c, task G receives an acknowledge from P and establishes a parent-to-child pointer to P. The new pointer may provide additional fault detection capability, but the impact of the failure remains similar to that of state b.

Residual effects, resulting from the failure of P, may happen at state d and successive states. Parent task G is left in the same situation as if it were in state b or c. However, there is a child task C lingering around the system. Task C may be stranded due to incomplete information from parent P. In this case, C commits suicide and the recovery from G is free from residual effects, or task C may complete the evaluation and try to return the result. C sends the result to G after failing to communicate with parent P. The case analysis in section 4.1 applies here.

State e has exactly the same recovery condition as state d, since the transient state d becomes state e as soon as task C finds an idle processor. The discussions on state d can be applied here and will not be repeated. State f is similar to state c as far as recovery is concerned.

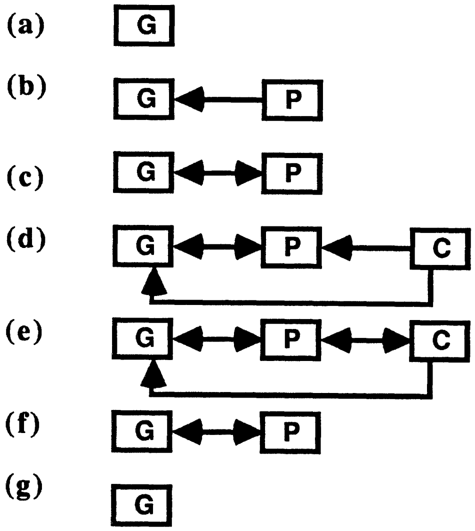

Figure 7: Available pointers among tasks

## 5. Discussion and Related Research

### 5.1 Robust Storage Structures

Using a resilient structure for fault-tolerant computing is not a new idea. Waldbaum [19], and Taylor, et al. [16, 17] proposed a robust storage structure to ensure data integrity in uniprocessor or shared memory machines. Item count, identifier field, and/or additional pointers are commonly added for error detection and recovery purposes. This paper extends the concept of resilient structure to a distributed applicative evaluation graph.

Conceptually, an evaluation structure is quite different from a storage structure. A storage structure is an object manipulated by programs, while an evaluation structure is a program itself. Furthermore, most techniques developed for resilient storage structure seem to be impractical in distributed systems. For example, item count of a linear list is a convenient way for checking broken links in a shared memory machine. To maintain a correct item count and verify it regularly in a network of processors would require significant traversing overhead.

### 5.2 Multiple Faults

Both the rollback and splicing recoveries use functional checkpoints to tolerate hardware failures. Although single node failure is assumed throughout the discussion, it is obvious that rollback recovery is not limited to tolerate only single node failure. The difference between multiple faults and single fault in the rollback algorithm is the placement of the recovery border in the evaluation graph.

Splicing recovery can handle some combinations of multiple faults gracefully. For example, multiple failures on different branches of a structure do not disturb the recovery algorithm at all. Separate recoveries take place at different parts of the program in parallel. However, if both the parent and grandparent processors of a task fail simultaneously, the orphan task would be stranded. It is noted that the resilient structure concept can be further extended to include pointers to the great grandparent and beyond to tolerate multiple failures on one branch of the graph.

### 5.3 Hardware Redundancy

In a hardware redundant fault tolerant system, several redundant machines execute an identical program on replicated data objects. An applicative system can emulate hardware redundancy by simply replicating the task packets. Eventually, a task is executed by several processors at random times. The results are sent back to the originating node asynchronously. The originating node compares these results and selects a majority consensus as the correct answer.

A fundamental difference between applicative replicated task redundancy and pure hardware redundancy is that applicative systems execute redundant tasks asynchronously, while most hardware redundant systems employ synchronous operation. Asynchronous operations are subject to timing delays because a node has to wait for the return from slower processors. But a node does not have to wait for the slowest answer if it has received the identical results from the majority of replicated tasks. Replicating tasks provides a means of emulating hardware redundancy in applicative systems. The user may specify certain critical sections of a program for such a highly reliable operation.

### 5.4 Related Research

Fault tolerant problems in data-driven systems have been studied [6, 7, 11, 14]. Misunas proposed a triple modular redundancy implementation of a dataflow machine [4, 11]. Three complete copies of the program are stored in the memory. Copies of each instruction are carefully distributed so that each copy is executed by a different processor and utilizes different communication paths. Thus, the failure of any single block affects at most one copy of the program.

Hughes [7] described a variation of periodic checkpointing, where a host processor periodically stored the whole system state. Also discussed was a recovery technique, node-by-node correction, which used a control unit of the system as a monitoring device. Erroneous packets were recomputed and re-sent.

Srini [14] suggested a node reassignment algorithm for error recovery purposes. The algorithm depends on a global system memory for collecting and communicating recovery messages. The checkpointed node state is stored in the global memory.

Grit [6] proposed a structural recovery method where each node in the system is limited to spawning child tasks to its immediate neighbors. At system initialization time, a node receives a list of recovery sites for each of its immediate neighbors. When a node fails, a neighbor notifies the recovery site. The recovery node polls all possible parent and child nodes of the failed processor and tries to reconstruct the lost task.

## 6. Summary

This paper discusses the reliability aspect of applicative multiprocessor systems and suggests means for fail-soft treatment. The concept of functional checkpointing is proposed. Unlike conventional checkpoint schemes, functional checkpointing is concise, distributed and asynchronous. Two fault recovery techniques based on the notion of functional checkpointing are proposed. The thrust of these recovery models is to minimize the overhead while the system is in a normal, fault-free operation.

The simple rollback recovery method attempts to reconstruct the faulty section of the program structure by redoing the functions from the most efficient parent task or tasks. In other words, the recovery starts from the most recent functional checkpoints. The scheme is simple and has very little overhead in a normal operation. But, if a fault happens at a later stage of the evaluation, the rollback recovery may be costly.

The splice recovery scheme also uses the most recent functional checkpoints for error recovery as in the rollback method. In addition, the splicing scheme tries to salvage as much intermediate partial results as possible. The salvage is made possible by a backward grandparent linkage along with a program graph stamping mechanism. This approach enables the parent tasks of a faulty processor to regenerate the corrupted substructure of the program and splice the recovery results into the framework preceding the failure.

Yokohama, 223, JAPAN

*ABSTRACT*

Parallel machines in which the Processing Units (PUs) are connected with a nearest neighbor mesh connection structure are ideal for solving partial differential equations. Here, a dynamical fault recovery scheme with such a structure is proposed.

In the case of the detection of a faulty PU within the execution process, connections of PUs are changed; the model is re-discretized by using the calculus of finite differences; the execution is continued from the faulty point.

This scheme was implemented on PAX-32, a parallel computer consisting of 32 microcomputers, and 2-dimensional Poisson equation was solved. As a result of simulation, the effectiveness of this scheme is demonstrated.

## 1. INTRODUCTION

Parallel computers with the nearest neighbor mesh (NNM) connection are ideal for solving partial differential equations (PDEs) by using iterative methods. For instance, PAX[1,2] or NASA's Finite Element Machine[3,4] has been proposed.

Through progress in VLSI technology, highly parallel computers with a great number (e.g., thousands or millions) of microprocessors can be developed. In these systems, the realization of fault tolerant computing is indispensable, and some inter-PU connection networks have been proposed. Most of these are a sort of multistage network (e.g., OMEGA[5], DELTA[6]), or have some redundancies (e.g., Chordal Ring[7], Lens[5]). There are only a limited number of references on the *dynamic fault recovery* within the execution processes.

When solving PDEs with an NNM structured machine, the processes may be divided broadly into two categories as follows:

1. Discretization Process: A PDE is converted with one of discretizing methods.
2. Iteration Process: The converted equations are solved by using some iterative methods.

These processes require a great number of computations; this type of recovery method is considerably important.

In this paper, we discuss the dynamic fault recovery within only the latter process, where it takes much more time than the former essentially. In the case of discretizing 2-dimensional Poisson equation by using the calculus of finite differences, the fault recovery algorithm and simulation results with PAX-32 are also proposed.

## 2. Fault Recovery in NNM Structured Machine

When trying to perform the fault recovery dynamically in an NNM structured machine, such actions as below may be taken:

1. Calculations for a faulty PU are executed by other fault-free PUs (e.g., HOBONET[8]). If these fault-free PUs are the surrounding PUs, a load balance for each PU may be unequal. On the other hand, if one of the redundant PUs takes over the executions for the faulty PU, irregular data-transfers may occur, or the fault recovery algorithms may be more difficult. These schemes are inefficient.
2. A faulty PU is logically disconnected, and processes belonging to this PU cease from executions. This scheme causes worm-eaten results, but has the advantage of easy recovering. In the case of numerical methods, solutions are obtained only on the mesh points. This means that a loss of data on a few mesh points can be negligible, if the accuracy loss is small.

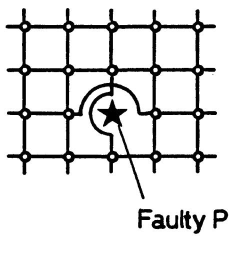

Fig. 2.1 Bypass Recovery

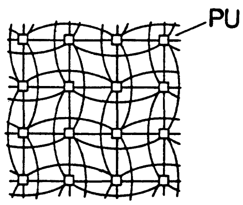

Fig. 2.2 Links for Bypass Recovery

The scheme in question for us is the latter one. In our scheme, damages caused from the faulty PUs can be reduced to the minimum, and executions of fault-free PUs continue. As shown in Fig. 2.1, with the detection of a faulty PU, interconnections of the surrounding PUs are changed and the faulty PU is disconnected. If there have been redundant links in the NNM in advance as shown in Fig. 2.2, this type of fault recovery can be executed easily. We call this a *Bypass Recovery*.

## 3. Discretization on irregular intervals

We first use the calculus of finite differences as a discretizing method, because, the bypass recovery can then be applied efficiently.

Suppose that any PU is assigned to one node of a PDE model respectively. If the bypass recovery mentioned above is performed, the model is changed around the faulty PU (Fig. 3.1). So in the process of the fault recovery, re-discretization of the model should be performed by using the finite difference method on irregular intervals. In the model of Fig. 3.1, the discrete equation on x-direction is

$$u_{i,j} = \frac{2u_{i-1,j} - 3u_{i,j} + u_{i+2,j}}{3h^2} + o(h)$$

where $h$ is the interval between the two neighboring nodes. This way of discretization can also apply to the y-direction's or a model with various physical constants; as well as, to sum up, all differential terms. The order of error changes from $o(h^2)$ to $o(h)$ around the faulty PU by re-discretization. However, the accuracy of results obtained will only be slightly affected quantitatively.

## 4. Method of Assigning PU to Nodes of Model

A PU assigning algorithm is needed, where the number of nodes of a model exceeds the number of PUs. Generally, an algorithm is taken as shown in Fig. 4.1(a). In this method, however, some continual nodes belonging to a faulty PU get lost. On the other hand, in the *modular mapping* as shown in Fig. 4.1(b), the number of lost nodes by one faulty PU is as the same as those in Fig. 4.1(a). In this method, it takes more communicating time since all the nodes on a PU must communicate with all the nodes in the 4 adjacent PUs. The modular mapping, however, has the advantage that lost nodes do not continually exist but scattered. Thus damages on the results of calculations by a faulty PU can be kept lower in this method. In conclusion, this mapping method is adopted for a PU assigning algorithm.

## 5. Implementation of Poisson Equation on PAX-32

The fault recovery algorithms mentioned above are implemented on the PAX-32 computer. PAX-32 is a parallel machine, consisting of 32 microprocessors combined into a nearest neighbor connected torus array, as shown in Fig. 5.1. As for a PU faulty, one PU out of 32 PUs is selected randomly within the iteration process. This machine does not have redundant links mentioned in chapter 2; corresponding data-transfers are supported with software routines. The target model is a 2-dimensional Poisson equation,

$$\Delta u = -1.0$$

A region of the model, boundary conditions, and physical constants are shown in Fig. 5.2.

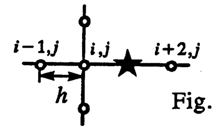

Fig. 3.1 Finite Difference Method on Irregular Intervals

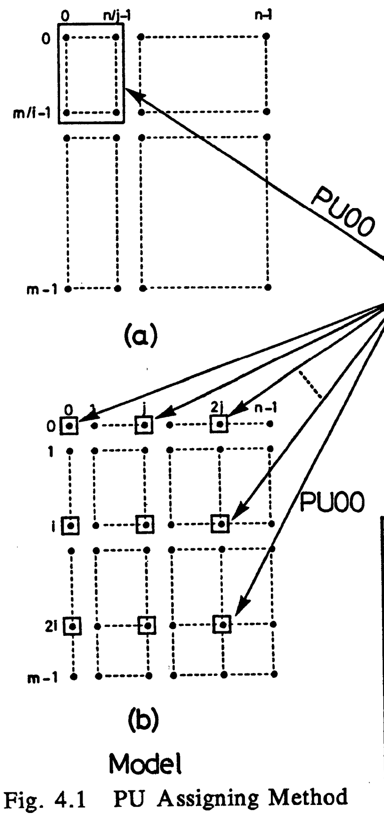

Fig. 4.1 PU Assigning Method

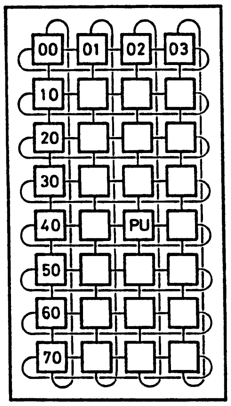

Fig. 5.1 PAX-32 System Configuration

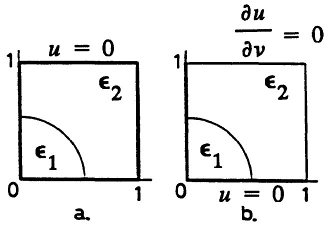
Fig. 5.3 illustrates the calculation time versus the number of nodes per PU. This figure shows that the calculation time is proportional to about the square of the number of nodes. The calculation time depends upon the iteration count and the number of nodes per PU. Undoubtedly, this time is directly proportional to the number of nodes. So, if the iteration count is proportional to the number of nodes, this rate is in agreement with those of theoretical analysis.

Fig. 5.4 illustrates the iteration count versus the total number of nodes. This count $K$ is proportional to the number of nodes. The $K$ can be calculated from the theoretical study, and is expressed as follows:

$$K = - \frac{4 + \log_{10}( 1 - \lambda )}{\log_{10}\lambda} ,$$

1. Region and Boundary Conditions



2. Physical Constants

α. $\epsilon_1 = 1$ , $\epsilon_2 = 1$

β. $\epsilon_1 = 1$ , $\epsilon_2 = 10$

γ. $\epsilon_1 = 1$ , $\epsilon_2 = 100$

3. Number of Nodes within a Region

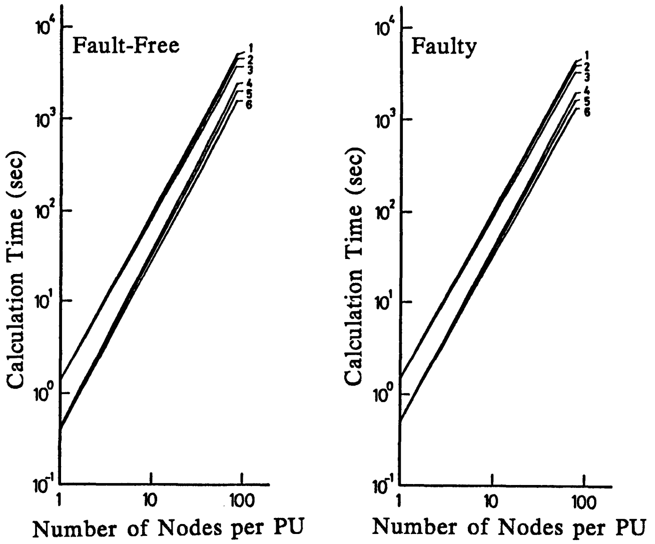
1. 32 ( 8* 4)
2. 128 (16* 8)
3. 800 (40*20)
4. 2304 (48*48)

Fig. 5.2 Simulation Conditions

where λ is the maximum eigenvalue of the coefficient matrix of the model. Some of the theoretical $K$ is illustrated in Fig. 5.5. In this figure, the slight difference between the theoretical $K$ and the actual $K$ is due to the approximation of the theoretical equation. As a result, both the calculation time and the iteration count agree with those of theoretical analysis.

TABLE 5.1 shows such error rates as defined below:

$$\textit{error rate} = \frac{\textit{result at faulty} \; - \; \textit{result at fault-free}}{\textit{result at fault-free}}$$



| | Boundary Conditions | Physical Constant | Slope |
|---|---|---|---|
| 1 | b | γ | 1.84 |
| 2 | b | β | 1.81 |
| 3 | b | α | 1.78 |
| 4 | a | γ | 1.92 |
| 5 | a | β | 1.88 |
| 6 | a | α | 1.85 |

| | Boundary Conditions | Physical Constant | Slope |
|---|---|---|---|
| 1 | b | γ | 1.85 |
| 2 | b | β | 1.82 |
| 3 | b | α | 1.79 |
| 4 | a | γ | 1.90 |
| 5 | a | β | 1.86 |

Note that lost results belonging to a faulty PU are left out of account. This is a result of simulations with 10 kinds of initial numbers of random number. This table shows that effects of a faulty PU are almost negligible.

## 6. Concluding Remarks

In this paper, we proposed a new scheme called *Bypass Recovery* for disconnecting faulty PUs, which is useful with an NNM connection structure. This is a dynamic fault recovery scheme, and efficient recovering can be performed by using the calculus of finite differences on irregular intervals as discretization.

Simulating this scheme on PAX-32, it appears that the proposed scheme realizes high efficiency and reliability.

It is desirable that this scheme can apply to the FEM. Basically, re-creation of the coefficient matrix of the model at the faulty point can be performed; the application will be possible with a small modification.

## ACKNOWLEDGEMENT

We are greatly indebted to Mr. Takashi Yokota for the concept of this study. Without him, this study could not have been realized. Also we would like to express our sincere gratitude to Prof. Mario Tokoro and Dr. Hideharu Amano for their advices. In the use of the PAX-32 computer, we thank to Prof. Tsutomu Hoshino of the University of Tsukuba.

## ABSTRACT

The Traveling Salesman Problem (TSP) is computationally expensive to evaluate. It can, however, be readily decomposed into subproblems that can be computed in parallel. Developing a distributed program taking advantage of such a decomposition, however, remains a difficult problem.

We developed such a distributed program to compute the TSP solutions, using a new set of distributed program performance tools to better understand our TSP program. These tools allowed us to discover the performance bottlenecks in our program and to revise the program to significantly improve its execution speed. This paper is a case study of the use of these performance tools.

### 1. Introduction

When a programmer implements a program that uses parallel computation, the goal is typically to increase the speed of the computation. Unfortunately, this goal is difficult to obtain. One reason for this is that communication between processes can be slow. This cost becomes greater when processes on different machines communicate. To obtain the goal of increased speed, the programmer must develop algorithms that minimize the effect of this communication cost.

It is essential for the programmer to be able to measure the performance of his or her program. The programmer needs to debug the program, and to know where the program is spending its time so that it can be modified or redesigned to increase its execution speed. The problems of debugging and performance monitoring become more difficult in a distributed environment due to a general lack of tools to aid the programmer. Tools for measuring distributed program performance have been implemented for Berkeley UNIX [4]. These tools allowed the development of the distributed program described here.

To examine the process of program development, we chose a problem that lends itself to this examination, the Traveling Salesman Problem. This problem is computationally intensive, but has well known solutions. We developed a program to find solutions to the problem without using parallel computation and, using that program as a basis, developed programs that would solve the problem using parallel processing. We debugged and measured our programs' execution using tools designed to passively measure parallel performance [5]. Using the information gained from these measurements, we improved our programs and measured how much these improvements enhanced performance. The TSP program development is a case study of the use of these measurement tools and of the program development process.

### 2. The Traveling Salesman Problem

### 2.1. Description of the Problem

The Traveling Salesman Problem (TSP) is a popular problem among both operations research experts and computer scientists. In general, the problem can be stated as follows: given N cities and the costs associated with going from each city to each of the other cities, find a minimum cost circuit that visits each of the N cities once and only once. Formally we have a *problem graph* G = (V, E) where V is the set of vertices (cities) and E is the set of edges, each representing the cost of going from each city to another. In a problem of size N, we have N vertices and m = N(N - 1) edges. The problem can also be represented as an N x N matrix, with each element $c_{ij}$ being the cost of going from city $i$ to city $j$. This matrix is called the *representative matrix* of the problem.

We address the problem in its most general form. In particular, we address the case of the asymmetric non-euclidean TSP. The problem is *asymmetric* because, in general, $c_{ij}$ does not equal $c_{ji}$. The problem is *non-euclidean* because the costs are arbitrary nonnegative numbers, unconstrained by the triangle inequality. There are many possible algorithms that can be used to efficiently solve the TSP. We have decided to follow the algorithm presented in [8].

### 2.2. General Algorithm

We use a *branch-and-bound* algorithm to solve the TSP. This algorithm is based upon the development of a *state tree* in which we record the paths that the TSP program has examined and the costs associated with those paths. Each node in the state tree corresponds to a collection of edges in the problem graph that make up a *partial path* through the problem. Each node of the state tree also contains a lower bound cost. The lower bound cost is the least cost that can be obtained by including that partial path in a full circuit. It is calculated by taking the representative matrix, and for each edge $c_{ij}$ setting all elements in row $i$ and column $j$ of the matrix to 0, and then reducing the matrix. The constants used to reduce the matrix are then added to the summation of the cost of each edge in the partial path; the result is the lower bound cost.

By examing the lower bound costs associated with the nodes of the state tree, the program can intelligently choose the best path to examine. This allows us a potentially large reduction in computation time with respect to that needed by solutions which compute the cost of every possible circuit through the problem. A decision to examine a particular path is called a *branching* decision, and it is based upon an examination of the lower bounds of all of the leaf nodes of the state tree [1]. Every time a branching decision is made, new nodes are created in the state tree that correspond to the possible extensions of the selected partial path.

Figure 2.1 shows an example of how a TSP problem is translated from a problem graph to a representative matrix to a state tree. In this example we have a small (three vertices, six edges) problem. The first representation is the problem graph, which shows the vertices and the directed edges of the problem. The representative matrix shows the cost of going from each of the three vertices to each of the other reachable nodes. Finally, the figure shows the development of the state tree. Vertex $A$ of the problem graph is arbitrarily selected as the root node of the state tree, and, by reducing the representative matrix, we find that the problem's lower bound is 17. We next set up the state tree nodes that correspond to the possible edges that include $A$, namely, $AB$ and $AC$. After setting row A and column B in the representative matrix to 0, we reduce the matrix with constants that sum to 10. Adding these constants to the cost of edge $AB$, which is 7, we find that the lower bound for a solution containing the edge $AB$ is 17. Similarly we find that the lower bound for $AC$ is 22. Examining all of the leaf nodes of the state tree, we decide to pursue the possibilities of a path containing $AB$, and set up nodes in the state tree for all of the problem graph edges that may be used after including $AB$ in a solution. There is only one such problem graph edge, $BC$, and a state tree node is set up for this edge, and its lower bound is computed to be 17. Once again, we examine the lower bound costs of the leaf nodes of the state tree, $BC$ and $AC$, and choose $BC$ because it has the lowest lower bound. Only one more edge exists beyond $BC$ : $CA$, which completes the circuit and solves the problem with a cost of 17, which is lower than any other possible circuit through the problem.

### 3. Computational Environment

The program was developed on a VAX 11/750 with 2 megabytes of memory. Occasionally, a other VAX'ss of the same configuration were used for data collection. These VAX computers are connected by a 3 megabit Ethernet. The operating system running on these VAXs is Berkeley UNIX 4.2BSD. This version of Berkeley UNIX supports virtual memory and processes with address spaces up to 16 megabytes. Most importantly, it supports interprocess communication [3]. We used the interprocess communication facilities built into 4.2BSD UNIX. The primary object of communication under this facility is the *socket*. A socket is an endpoint of communication. These sockets can be connected to form bidirectional communication streams.

## 4. Measurement Tools

The DPM measurement tools were used for this performance study. These tools are described in [4] and [5]. The raw data produced by the measurement tools is analyzed by a program that builds a graph of all interactions between the processes. The program uses this graph to compute the amount of parallelism achieved by the program, given various assumptions about message transmission costs. It can also project performance in the case of multiple CPU's for various assignments of processes to processors. The parallelism analysis is described in detail in [6].

The measurement procedure is an iterative one. First, we execute the distributed program, collecting the performance trace data. We may repeat this step, varying (for the TSP program) the problem size (number of cities) and number of processes that are used to computed the solution. Second, we analyze the performance data, computing the actual amount of parallelism, and computing the projected amount of parallelism for other assignments of processes to processors. Third, we use this data to modify our program. These three steps can be repeated until a satisfactory solution is reached.

The data analyses are being used to predict program performance. The question arises: How accurate are these predictions? While we do not test our predictions in the TSP study, previous case studies have shown the accuracy of these predictions to be within 5% of the actual program performance [7].

## 5. Evolution of a Program

The unit of measurement of performance that we use in this paper is the parallelism factor, **P**. This is a measure of speed-up in the computation, or how much of our computation is done in parallel. In the case where there is no parallel execution, **P** is 1; in the case where there are *n* processes in a computation and each process is concurrently performing $1/n$ of the work, **P** is equal to *n*. For this study, improving the performance of the computation means, for a given problem size (number of cities), increasing the value of **P**. In section 5.6 we comment on the effect that speed-up has on machine utilization.

In the measurements of the TSP programs, we use two forms of the factor **P**. The first form of **P** assumes that communication delays between processes are zero (i.e., communication is instantaneous), and that no process competes for the CPU with any other process. This gives an upper bound on the amount of parallelism that could be achieved by the measured execution of the program. The second form of **P** incorporates communication delays and contention caused by multiple processes executing on the same machine. The parallelism analysis can project the value of **P** for different assignments of processes to machines.

During the course of this research project, we developed three primary versions of the TSP program. These are referred to (in order) as the Non-Blocking Server, the Low-Node Caching and the Overlapping Requests versions. Note that each of these versions represents successive improvements to its predecessors, and *not* complete re-implementations.

Due to time considerations, we were not able to measure the performance of all of our implementations over a large variety of TSP problem sizes. For comparison purposes, all the implementations were measured for problems of size sixteen, with four, eight, twelve and sixteen processes.

### 5.1. Single Process Solution

We began by writing a single process implementation of our algorithm. This familiarized us with the TSP while ignoring the complexities of interprocess communication.

The basic algorithm of the program is as follows: First a matrix representing the problem is created. Second, the root node of the state tree is created. Each node of the state tree is identified with an edge's entry from the representative matrix, and represents a partial path through that matrix. This partial path can be obtained by traversing up the state tree to the root node. At each step of this traversal, the edge that the state tree node represents is a part of the partial path. The node also holds the lower bound cost associated with the partial path of which it is a part, and the lower bound cost of the solution that could be obtained by following that partial path. A node of the problem is arbitrarily selected as the starting point of the solution.

In each iteration of the main loop of the program, a node is selected as having the best possible chance of being on the optimal path. This is done by traversing the entire state tree and choosing the leaf node with the lowest lower bound value. This node represents the path most likely to yield an optimal circuit.

Child nodes are now set up for the chosen node. For each node that could be reached from the chosen node (that is, all of the reachable cities that are not already in the path), a child node is created, and lower bound costs for the child node are computed.

This loop is repeated until a complete path is found. The first complete path found will be an optimal path because the cost associated with it will be less than or equal to the cost associated with any other path.

### 5.2. Multiple Process Solution

There are many possible approaches to converting this computation into a parallel computation. We introduce parallelism by creating *child* processes that do some of the calculations needed by the *parent* process for each iteration. In other words, each child performs the part of the calculation that it is given, and all of the decisions are made by the parent process.

Most of the computation time is spent when new nodes are added to the state tree and the lower bound cost for each new node must be calculated. Our implementation of this program calculates these lower bound costs for each new node in parallel. When the program starts, a number of child processes are created. Instead of having the single parent calculate the lower bounds, these computations are handed to the child processes in the form of requests. Later, the results are returned to the parent, which stores the values in the appropriate node. There are other possible partitionings of this problem, but for this case study we chose a single design and attempted to improve its performance. single

In the first multiple process version, the parent sends requests to each of the children and then awaits responses from all of the children before sending out the next batch of requests. Although this version of the program ran and produced accurate answers, we did not start the actual performance measurements on our program until we had solved the simple problem described in the next section.

### 5.3. Non-blocking Server

After examining the program and its performance, it became apparent that most of the benefits of parallel execution were being lost because the parent process waited until all children sent back answers before sending out the next batch of computation requests. This was solved by having the parent hand out new requests to a child as soon as it returned an answer. We considered this version to be our first successful implementation, and the following measurements show its performance.

Figures 5.1, 5.2 and 5.3 show the projection of how this implementation of the program performed. Figure 5.1 shows the achievable degree of parallelism for problems with various matrix sizes and numbers of processes. This graph assumes that communication costs are zero, and that the processes do not compete with each other for the CPU. Figure 5.2 presents the performance of the program when each process is run on its own machine, over varying problem sizes and numbers of processes. Figure 5.3 illustrates the amount of parallelism achieved by our program when two processes are allocated to each processor under a variety of problem sizes and number of processes.

The results show that the amount of parallelism achieved increases with the size of the problem. As the problem size increases, a larger percentage of the program's time is spent computing the lower bounds. Since we do the computation of the lower bounds in parallel, it is natural that the degree of parallelism should increase with the problem size.

If we compare the corresponding curves from graphs 5.1 and 5.2 for a single problem size, we can see the cost (loss of parallelism) from communications delays. Comparing graphs 5.2 and 5.3, we see the loss of parallelism when two processes contend for a single CPU.

### 5.4. Low-Node Caching

The process status of the running program showed that it was using large amounts of memory. This memory was obviously being used for the state tree. However, this meant that we were spending a large percent of program time searching through the state tree for the lowest node. During this time the child processes were sitting idle, and parallelism was being lost.

To eliminate this waiting time, we decided to save 100 of the previously calculated nodes with the lowest values in an array. For each child node that is created, if the array is not full or if the value of the child node is less than the cost of the last (highest value) element in the array, this value is inserted, in order, into the array. The result is an ordered array of the leaf nodes from the state tree with the smallest values. Our branching decision is made by selecting the leaf node of the state tree that has the smallest value associated with it, in this case the first node in the array. When this node is selected, it is eliminated from the array.

Performance measurement of this Low-Node Caching version of our program shows a significant improvement in the parallelism achieved by the program. Our measurements where made for problems of size 16 with 4, 8, 12 and 16 processes. Figure 5.4 compares this Low-Node Caching version with the Non-Blocking Server version. These figures show that this Low-Node Caching version performed significantly better than the non-blocking server implementation. We also find that this improvement in performance is more pronounced as the number of processes increases.

This improvement is the result of the parent process doing less computation relative to the computations it gives to its children processes. That is, less time is spent in the parent process in this version, while the children are still doing the same amount of computation as in the Non-Blocking Server version.

### 5.5. Overlapping Requests

Experimental measurements show that communications costs are actually very high, taking approximately 8 ms for communications between processes on a single machine and 20 ms for processes on different machines [2]. This means that a child process remains idle while information is transferred back to its parent and while waiting for a new request to arrive from the parent.

To eliminate the idle time in the case where the number of requests exceeds the number of servers, we overlapped the requests to the children by initially sending out two requests to each child. Children no longer had to wait for the parent to receive the result before beginning work on a new request, since another request was usually waiting. This is an important innovation, and is aimed solely at trying to cut down the effect of the communications cost. As the following results show, this minor change enhanced the program's performance.

Figure 5.5 shows the performance of the Overlapping Requests implementation, as well the performance of the previous two versions, for a problem of size 16 with 4, 8, 12 and 16 processes.

Note that the Overlapping Requests version performs better than the Low-Node Caching version when the number of processes is small, but that the difference in performance between the two diminishes as the number of processes approaches the size of the problem. If there are as many processes as the size of the problem, then all of the computations are done by having each child do only one computation, thus there is no opportunity to use overlapping to reduce communication delay effects.

#### 5.5.1.1. Is Faster Always Better?

In this study, we have based our evaluation of program performance on the amount of parallelism or speed-up achieved in the different versions of the TSP program. By using P as our only evaluation criterion, we have stated: faster is better. This view of performance dictates that even a small increase of parallelism is worth the addition of more hardware.

It is also important to know how well we are using our computing resources. This can be stated as: how much of our available computing resources are we using? For the TSP programs, we ask: how much of the machines (CPU's) involved in the computation are we utilizing? We can compute CPU utilization from the parallelism factor. We define $\text{Utilization} = P/N$, where $N$ is number of machines used in the computation. Figure 5.6 graphs the values of the utilization (corresponding to the graphs in Figure 5.5) for the three versions of the TSP program.

Our first observation from the graph in Figure 5.6 is that when two processes run on each machine, we have a higher utilization (and from Figure 5.5, a lesser amount of parallelism) than when one process runs on each machine. This means that while running one process per machine is a less efficient use of resources, it results in a faster execution.

Our second observation from Figure 5.6 is that each successive version of the TSP program made better (more efficient) use of the CPU's. We know that the successive versions are better (and not just requiring more computation time) since the amount of CPU time needed for each successive version also decreased. The fact that the curves for the Overlapping Requests version and the Low-Node Caching version meet when 16 processes are used reflects the fact that the problem size is the same as the number of processes.

A person who uses a distributed program, such as the TSP program, wants his/her program to execute as quickly as possible. The parallelism factor, P, gives a measure of how much we can increase the speed of execution. It is also important to know how efficient is a program. We need metrics such as CPU utilization to evaluate efficiency.

## 6. Conclusion

The purpose of this study was to evaluate a collection of measurement tools for distributed programs through the development of a simple program. The question was: could these tools help us better understand our program, and help us improve its performance?

While the main intent of this study was to evaluate the performance monitoring abilities of the measurement tools, these tools also proved useful for debugging. When the first version of the TSP program was being tested, its execution speed seemed slower than expected. A visual examination of the trace records produced by the measurement tools quickly (that is, in less than one minute) showed that the master process in the computation was only creating a single child process. This was caused by a simple typing error in the program. After this error was corrected, the performance seemed unchanged. A second inspection of the traces showed that, while the correct number of child processes were being created, the master was sending requests only to a single child – again a typing error. After this, the program worked correctly. The discovery of these errors is an indication that the measurement tools are providing some of the additional information needed for developing distributed programs.

The main direction of this study was the investigation of the performance of the TSP program. In particular, we wanted to maximize the amount of parallel activity in the program. The distributed program measurement tools, in conjunction with other existing tools, provided the information necessary to measure the program's performance, identify bottlenecks, correct the problem, and evaluate the corrections.

Traditional performance tools provide information as to *how much* time a program spends in its various procedures and modules. Our measurement tools in conjunction with the analysis of parallelism also provide an insight into *when* a program spends its time in these modules.

# Optimized Demand-driven Evaluation of Functional Programs on a Dataflow Machine

*Satoshi ONO* , *Naohisa TAKAHASHI* *and* *Makoto AMAMIYA*

NTT Electrical Communications Laboratories
Nippon Telegraph and Telephone Corporation
3 - 9 - 11 Midori-cho Musashino-shi Tokyo 180 Japan

## Abstract

This paper presents a new program transformation algorithm for functional programs named the mixed-mode fixpoint evaluation method. This method realizes optimized demand-driven computation on a dataflow machine. This evaluation scheme takes advantage of both data-driven and demand-driven evaluations in that it offers sufficient parallelism and safeness for nonstrict sequential functions. This can be achieved by eliminating demand propagation predictable during compilation time, and by replacing the lengthy recipe creation and evaluation required in demand-driven function applications with the call-by-value method. These optimizations are based on an inter-function global dataflow analysis called the Extended Dependency Property Set.

## 1. Introduction

Functional programming languages have various attractive features facilitating the writing of short and clear programs, as well as verifying and transforming programs automatically due to their formal mathematical semantics. For the efficient execution of functional programs, several language-oriented machines based on dataflow and reduction models have been proposed and implemented.[15]

Although dataflow machines inherently have conformed excellently to a special subset of functional programming languages[3], several drawbacks exist[3] in dataflow models compared to reduction models. One of these is the difficulty in implementing the fixpoint computation rule[8] for nonstrict[16] functions. In order to overcome this drawback, several studies have been conducted in an attempt to achieve demand-driven computation on dataflow models. These studies have focused on demand-controlled stream creation,[7,12] the *lazy cons* operator[2] and the semi-result concept.[17] These approaches extend the computation domain to nonstrict data structures such as infinite sequences. However, they have only limited capability for handling nonstrictness of sequential[16] functions.

In addition, several inefficiencies commonly arise during demand-driven evaluation. One is the cost of demand propagation from the outermost expression to the innermost expressions. An algorithm based on simplified global dataflow analysis has been proposed.[14] Such a simple method, which first makes the assumption that all nonprimitives are nonstrict (or strict), however, has been shown to have only a restricted analysis capability.[4] Another inefficiency is the cost required for creating and evaluating recipes.[6] The recipe-based demand-diven method (call-by-recipe) requires much more complicated computation than does the simple call-by-value method adopted in the data-driven evaluation.

This paper proposes a new method for realizing an optimized fixpoint computation rule on dataflow machines, named the *mixed-mode fixpoint evaluation method.* The name is so chosen because the method realizes the fixpoint computation rule for the class of sequential functions, and because both data-driven and demand-driven evaluations are scattered throughout the computation process.

The method consists of two principal algorithms: the *demand propagation algorithm* and the *recipe creation elimination algorithm.* The demand propagation algorithm predicts successive demand propagation sequences by analyzing the dependency between functions and values. Then, it transforms dataflow graphs such that each demand is propagated directly toward the innermost expressions as long as the safeness property is preserved. The recipe creation elimination algorithm analizes the lifetime of recipes and detects all cases where a call-by-recipe can be safely replaced with a call-by-value.

To insure the safeness of the above optimizations, these algorithms make use of an inter-function global dataflow analysis named the *Parameter Dependency Property Set* (PDPS).[9,10] In this paper, the concept of the PDPS is generalized to the *Extended PDPS* (EDPS) in order to process the recipe lifetime property. In order to reduce the amount of computation required for the optimization, a hierarchical approach is adopted. As the first step, a program is analyzed in the inter-function level. Then, each function is analyzed and optimized internally based on the collected global data.

The algorithms proposed in this paper make use of a hardware-implemented lazy synchronization mechanisms,[2] such as that used in the Structure Memory[1,5] for storing structured data. In combination with this kind of intelligent operation memory, the proposed method realizes the fixpoint computation rule for the class of sequential functions on nonstrict data structures.

## 2. Background

### 2.1 Global Dataflow Analysis

Mixed-mode fixpoint evaluation requires that evaluation of a function application be initiated only if the result contributes essentially to the final computation result. In contrast, the hardware-supported redex (*reducible expression*) detection mechanism in dataflow machines is so restricted that only local information about value availability is used as a criterion for initiating computation. This gap inevitably leads us to a global dataflow analysis which gathers the property data of program fragments (function, function application, etc.) that can be made apparent only by analyzing the entire program text.

For reducing the computation required for such global analysis, the concept of *autonomousness* is introduced. Suppose that an inter-function analysis computes the property $P$ for each function in a program. Property $P$ is said to be autonomous if the property $P$ of a function $f$ is computable using only the property data of functions referred to by the function $f$ (i.e., computable without using the definitions of referred functions).

The result of the conventional strictness analyses,[4,13] i.e., requisite parameters, is not autonomous. For example, suppose the program

$$f(x,y) = g(x, x+y, x-y) \;;$$
$$g(x,y,z) = \textbf{ if } x \geq 0 \textbf{ then } y \textbf{ else } z \textbf{ fi } .$$

Function $f$ refers to $g$, and the requisite parameter of $g(x,y,z)$ is $x$. The requisite parameters for $f(x,y)$ are $x$ and $y$. However, this fact cannot be deduced from the requisite parameter information concerning $g$.

The autonomousness of property $P$ is desirable, since computation required for the inter-function analysis can be reduced using the caller-callee relation of the functions in a program. In addition, autonomousness means that the property contains enough information to enable computation of the property of the elements referring to it. Therefore, inter-function property data can be propagated to clarify the property of each element in a function without referring to the entire program text.

### 2.2 Parameter Dependency Property Set (PDPS)

The PDPS is the generalization of requisite parameter in such a way that it satisfies autonomousness. The PDPS for a function $f$ is a set of *Minimally Sufficient Parameter Sets* (MSPSs) for $f$ that is defined below.

[Definition 1] Minimally Sufficient Parameter Set

Given an $(m+n)$-ary function, $f(x_1, x_2, \ldots, x_m, y_1, \ldots, y_n)$, a set of parameters $\{x_1, \ldots, x_m\}$ is said to be minimally sufficient if and only if there exist values $a_1, \ldots, a_m$ such that

(a) $f(a_1, \ldots, a_m, y_1, \ldots, y_n)$ gives a defined value even if $y_1, \ldots, y_n$ are undefined.

(b) Suppose $y_1 \equiv \omega, \ldots, y_n \equiv \omega$ where $\omega$ represents an undefined value. Then, $f(a_1, \ldots, a_m, y_1, \ldots, y_n)$ becomes undefined if at least one of the values $a_1, \ldots, a_n$ are replaced with $\omega$.

The PDPS computation algorithm for monotonic recursive function systems has been previously provided.[9,10] The PDPS of an expression, defined similarly regarding free variables of the expression as parameters, can be computed using the algorithm called PDPS reduction.[9] It is apparent that the intersection of all MSPSs in the PDPS of function $f$ becomes the set of requisite parameters of $f$.

For example, consider the function, $g(x,y,z)$, defined in Subsection 2.1. $D(g(x,y,z)) = \{\{x,y\},\{x,z\}\}$, where $D(e)$ stands for the PDPS of $e$. The PDPSs of subexpressions $x+y$ and $x-y$ are both $\{\{x,y\}\}$. The PDPS of the function $f(x,y)$ becomes $\{\{x,y\}\}$. This means that the requisite parameters of $f(x,y)$ are $x$ and $y$.

## 3. Realization of Mixed-mode Fixpoint Evaluation

### 3.1 Value Property Classification

Parameters and free variables (hereafter, simply referred to as values) of a function can be discussed in terms of two properties in combination with each other: *requisiteness* and *recipe lifetime.* Requisiteness refers to the causal relation between values, whereas recipe lifetime means the form of value references in the function body.

Regarding requisiteness, a value is classified as either *requisite, suspended* or *irrelevant.* A requisite value is a value such that if it becomes undefined, the result always becomes undefined. The intersection of all MSPSs in the PDPS of the function gives the set of requisite values. If there exists a case such that the result becomes undefined when the value becomes undefined, but the value is not requisite, it is said to be suspended. $S(f)$, the set of suspended values for a function $f$, can be computed as

$$S(f) = \langle \text{ Union of all MSPSs of } f \; \rangle - \langle \text{ Requisite values of } f \; \rangle \,,$$

where "−" is a set difference operator. A value is said to be irrelevant if the result is computed independently of the value.

From the viewpoint of recipe lifetime, a value is classified as either *scalar* or *nonscalar.* A value is said to be scalar if the value always requires evaluation when it is referred. In contrast, a value is said to be nonscalar if a case exists such that the result of a function application is computable using the value only in its recipe form. In other words, if the demand to the value does not necessarily mean the evaluation of the expression that gives the value, the parameter is said to be nonscalar. To give an example, numerical values in arithmetic expressions are scalar, while parameters of a *lazy cons* operator are nonscalar.

### 3.2 Mixed-mode Fixpoint Evaluation

The principle of mixed-mode fixpoint evaluation is that actual parameter passing is deferred until the parameter becomes requisite for computing the resulting value, and that the parameter is passed on in an evaluated form whenever evaluation of the actual parameter is safe.

To achieve the above principle, two primary function application criteria are adopted. First, if a parameter is requisite, the actual parameter is unconditionally passed on to the function body. If a parameter is suspended, it is passed on only if the expanded function sends a demand for it. If a parameter is irrelevant, no code for it is generated.

Second, if a parameter is scalar and it is requisite or demanded, the actual parameter is evaluated, and the resulting value is passed on to the expanded function. Thus, if the actual parameter is a recipe, it is forced at first, and then passed on. If a parameter is nonscalar and it is requisite or demanded, a recipe for the expression that gives the actual parameter is created (if not already created), and a pointer to the recipe is passed on to the expanded function. If the recipe is forced in the body of the expanded function, the evaluation of the recipe is initiated with the resulting value taking the place of the recipe as in call-by-need computation.[6] In this paper, the recipe creation and evaluation mentioned above are assumed to be executed in an intelligent operation memory such as a Structure Memory. For details of the implementation, please refer to [2].

The function application method of the mixed-mode fixpoint evaluation is an optimized version of a joint data-driven, demand-driven scheme in terms of three principal points. First, evaluated values are passed on instead of recipes to an expanded function if scalar parameters are requisite or demanded. Second, recipe creation for a suspended nonscalar parameter is delayed until it is actually demanded. Third, the method completely eliminates computation of irrelevant parameters.

### 3.3 Function Expansion Strategy

The function expansion strategy controls the function expansion time during function application. One strategy is that a function is expanded when all requisite parameters are available. This is a natural extension of the data-driven computation for strict functions, and is called the *strict expansion strategy*. Functions may be expanded at the time the first requisite parameter becomes available. This is called the *hasty expansion strategy*. In this paper, the strict expansion strategy is assumed. If the hasty expansion strategy is adopted, the algorithm in Section 4 should be slightly modified.

Figure 1(a) is a graphic representation of function applications. Primitives and strict functions are computed in a data-driven manner. For each suspended parameter of a nonstrict function, a *demand arc* (dashed arrow) extends from the node. When a token is put on this arc, the corresponding parameter is demanded. Conditional function "**if_then_else**" is also represented as one of the nonstrict functions, although it is a macro-node expanded in-line during program compilation.

In demand-driven computation, the case exists in which function expansions should be controlled by demands. This is because a function should be applied if and only if the resulting value of the function application is requisite. For this purpose, we introduce a new notation for the dataflow graph as shown in Fig. 1(b). The horizontal dashed arrow is a demand arc for function expansion. This notation is referred to as *demand expansion*. In the strict expansion context, a function is expanded if and only if all requisite parameters are available and a demand token exists on the demand arc. In contrast, conventional notation is referred to as *self expansion*.

## 4. Demand Propagation Algorithm

During the function application of the mixed-mode fixpoint evaluation, the necessity for a suspended parameter is signalled by a demand token from the expanded function body. For a scalar parameter, this demand is propagated to evaluate the corresponding actual parameter. The proposed method optimizes the propagation using the result of inter-function analysis. This section describes the outline of this optimizing algorithm.

### 4.1 Principle of Demand Propagation

In the evaluation process of a function application, value tokens are generated as a result of sub-expression evaluation. Such tokens are named *Partial Resulting Values* (PRVs). In the following, two important concepts regarding PRVs and demands are introduced.

[Definition 2] Total Requisite Value Set (TRVS)

For a PRV $v$, a set of PRVs and/or parameters (hereafter referred to as values) exists such that the values in the set are requisite to the evaluation of $v$. This set is named the *Total Requisite Value Set* of $v$. The PRV $v$ itself is also included in $T(v)$, where $T(v)$ stands for the TRVS of $v$.

[Definition 3] Demand-generated
Requisite Value Set (DRVS)

Suppose that the function definition contains a function application of a nonstrict function, and that $dv$ is a demand arc for the suspended parameter $v$ of this function application. A set of values would then exist such that the values in the set become requisite when a demand is generated on the demand arc $dv$. This set is named the *Demand-generated Requisite Value Set* (DRVS) of $dv$, and is indicated by $R(dv)$.

Using the above concepts, the optimization principle is described as follows.

(1) Suppose that PRV $v$ is a result of some function application, and that PRV $r$ is an actual parameter corresponding to the requisite parameter of the applied function. If PRV $v$ becomes requisite, the PRVs in $T(r)$ are evaluated in a data-driven manner.

(2) Suppose that PRV $s$ is an actual parameter corresponding to the suspended parameter of some function application. If this parameter becomes requisite in the applied function body, it is signalled to the caller of the function through the demand arc $ds$. With this demand signal, the PRVs in $R(ds)$ are evaluated in a data-driven manner.

An outline of the computation algorithm for the TRVS and the DRVS will be discussed in Subsection 4.3.

### 4.2 Example of Demand Propagation

The optimized demand propagation described in the previous subsection is accomplished through the transformation of dataflow graphs. This transformation process and the operation of the transformed program are intuitively explained using an example.

Consider the following function:

$$\begin{aligned} p(x,y,z) = \{c = f_2(z);\quad & i = f_3(y);\\ e = h_2(g_1&(y,z), c, g_2(c,i));\\ j = h_1(f_1&(x), e, i);\ \textbf{return}\ j\}, \end{aligned}$$

where $f_k$ $(k = 1,2,3)$ are unary strict functions and $g_k$ $(k = 1,2)$ are binary strict functions. In addition, the PDPS of the nonstrict function $h_k(x,y,z)$ $(k = 1,2)$ is assumed to be $\{\{x,y\},\{x,z\}\}$. All values are assumed to be scalar.

Figure 2 shows a data-driven version of the function codes. For each PRV in this figure, a unique name is attached. All parameters for $p$ should be evaluated prior to the function application. At the beginning of the transformation, a demand arc is created for each requisite parameter. Figure 3 shows this partially transformed graph. The PDPS of $p(x,y,z)$ is computed to be $\{\{x,y\},\{x,y,z\}\}$. Therefore, $x$ and $y$ are requisite parameters, and $z$ is a suspended parameter. In this figure, the demand arc for $z$ is represented as $dz$, a naming convention which will be used throughout this paper. Nonstrict functions $h_1$ and $h_2$ should also be transformed in the same way as function $p$. Strict functions require such transformation only if they contain nonstrict functions.

The completely transformed program is shown in Fig. 4. In the figure, a new primitive node, "*Demands Merge, Value Distribution*" (DMVD), is introduced. This node corresponds to the combination of a *d-union operator*[12] and a distribution node. The DMVD operator accepts multiple (demand input, value output) arc pairs as well

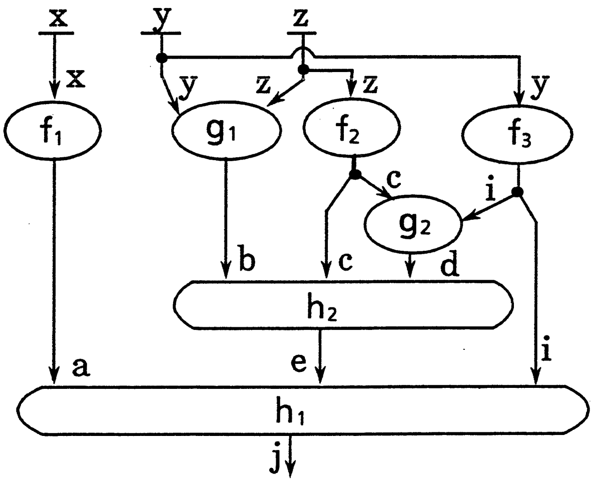

Fig. 2 Original Data-driven Program

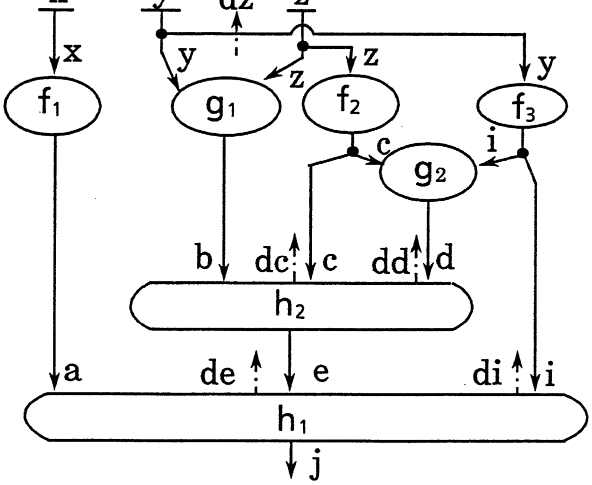

Fig. 3 Partially Transformed Program

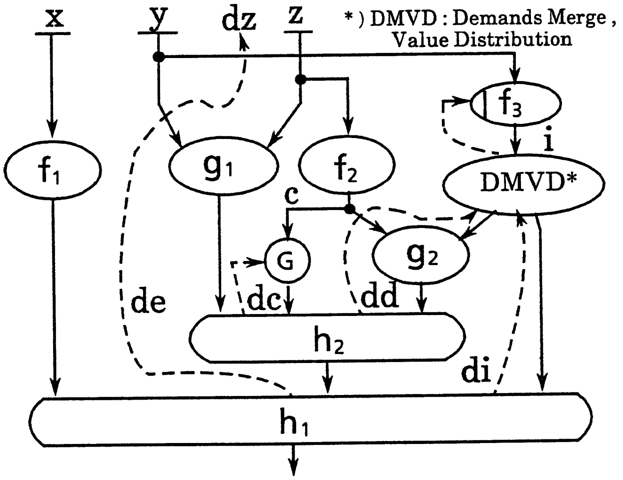


*) DMVD : Demands Merge, Value Distribution

Fig. 4 Completely Transformed Program

as one ⟨demand output, value input⟩ arc pair. The operator receives at most one demand token from each demand input arc. After receiving the first demand token, the demand token is forwarded through its demand output arc. When a value comes to its value input arc, it is distributed to all value output arcs that have demanded the value through associated demand arcs. If the value is available when a demand comes, it is immediately forwarded to the associated value arc. Another new primitive is the *gate* (represented as **G** in the figure). The *gate* primitive is defined as a strict function, $gate(x, y) = x$. The arc corresponding to parameter $y$ of $gate(x, y)$ is called the *control* arc (described as a horizontal arc in the figure).

When function $p$ is applied, PRV $j$, the final PRV to be returned, is requisite. In addition, $T(j) = \{x, y, a, j\}$. Therefore, parameters $x$ and $y$ are passed on in evaluated forms, and the PRVs $a$ and $j$ are computed in a data-driven manner. When the second parameter of function $h_1$ becomes requisite, demand $de$ is generated. Since $de$ is connected to $dz$, the suspended parameter $z$ is evaluated and passed on. The PRVs $b$, $c$ and $e$ are then evaluated in a data-driven manner because $R(de) = \{b, c, e, z\}$.

### 4.3 Outline of Demand Propagation Algorithm

Since the demand propagation algorithm explanations are considerably lengthy and complicated, the algorithm is explained only intuitively in this paper. For details, please refer to [11].

The demand propagation algorithm consists of four phases. In Phase 1, the PDPS is computed for every function defined in a program. This phase is an inter-function analysis. In Phase 2, each function is analyzed using PDPSs. As a result, the *Value Dependency Property Set* (VDPS) is computed. As will be described below, the VDPS is the generalization of the TRVS in the same way as requisite parameters are generalized into the PDPS. This phase and the succeeding phases are intra-function analyses. Phase 3 analyzes each suspended parameter of the function application in a function definition, and computes the DRVS for every demand arc. In Phase 4, demand arcs are connected to proper points such that each demand arc triggers evaluation of values belonging to its DRVS.

In the following, Phases 2-4 are explained using the function example $p(x, y, z)$ introduced in the previous subsection. Here, we assume that the PDPSs of all functions referred to in $p$ have already been computed as a result of Phase 1.

[Phase 2] The final value returned by function $p$ is PRV $j$. In Fig. 2, parameters $x$, $y$, $z$ and PRVs $a, \ldots, e$, $i$ are also included. However, not all values are required to compute PRV $j$, since functions $h_k(x, y, z)$ $(k = 1, 2)$ are nonstrict. For example, if function $h_1$ demands the third parameter, only values $x, y, a$ and $i$ are required to compute PRV $j$. Such a set of values is named the *Minimally Sufficient Value Set* (MSVS) of PRV $j$. PRV $j$ itself is included in each MSVS of $j$. The set of all MSVSs of $j$ is called the VDPS of $j$, and is indicated by $V(j)$. For example, $V(j)$ in Fig. 2 is computed as

$$V(j) = \{\{a, b, c, d, e, i, j, x, y, z\}, \{a, b, c, e, j, x, y, z\}, \{a, i, j, x, y\}\} .$$

The intersection of all MSVSs in $V(j)$ gives $T(j)$. As a result of Phase 2, the VDPS of the final value is computed for each function in a program. Since the dataflow graph of a function is acyclic, the VDPS computation algorithm is similar to the PDPS computation algorithm for a block expression.[9]

[Phase 3] In Phase 3, the DRVS is computed for each demand arc. In general, when a demand $dv$ is generated for value $v$, some values have already been demanded or evaluated. A set of these values is named the *Pre-demand Requisite Value Set* of $dv$, and is indicated by $Pre(dv)$. Similarly, the *Post-demand Requisite Value Set* is defined as a set of demanded / evaluated values after demand $dv$, and is indicated by $Post(dv)$. The DRVS of $dv$, namely, $R(dv)$, is computed as

$$R(dv) = Post(dv) - Pre(dv) .$$

For example, consider the demand $di$ in Fig. 3. In order to generate demand $di$, evaluation of PRV $a$ as well as parameter $x$ must be finished. In addition, PRV $j$ must be demanded. Furthermore, parameter $y$ is requisite to compute PRV $j$. Therefore, $Pre(di) = \{a, j, x, y\}$. Similarly, $Post(di)$ becomes $\{a, i, j, x, y\}$. Therefore, $R(di) = \{i\}$. Similarly, $R(de) = \{b, c, e, z\}$, $R(dc) = \{\}$ and $R(dd) = \{d, i\}$.

Let us now discuss the algorithm for $Pre(di)$ and $Post(di)$ using Fig. 3. The demand $di$ is a demand for PRV $i$, and the PRV $i$ is used to compute the PRV $j$. At the time the demand $di$ is generated, PRV $j$ has already been demanded. After this demand, PRV $i$ also becomes demanded. Assume $V_p$ to be the VDPS of the final PRV of function $p$. In this case, $V_p$ is equal to $V(j)$. Then, each MSVS in $V_p$ represents a possible combination of the PRVs demanded / evaluated during the function application of $p$. Thus, $Pre(di)$ is computed as the intersection of all MSVSs in $V_p$ that contain PRV $j$. Similarly, $Post(di)$ is the intersection of all MSVSs in $V_p$ that contain PRVs both $i$ and $j$.

[Phase 4] Each demand arc is used as a trigger for the evaluation of values belonging to its DRVS. In this phase, the values in a DRVS of each demand are classified by the availability of requisite values. This algorithm is explained below using the example presented in Figs. 3 - 4.

Consider the demand $de$ whose DRVS is $\{b, c, e, z\}$. The parameter $z$ is a suspended parameter of function $p$, and demand arc $dz$ is associated with $z$. PRVs $b$, $c$ and $e$ cannot be evaluated without parameter $z$. In addition, if $z$ is evaluated, the requisite parameters for these PRVs become available. Therefore, demand arc $de$ is connected to $dz$.

Next, consider the demand $dd$ where $R(dd) = \{d, i\}$. PRV $d$ cannot be evaluated without PRV $i$. In contrast, the requisite value for PRV $i$, namely parameter $y$, is passed on in an evaluated form. Thus, the function application $f_3(y)$ is demand expanded using demand arc *dd*.

For the demand *dc*, the DRVS is empty. This fact means that although *dc* is a demand for PRV $c$, the value is already requisite even before it is demanded. Therefore, a *gate* node, **G** is inserted as shown in Fig. 4. The parameter passing of PRV $c$ is deferred by this node until demand *dc* is generated.

If more than two demand arcs are connected to one node, a DMVD node is inserted for merging demands and distributing the resulting value. For example, in Fig. 3, function application $f_3(y)$ should be demand expanded by both demands *dd* and *di*. Therefore, a DMVD node is inserted in Fig. 4.

## 5. Recipe Creation Elimination Algorithm

### 5.1 Extended Dependency Property Set

Parameters for primitives for arithmetic, logical and relational operations such as "+", "*and*", ">" are all requisite and scalar. By contrast, nonstrict data constructors such as *lazy cons* require all parameters to be requisite and nonscalar (i.e., recipes should always be passed). In this section, we describe the computation algorithm for these properties for the class of monotonic recursive functions.

For non-recursive functions, the recipe lifetime analysis is rather self-evident. For example, consider the function $f$ such that

$$f(x,y,z) = \textbf{ if } x > 0 \textbf{ then } x + y \textbf{ else } cons(z, \text{NIL}) \textbf{ fi.}$$

In function $f$, parameter $x$ is requisite, and parameters $y$ and $z$ are suspended. Furthermore, $x$ and $y$ are scalar, and $z$ is nonscalar.

An *Extended Dependency Property Set* (EDPS) notation is introduced in order to describe both requisiteness and recipe lifetime properties in one data structure. The EDPS is defined as a set of *Extended MSPSs* (EMSPSs). The EMSPS is a set of ordered pairs ⟨value name, recipe lifetime property⟩. For example, $E(f(x,y,z))$, the EDPS of above function $f(x,y,z)$, is described as

$$E(f(x,y,z)) = \{\{\langle x,S\rangle, \langle y,S\rangle\}, \{\langle x,S\rangle, \langle z,N\rangle\}\},$$

where $\langle x,S\rangle$ and $\langle z,N\rangle$ mean that value $x$ is scalar, and value $z$ is nonscalar, respectively.

### 5.2 EDPS Computation for Recursive Functions

Consider the composite function, $f(x) = f_1(f_2(x))$. Parameter $x$ is scalar only if the parameters of both $f_1$ and $f_2$ are scalar. For example, parameter $x$ of $f(x) = cons(2 * x, \text{NIL})$ is nonscalar, whereas $f(x) = (2 * x) + 3$ is scalar.

For general composite functions, the EDPSs can be computed using the above rule and the general PDPS reduction rule.[9] At this time, the same parameter can be used in both scalar and nonscalar form. An example of this conflict is shown below as

$$f(x,y,z) = \textbf{ if } x > 0 \textbf{ then } cons(x,y) \textbf{ else } y + z \textbf{ fi.}$$

The EDPS of $f(x,y,z)$ becomes

$$\{\{\langle x,S\rangle, \langle x,N\rangle, \langle y,N\rangle\}, \{\langle x,S\rangle, \langle y,S\rangle, \langle z,S\rangle\}\}$$

if $\langle x,S\rangle$ and $\langle x,N\rangle$ are distinguished.

If the same parameter is classified as scalar and nonscalar in a single EMSPS, it can be safely classified as scalar. This is because if the computation of $x$ diverges, the final value of the function application always becomes undefined. Therefore,

$$E(f(x,y,z)) = \{\{\langle x,S\rangle, \langle y,N\rangle\}, \{\langle x,S\rangle, \langle y,S\rangle, \langle z,S\rangle\}\}.$$

If the same parameter is classified as scalar in one EMSPS, and nonscalar in another EMSPS, the parameter is classified as nonscalar. This is because computation may exist which requires the parameter to be only in a recipe form. For example, $y$ in the above example is classified as nonscalar in the "**then**" part, and as scalar in the "**else**" part of the conditional expression. The first EMSPS corresponds to the "**then**" part, and the second to the "**else**" part. Thus, the $y$ of $f(x,y,z)$ is classified as nonscalar. As a result, the parameters of $f(x,y,z)$ are classified as

$$\begin{array}{ll} \text{Requisite} : \{x,y\}\,, & \text{Suspended} : \{z\}\,, \\ \text{Scalar} \quad : \{x,z\}\,, & \text{Nonscalar} \; : \{y\}\,. \end{array}$$

The EDPS of recursive functions can be computed similarly to the PDPS computation in another work.[9] The only difference is the reduction domain, which is not PDPS but EDPS. To show an example, consider the following functions which create an infinite sequence of factorial values:

$$seqf(n) = str\_cons(fact(n), seqf(n+1))\,;$$

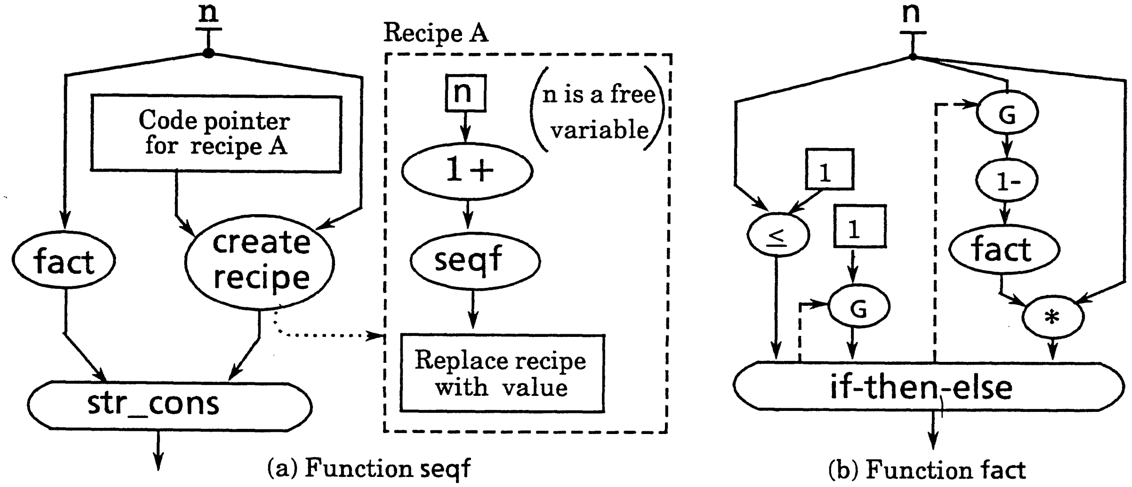
$$fact(n) = \textbf{ if } n \leq 1 \textbf{ then } 1 \textbf{ else } n * fact(n-1) \textbf{ fi.}$$

where *str_cons* is a stream-oriented asymmetrical *cons* operator whose EDPS is $\{\{\langle x,S\rangle, \langle y,N\rangle\}\}$. The EDPSs of these functions are found to be

$$E(seqf(n)) = \{\{\langle n,S\rangle\}\} \text{ and } E(fact(n)) = \{\{\langle n,S\rangle\}\}.$$

### 5.3 Recipe Creation Elimination based on EDPSs

As described in Subsection 3.2, scalar parameters are passed on in an evaluated form. For example, a graph for functions *seqf* and *fact* described in Subsection 5.2, is shown in Fig. 5. The parameter $n$ of function *fact* is requisite and scalar. Therefore, in recipe $A$ in Fig. 5, the expression $n+1$ is evaluated before it is passed on to the function body. In the figure, the "create recipe" node is a macro-node which accepts the pointer of the machine code for an expression as well as the environment for the expression. It then creates the recipe, and returns its pointer. The "replace recipe with value" node is also a macro-node which replaces the recipe with the evaluated value. After replacement, the value is immediately available for any expression that refers to the recipe without repetitive evaluation. An example of dataflow machine implementation of these macro-nodes as well as *lazy_cons* / *str_cons* functions is described elsewhere.[2]



(a) Function seqf

(b) Function fact

Fig. 5 Program Example of Infinite Sequence

### 5.4 Autonomousness of the EDPS

When only the function application method is concerned, the EDPS can be said to be redundant for scalar / nonscalar distinction. For example, for function $f(x, y, z)$ in Subsection 5.2, the EDPS

$$\{\{\langle x, S\rangle, \langle y, N\rangle\}, \{\langle x, S\rangle, \langle y, S\rangle, \langle z, S\rangle\}\}$$

can be reduced to $\{\langle x, S\rangle, \langle y, N\rangle, \langle z, S\rangle\}$.

However, such a reduced property is problematic in that it is not autonomous. As an example, consider the functions $f_1(x, y, z)$ and $f_2(x, y, z)$, whose reduced properties are both $\{\langle x, S\rangle, \langle y, N\rangle, \langle z, S\rangle\}$ :

$$f_1(x, y, z) = \textbf{ if } x > 0 \textbf{ then } x + y \textbf{ else}$$
$$\textbf{if } z > 0 \textbf{ then } cons(x, z) \textbf{ else } cons(y, z) \textbf{ fi fi};$$
$$f_2(x, y, z) = \textbf{ if } x > 0 \textbf{ then } cons(x, y) \textbf{ else}$$
$$\textbf{if } z > 0 \textbf{ then } x + z \textbf{ else } y + z \textbf{ fi fi}.$$

For the function applications $f_1(a, b, b)$, actual parameter $b$ is scalar, since $b$ is used as scalar in both the "**then**" part and the "**else**" part of the outermost conditional expression. However, $b$ is nonscalar in $f_2(a, b, b)$. Such a distinction cannot be drawn when the reduced property is used. In contrast, when EDPS is used, these cases are correctly distinguished. The EDPSs of $f_1$ and $f_2$ are

$$E(f_1(x, y, z) = \{\{\langle x, S\rangle, \langle y, S\rangle\}, \{\langle x, S\rangle, \langle y, N\rangle, \langle z, S\rangle\}\} ;$$
$$E(f_2(x, y, z) = \{\{\langle x, S\rangle, \langle y, N\rangle\}, \{\langle x, S\rangle, \langle y, S\rangle, \langle z, S\rangle\}\} .$$

Therefore, the EDPS of $f_1(a, b, b)$ becomes $\{\{\langle a, S\rangle, \langle b, S\rangle\}\}$, indicating that $b$ is scalar. In contrast, the EDPS of $f_2(a, b, b)$ becomes $\{\{\langle a, S\rangle, \langle b, N\rangle\}, \{\langle a, S\rangle, \langle b, S\rangle\}\}$, confirming that $b$ is nonscalar.

The inter-function level properties used in this paper, namely requisiteness and recipe lifetime, can be described using only the EDPS. Since the EDPS is autonomous for both requisiteness and recipe lifetime properties, the computation required for inter-function optimization can be significantly reduced.

### 6. Conclusion

This paper proposed a new program transformation algorithm for functional programs, named the mixed-mode fixpoint evaluation method. This method realizes optimized demand-driven computation on a dataflow machine. The evaluation scheme takes advantage of both data-driven and demand-driven evaluations in that it offers sufficient parallelism and safeness for nonstrict sequential functions. This can be achieved by eliminating demand propagation predictable during compilation time, and by replacing lengthy recipe creation and evaluation incurred in demand-driven evaluation with the call-by-value method.

The optimization algorithm makes use of two kinds of properties, namely, requisiteness and recipe lifetime. These properties are described using an Extended Dependency Property Set (EDPS). Since the EDPS is autonomous, the computation required for the optimization can be significantly reduced.

The algorithm proposed in this paper assumes a lazy synchronization mechanism, such as that used in a Structure Memory for storing structured data. In combination with this kind of intelligent operation memories, the proposed algorithm realizes the fixpoint computation rule for the class of sequential functions on nonstrict data structures.

This paper intentionally leaves the machine architecture abstract. Further research will be carried out on the construction of an effective and high-speed dataflow machine that can execute all operations described in this paper.

# Optimizing Matrix Operations on a Parallel Multiprocessor with a Hierarchical Memory System

William Jalby[1] and Ulrike Meier[2]
Center for Supercomputing Research and Development
University of Illinois, Urbana, IL 61801

ABSTRACT - Memory organizations of supercomputers (CRAY 2, CEDAR) tend to become more and more complex, and correspondingly data management in these memories becomes a crucial factor for achieving high performance. We study here an architecture combining vector and parallel capabilities on a two-level shared memory structure. For this class of architecture, we analyze and optimize matrix multiplication algorithms so as to obtain high efficiency kernels which can be used for many numerical algorithms such as LU and Cholesky factorizations, as well as Gram-Schmidt and Householder orthogonal factorization schemes. The performance of such kernels on the Alliant FX/8 multiprocessor is described in detail.

## 1. INTRODUCTION

One of the main issues in supercomputer architecture is the design of a memory system that is able to provide the arithmetic operators with operands at a sufficient rate. Several solutions have been proposed; first fully parallel memories (implemented either in a global way: BSP or in a distributed one: ILLIAC IV or more recently Hypercube machines [15]), followed by highly interleaved memories (CRAY, CDC CYBER 205, FUJITSU) and now complex hierarchical memory systems which consist of two levels - a first level of small fast memory and a second level of slower larger memory (which is, in fact, generally interleaved itself). Implementations of these multilevel memory organizations for parallel processors have been studied [5][17] and are currently being used in several supercomputers; the ST-100 provides a fully programmable cache, the CONVEX C1 and ALLIANT FX/8 a hardware managed cache, and the CRAY 2 a programmable local memory for each processor.

While the use of global parallel or interleaved memories only slightly affects the design of numerical algorithms (the main constraint is to avoid accessing vectors by using increments of a power of two , in order to avoid memory bank conflicts [11]), the use of distributed or hierarchical memories requires a careful design of algorithms; more precisely, data management becomes a key factor in realizing high performance. Significant progress has been achieved in developing efficient algorithms for the distributed memory case and in understanding the impact of the communication medium on the algorithm design [7][13][14]. On the other hand, much work remains to be done in the case of a hierarchical memory system especially when it is combined with both vector and parallel capabilities (e.g ALLIANT FX/8). For those architectures, algorithms must not only be designed as to be suitable for vector and parallel processing but also to provide good data locality. These requirements may be contradictory. For example, increasing the vector length may destroy data locality and so give a poor performance. In this paper, our goal will be to study the tradeoffs involved in designing high-performance algorithms for such architectures.

For reducing the complexity of the problem, the decomposition of algorithms into high level modules (e.g. vector/vector, matrix/vector and matrix/matrix operations) seems to be a promising approach.This technique has been successfully used on vector machines, e.g. BLAS, [3] and on MIMD machines (extended BLAS). In our case, the use of BLAS (vector/vector operations) or even extended BLAS (matrix/vector operations) may not be efficient since they mainly contain primitives involving an amount of data of the same order as the number of floating point operations; for example DAXPY (one of the BLAS) operating on vectors of length $N$ will manipulate $3N+1$ data elements for executing only $2N$ operations. This may often result in an inefficient use of the cache, since less than one floating point operation per data accessed has to be performed. However, multiplying two square matrices of order $N$, involves $3N^2$ data elements for $(2N-1)N^2$ operations, so data elements fetched from the memory can be used several times before they are stored back again. We study this primitive in depth since many algorithms may be expressed in terms of matrix / matrix operations as e.g. the Modified Gram-Schmidt algorithm [10] or the Householder reduction [2][8]. The use of the here described methods instead of the conventional BLAS within these two algorithms improved their performance on the ALLIANT FX/8 by a factor of two to three.

In the first section, we describe our target architecture. In the following sections we develop and analyze algorithms for multiplying large matrices. Finally, we present some computational results on an Alliant FX/8 that support our theoretical results in the preceding sections.

## 2. THE TARGET ARCHITECTURE

In this section, we describe briefly the main features of the architecture we plan to study. Our target machine consists of $p$ vector processors (CE = computational element) sharing a memory which is organized in two levels: first a fast small one (cache), second a slower bigger one (main memory). The processors are connected to the cache through a network allowing each of them to read or write any of the cache locations. The set of processors is provided with a synchronization mechanism enabling it to distribute the computations of a single program unit among the $p$ CE's.

A good example of the architecture described above is the ALLIANT FX/8. This machine consists of p=8 pipelined CE's, each of them having a register-oriented architecture (vector register length: 32) elements. The CE's share the

physical memory as well as a 16K-word cache. The bandwidth between main memory and CE's is half of that between the cache and the CE's. However, due to managing cache misses, accessing a vector from main memory may require a time larger than twice the time required for accessing the same vector if it is present in cache.

## 3. DESCRIPTION OF THE MATRIX MULTIPLICATION ALGORITHM

For the sake of simplicity, we consider here only the matrix operation: $C = C + A * B$. The similar cases $C = A * B$ and $D = C + A * B$ can be easily derived.

In order to evaluate the matrix multiplication algorithms it is necessary to model the conditions under which we assume they will be executed. We suppose that the replacement policy of the cache blocks is optimal (similar to Belady's MIN algorithm [1]); this assumption yields a standard of comparison on which the design of several algorithms can easily be based.

Previous studies [12][16] have shown that data locality can be improved efficiently by partitioning matrices into square submatrices. This method was primarily used for reducing the number of page faults on a sequential computer using a virtual memory system (first level: transistor memory, second level: disk memory). Our case presents two major differences: first the two different kinds of parallelism available in our machine and second the management of data motion between the two memory levels. In a virtual memory system, the mapping of data arrays into pages is crucial and leads to use square submatrices each of which can be contained in one page. We do not restrict ourselves to square submatrices and we will even see later that the best performance is obtained by using "very" rectangular blocks.

Let the $n_1 X n_2$-matrix $A$ be partitioned into $m_1 X m_2$-blocks $A_{ij}$, the $m_2 X m_3$-matrix $B$ into $n_2 X n_3$-blocks $B_{ij}$ and the $n_1 X n_3$-matrix $C$ into $m_1 X m_3$-blocks $C_{ij}$.

The matrix multiplication is performed as follows:

```
do $i = 1, k_1$
  do $j = 1, k_3$
    do $k = 1, k_2$
      $C_{ij} = C_{ij} + A_{ik} * B_{kj}$
end do
```

where $n_1 = k_1 m_1$, $n_2 = k_2 m_2$ and $n_3 = k_3 m_3$ with $k_1$, $k_2$ and $k_3$ being integers greater than 1.

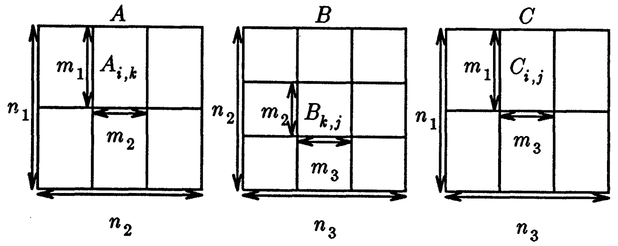

Fig. 1. Partitioning of $A$, $B$ and $C$

The block operations $C_{i,j} = C_{i,j} + A_{i,k} * B_{k,j}$ contain a reasonable amount of potential parallelism, so our algorithms proceed by first partitioning the matrices and then executing the block operations one after another; parallelism and vectorization being inside the multiplication of two submatrices.

Several points with respect to the above algorithm need to be addressed. These are:

(1) the order in which the submatrix computations are performed,

(2) the algorithm used for multiplying two submatrices of $A$ and $B$, and

(3) the sizes of the submatrices.

Concerning the first point, the three loops may be interchanged leading to a different sweep of the matrices. We will only consider the defined case where the inner loop is the k-loop. The cases where the i-loop or the j-loop are the inner loops can be derived accordingly.

The second and the third points are strongly related. The choice of submatrix sizes is obviously vital since potential parallelism is a direct function of these sizes. On the other hand, a bad design of the algorithm (second point) may prevent using the submatrix sizes which provide a good data locality.

The total time required to perform the matrix multiplication can be expressed as:

$$T = lT_l + n_S T_S \tag{3.1}$$

where $l$ denotes the total number of loads executed directly from the memory, $T_l$ the time of one load, $n_S$ the number of submatrix multiplications that have to be performed, and $T_S$ the time for one submatrix multiplication with the three submatrices kept in the cache. The first term represents the total time spent in fetching data from the memory (pure transfer time) while the second represents mainly the time spent in computations (pure computation). Each of them is a complex function of the three parameters $m_1$, $m_2$ and $m_3$, and trying to minimize their sum is difficult. For overcoming this difficulty, we decouple the problem in two independent subproblems: minimization of the transfer time and minimization of the computation time. For each, we determine a region in the parameter space where the value of the cost function is close to the minimum. By choosing a set of parameters within the intersection of the two regions, near-optimal performance can be achieved in most cases.

## 4. COMPUTATION TIME OPTIMIZATION

Let us describe the algorithm for multiplying $A_{ik}$ and $B_{kj}$:

```
do $r = 1, m_3$
  do $s = 1, m_1$
    do $t = 1, m_2$
      $c_{s,r} = c_{s,r} + a_{s,t} b_{t,r}$
end do
```

where $c_{sr}$, $a_{st}$ and $b_{tr}$ denote the elements of $C_{ij}$, $A_{ik}$ respectively $B_{kj}$.

We introduce parallelism by performing the r-loop concurrently on all $p$ processors using vectorization for the s-loop in each of them. Each processor computes an $m_2$-adic operation, the product of the submatrix $A_{ik}$ with a column of $B_{kj}$.

Let us analyze the effect of varying the three parameters on the performance of this kernel, in order to determine general guidelines for the best choice of $m_1$, $m_2$ and $m_3$:

(1) Since the operations on the columns of the submatrices of $A$ are vector operations of length $m_1$, $m_1$ should be chosen as large as possible. For CRAY-like computers however it is preferable to choose $m_1$ as a multiple of the length of a vector register.

(2) Since each processor computes a linear combination of $m_2$ columns of $A_{ik}$, we observe here the effect of the $m_2$-adic operation. The performance is an increasing function of $m_2$, and as shown in [3][4] performance close to the peak is obtained for small values (less than 50) of $m_2$; for example, an optimal value of 16 has been observed for CRAY, and 32 for the ALLIANT FX/8.

(3) Since we operate simultaneously on the columns of the submatrices of $B$, the peak performance is reached when $m_3$ is a multiple of the number of processors, i.e. the computational load is perfecly distributed among the processors.

Another possibility would be to introduce concurrency as well as vectorization for one loop, e.g. the s-loop. The disadvantage of this method is that a large value of $m_1$ may be required to achieve good performance in the submatrix operations. This tends to conflict with the data locality requirements.

We will not consider the problem of how to obtain a minimal $T_S$ any further here as it is too computer dependent. A practical approach for the ALLIANT FX/8, however, is given in [10], a more general approach might be to use a more precise parametrization of vector and parallel processors as in [9], however it will only modify slightly our main results.

## 5. MINIMIZATION OF THE TRANSFER TIME

In this section, we determine the optimal values for submatrix sizes in order to minimize the number of data loads from main memory. For doing this, it is necessary to express the number of data loads as a function of the submatrix sizes. We will consider first the case of large $n_1$, $n_2$ and $n_3$, since for small $n_1$, $n_2$ and $n_3$ all three matrices can be kept in the cache.

In order to determine the total number of loads into the cache by using the given partitioning scheme we assume the following :

(1) Multiplication of the single blocks $A_{ik}$ and $B_{kj}$ is performed according to the method described in section 3.

(2) Each block $C_{ij}$ is loaded into the cache only once and kept there for the duration of the k-loop.

(3) The blocks $A_{ik}$ and $B_{kj}$ have to be loaded each time they are involved in a submatrix multiplication.

Assumption (2) results from the order of the loops that we chose. $C_{ij}$ is independent of the inner loop. If we reorder the loops and choose e.g. the j-loop as the inner loop, $A_{ik}$ could be kept in the cache.

Now the number of loads for computing each submatrix $C_{ij}$ is $m_1n_2+m_3n_2+m_1m_3$ and therefore the total number of loads for computing $C$ is

$$l = \frac{m_1+m_3}{m_1m_3}\, n_1n_2n_3+n_1n_3. \tag{5.1}$$

Note that $l$ is of the same order of magnitude as the number of floating point operations for this matrix multiplication: $fl=2n_1n_2n_3$. This is not the case if the three matrices $A$, $B$ and $C$ are small enough to be kept in the cache during the computation of $C$, where the number of loads equals the total number of data elements: $n_1n_2+n_2n_3+n_1n_3$.

Since $n_1$, $n_2$ and $n_3$ are given, the problem of minimizing $l$ is reduced to minimizing

$$\rho = \frac{m_1+m_3}{m_1m_3} = \frac{1}{m_1} + \frac{1}{m_3} \tag{5.2}$$

under the constraint

$$m_1m_2+m_1m_3 < CS \tag{5.3}$$

where $CS$ denotes the cache size. Inequality (5.3) is justified by regarding hypotheses (2) and (3), and by assuming that the submatrix multiplication is performed so that $A_{ik}$ is swept columnwise. In this case only $p$ row elements of $B_{kj}$ are used at the same time and are not needed afterwards hence, they are neglected in (5.3). If $m_3=p$, $A_{ik}$ can also be neglected, but since a small $m_3$ will lead to a bad data locality, as can easily be verified, we concentrate here on the case $m_3>p$.

The solution of (5.2) that can be obtained by assuming equality in (5.3) gives us the following estimate of the optimal parameters as a function of $m_2$ and the cache size $CS$:

$$m_1 \approx \frac{CS}{m_2+\sqrt{CS}} \quad ; \quad m_3 \approx \sqrt{CS}. \tag{5.4}$$

The optimal $\rho$ is then given by

$$\rho_{opt} \approx \frac{m_2}{CS} + \frac{2}{\sqrt{CS}}. \tag{5.5}$$

(5.4) requires $m_1$ and $m_3$ to be large which fits well the constraints for the computation time. (5.5) indicates that the effect of $m_2$ is not dominant, allowing us to choose $m_2$ large enough to get an efficient $m_2$-adic operation.

Note also that enlarging the cache by a factor of 4 leads to reducing $\rho_{opt}$ only by a factor of 2.

Let us consider the case where one (or two) of the three parameters $n_1$, $n_2$ and $n_3$ is (are) small. In these cases at least one of the matrices to be multiplied is either tall and narrow or short and wide, i.e. "very" rectangular. The idea here is to choose the small dimensions as submatrix sizes: i.e. when $n_i$ is small, set $m_i=n_i$, $i=1,2$ or 3. The optimal parameters $m_1$, $m_2$, $m_3$ and $l$ for these cases can be derived according to the standard case. It can easy be verified that in these cases $l$ is close to the lower bound achievable (i.e. each matrix has to be loaded yat least once). For the cases where one parameter is small, the optimal parameters and the corresponding $l$ are given in Table 1.

|  | $m_1$ | $m_2$ | $m_3$ | $l$ |
|---|---|---|---|---|
| $n_1$ small | $n_1$ | $m_2$ | $\frac{CS}{n_1}-m_2$ | $\left(1+\frac{n_1^2}{CS-n_1m_2}\right)n_2n_3+n_1n_3$ |
| $n_2$ small | $\frac{CS}{n_2+p}$ | $n_2$ | $m_3$ | $\left(1+\frac{n_2^2+n_2p}{CS}\right)n_1n_3+n_2n_1$ |
| $n_3$ small | $\frac{CS}{m_2+n_3}$ | $m_2$ | $n_3$ | $\left(1+\frac{n_3^2+m_2n_3}{CS}\right)n_1n_2+n_1n_3$ |

Table 1. Parameters for rectangular matrices (one matrix size small)

## 6. COMPUTATIONAL RESULTS

In this section, we apply the theoretical results obtained above to the ALLIANT FX/8. We deal only with the case where $n_1$, $n_2$ and $n_3$ are large.

Let us determine here our optimal partitioning. A good choice seems to be $m_1=96$, $m_2=32$ and $m_3=128$. Note that $m_1$ is a multiple of the length of a vector register, $m_2$ the optimal value for the $m_2$-adic operation and $m_3$ a multiple of the number of CE's. Fig.7 shows the experimental results for our optimal partitioning and for two other partitionings achieving the same kernel performance as the optimal one but involving a larger number of loads. We can observe, as predicted by the theory a good correspondence between the decrease of the value $\rho$ ($\rho$=0.15625, for $m_1$=32 and $m_3$=8; $\rho$=0.03125, for $m_1=m_3$=32; and $\rho$=0.01823, for $m_1$=96 and $m_3$=128) and the improvement in performance. Also note that our optimal partitioning achieves a constant high performance for a large range of matrix sizes.

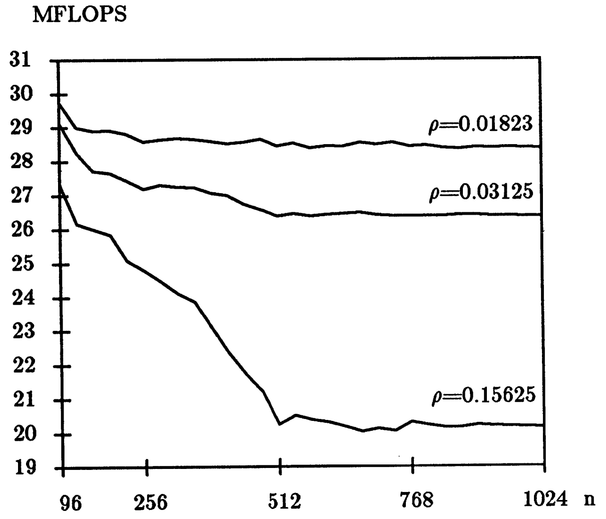

Fig. 2. Performance of the multiplication of two square matrices of order $n$

ACKNOWLEDGEMENTS - We are very grateful to Kyle Gallivan, Dennis Gannon and Ahmed Sameh who took the time to make detailed and constructive comments on the first draft, resulting in a much better exposition.

# Multiprocessor Jacobi Algorithms for Dense Symmetric Eigenvalue and Singular Value Decompositions

Michael Berry and Ahmed Sameh
Center for Supercomputing Research and Development
University of Illinois, Urbana, IL 61801

**Abstract** – – We present two parallel algorithms based on Jacobi's method for real symmetric matrices to determine the complete eigensystem of a dense real symmetric matrix and the singular value decomposition of rectangular matrices on a multiprocessor. Our intent is to study the advantages of using Jacobi and Jacobi-like schemes over new and existing EISPACK and LINPACK routines on an Alliant FX/8 computer system. For the dense symmetric eigenvalue problem, we show promising results for small-order matrices. A "one-sided" Jacobi-like algorithm which produces the singular value decomposition of a rectangular matrix is shown to provide superior performance for rectangular matrices in which the number of rows is much larger than the number of columns.

## 1. Introduction

Consider the standard eigenvalue problem

$$\mathbf{A}\mathbf{x} = \lambda\mathbf{x} \tag{1.1}$$

where $\mathbf{A}$ is a real $n \times n$ dense symmetric matrix. One of the best known methods for determining all the eigenvalues and eigenvectors of (1.1) was developed by the nineteenth century mathematician, Jacobi. We recall that Jacobi's sequential method reduces the matrix $\mathbf{A}$ to diagonal form by an infinite sequence of plane rotations

$$\mathbf{A}_{k+1} = \mathbf{U}_k\mathbf{A}_k\mathbf{U}_k^T, \quad k = 1,2,\cdots,$$

where $\mathbf{A}_1 \equiv \mathbf{A}$ and $\mathbf{U}_k = \mathbf{U}_k(i,j,\theta_{ij}^k)$ is an orthogonal plane rotation matrix which deviates from the identity matrix only in the elements

$$u_{ii}^k = u_{jj}^k = c_k = cos(\theta_{ij}^k) \text{ and } u_{ij}^k = -u_{ji}^k = s_k = sin(\theta_{ij}^k).$$

The angle $\theta_{ij}^k$ is determined so that $a_{ij}^{k+1} = a_{ji}^{k+1} = 0$. It can be shown that for $i < j$

$$a_{ij}^{k+1} = a_{ij}^k \cos 2\theta_{ij}^k - ½(a_{ii}^k - a_{jj}^k) \sin 2\theta_{ij}^k,$$

and hence the annihilation of $a_{ij}^{k+1}$ requires

$$\tan 2\theta_{ij}^k = \frac{2a_{ij}^k}{a_{ii}^k - a_{jj}^k}$$

where $\theta_{ij}^k$ is chosen such that $|\theta_{ij}^k| \leq \pi/4$.

For numerical stability, we determine the plane rotation by

$$c_k = \frac{1}{\sqrt{1+t_k^2}}, \text{ and } s_k = c_k t_k, \tag{1.2}$$

where $t_k$ is chosen as the smaller root (in magnitude) of the quadratic equation

$$t_k^2 + 2\alpha_k t_k - 1 = 0, \quad \alpha_k = cot\ 2\theta_{ij}^k.$$

Hence, $t_k$ may be written as

$$t_k = \frac{(sign\ \alpha_k)}{|\alpha_k| + \sqrt{1+\alpha_k^2}} \tag{1.3}$$

With each $\mathbf{A}_{k+1}$ remaining symmetric and differing from $\mathbf{A}_k$ only in rows and columns $i$ and $j$, the modified elements are

$$a_{ii}^{k+1} = a_{ii}^k + t_k a_{ij}^k,$$

$$a_{jj}^{k+1} = a_{jj}^k - t_k a_{ij}^k,$$

and

$$a_{ir}^{k+1} = c_k a_{ir}^k + s_k a_{jr}^k, \tag{1.4}$$

$$a_{jr}^{k+1} = -s_k a_{ir}^k + c_k a_{jr}^k. \tag{1.5}$$

where $r \neq i,j$. If we represent $\mathbf{A}_k$ by

$$\mathbf{A}_k = \mathbf{D}_k + \mathbf{E}_k + \mathbf{E}_k^T \tag{1.6}$$

where $\mathbf{D}_k$ is diagonal and $\mathbf{E}_k$ is strictly upper triangular, and

$$\sigma_k = \|\mathbf{D}_k\|_F,$$

$$\omega_k = \|\mathbf{E}_k\|_F,$$

where $\|\cdot\|_F$ denotes the Frobenius norm, then from

(1.4) and (1.5) it follows that

$$\omega_{k+1}^2 = \omega_k^2 - (a_{ij}^k)^2,$$

and

$$\sigma_{k+1}^2 = \sigma_k^2 + (a_{ij}^k)^2.$$

If at each step $k$ we annihilate an element $a_{ij}^k$ which is at least of average magnitude, i.e.,

$$(a_{ij}^k)^2 \geq \frac{2}{n(n-1)} \omega_k^2,$$

then

$$\omega_{k+1}^2 \leq \left(1 - \frac{2}{n(n-1)}\right) \omega_k^2,$$

and $\mathbf{A}_k$ approaches the diagonal matrix $\Lambda = diag(\lambda_1, \lambda_2, \cdots, \lambda_n)$. Similarly, $(\mathbf{U}_k \cdots \mathbf{U}_2\mathbf{U}_1)^T$ approaches a matrix whose $j$-$th$ column is the eigenvector corresponding to $\lambda_j$ .

Several schemes are possible for selecting the sequence of elements $a_{ij}^k$ to eliminate via the plane rotations $\mathbf{U}_k$. Unfortunately, Jacobi's original scheme, which consisted of sequentially searching for the largest off-diagonal element, is too time consuming for implementation on a multiprocessor. Instead, a simpler scheme in which the off-diagonal elements $(i,j)$ are annihilated in the cyclic fashion $(1,2), (1,3), \cdots, (1,n); (2,3), \cdots, (2,n); \cdots; (n-1,n)$ is certainly more suitable. We refer to each sequence of $n$ rotations as a sweep. Quadratic convergence for this sequential cyclic Jacobi scheme has been well documented, see [13] and [15]. Convergence usually occurs within 6 to 10 sweeps, i.e. from $3n^2$ to $5n^2$ Jacobi rotations.

A parallel version of this cyclic Jacobi algorithm is obtained by the simultaneous annihilation of several off-diagonal elements by a given $\mathbf{U}_k$ rather than only one as is done in the serial version. For example, let $\mathbf{A}$ be of order 8 and consider the orthogonal matrix $\mathbf{U}_k$ as the direct sum of 4 independent plane rotations in Figure 1, where the $c_i$'s and $s_i$'s for $i = 1,2,3,4$ are simultaneously determined.

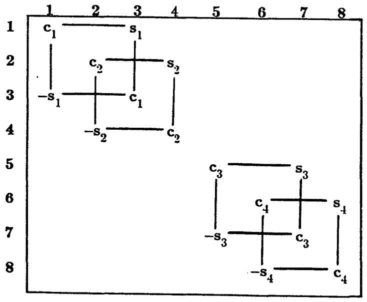

*Figure 1. Sample* $\mathbf{U}_k$ *of Multiprocessor Jacobi Algorithm for* $n = 8$.

Then,

$$\mathbf{U}_k = \mathbf{R}_k(1,3) \oplus \mathbf{R}_k(2,4) \oplus \mathbf{R}_k(5,7) \oplus \mathbf{R}_k(6,8),$$

where $\mathbf{R}_k(i,j)$ is that rotation which annihilates the $(i,j)$ off-diagonal element. If we consider one sweep to be a collection of orthogonal similarity transformations that annihilate the element in each of the $n(n-1)/2$ off-diagonal positions (above the main diagonal) only once, then for a matrix of order 8 the first sweep will consist of 8 successive $\mathbf{U}_k$'s with each one annihilating 4 elements simultaneously. For the remaining sweeps, the structure of each subsequent transformation $\mathbf{U}_k$, $k > 8$ is chosen to be the same as that of $\mathbf{U}_j$ where $j = 1 + (k-1)\ mod\ 8$. In general, the most efficient annihilation scheme consists of $(2r-1)$ similarity transformations per sweep, where $r = \lfloor (n+1)/2 \rfloor$, in which each transformation annihilates different $\lfloor n/2 \rfloor$ off-diagonal elements, see [10]. Although several annihilation schemes are possible, the Multiprocessor Jacobi Algorithm we present in the next section utilizes an annihilation scheme which requires a minimal amount of indexing for computer implementation. Whereas Brent and Luk [2] have demonstrated the implementation of similar Jacobi schemes using systolic arrays on a multiprocessor, the success of using block-matrix Jacobi schemes on a linear array of processors has also been shown (see [14]). However, the algorithms presented in this paper have yet to be implemented with blocking techniques suitable for the Alliant FX/8 computer.

## 2. A Multiprocessor Jacobi Algorithm

The algorithm we present requires $n$ similarity transformations per sweep for a dense real symmetric matrix of order $n$ ($n$ may be even or odd). Each $\mathbf{U}_k$ is the direct sum of either $\lfloor n/2 \rfloor$ or $\lfloor (n-1)/2 \rfloor$ plane rotations, depending on whether $k$ is odd or even, respectively.

**Algorithm 1.**

**Step 1** (Apply orthogonal similarity transformations via $\mathbf{U}_k$ for current sweep)

**1.a** For $k = 1,2,3,...,n-1$ (serial loop)
Simultaneously annihilate elements in positions $(i,j)$, where

$$\begin{cases} i = 1,2,3,..., \lceil (n-k)/2 \rceil \\ j = (n-k+2)-i \end{cases},$$

and for $k > 2$

$$\begin{cases} i = (n-k+2), (n-k+3),..., n - \lfloor k/2 \rfloor \\ j = (2n-k+2)-i \end{cases}$$

**1.b** For $k = n$

Simultaneously annihilate elements in positions $(i,j)$, where

$$\begin{cases} i = 2,3,\ldots,\lceil n/2 \rceil \\ j = (n+2)-i \end{cases}$$

**Step 2** (Convergence test)

**2.a** Compute $\|D_k\|_F$ and $\|E_k\|_F$ as in (1.6).

**2.b** If $\dfrac{\|E_k\|_F}{\|D_k\|_F} < (\textit{tolerance})$, then stop.

Otherwise, go to **Step 1** to begin next sweep.

The annihilation patterns for $n = 8$ is shown in Figure 2, where the integer $k$ denotes an element annihilated via $U_k$.

*Figure 2. Annihilation Scheme for Multiprocessor Jacobi Algorithm.*

In the annihilation of a particular $(i,j)$ element in **Step 1** above, we update the off-diagonal elements in rows and columns $i$ and $j$ as specified by (1.4) and (1.5) in Section 1. With regard to storage requirements, it would be advantageous to modify only those rows or column entries above the main diagonal and utilize the guaranteed symmetry of $A_k$. However, to take advantage of the vectorization supported by the Alliant FX/8 computer system, we disregard the symmetry of $A_k$ and operate with full vectors on the entirety of rows and columns $i$ and $j$ in (1.4) and (1.5) i.e., we are using a full matrix scheme. To avoid the necessity of synchronization on the Alliant FX/8, all row changes specified by the $\lfloor n/2 \rfloor$ or $\lfloor (n-1)/2 \rfloor$ plane rotations for a given $U_k$ are performed concurrently with one processor updating a unique pair of rows. After all row changes are completed, we perform the analogous column changes in the same manner. The product of the $U_k$'s, which eventually yields the eigenvectors for $A$, is accumulated in a separate two-dimensional array by applying (1.4) and (1.5) to the $n \times n$ identity matrix.

In **Step 2**, we monitor the convergence of the algorithm by using the ratio of the computed norms to measure the systematic decrease in the relative magnitudes of the off-diagonal elements with respect to the relative magnitudes of the diagonal elements. For double precision accuracy in the eigenvalues and eigenvectors, a *tolerance* of order $10^{-16}$ will suffice for **Step 2.b.** If we assume convergence, this multiprocessor algorithm can be shown to converge quadratically by following the work of Henrici [5], and Wilkinson [15]. In the next section, we discuss the adaptation of a "one-sided" Jacobi algorithm to compute the singular value decomposition on a multiprocessor.

## 3. Singular Value Decomposition

Suppose $A$ is a real $m \times n$ matrix with $m >> n$. The singular value decomposition of $A$ can be defined as

$$A = U\Sigma V^T \qquad (3.1)$$

where $U^TU = V^TV = I_n$ and $\Sigma = diag(\sigma_1, \cdots, \sigma_n)$. The orthogonal matrices $U$ and $V$ define the orthonormalized eigenvectors associated with the $n$ eigenvalues of $AA^T$ and $A^TA$, respectively. The singular values of $A$ are defined as the diagonal elements of $\Sigma$ which are the nonnegative square roots of the $n$ eigenvalues of $AA^T$.

As indicated in [11] for a ring multiprocessor, using a method based on the one-sided iterative orthogonalization method of Hestenes (see also [7] and [9]) is an efficient way to compute (3.1). Luk recommended this scheme for the singular value decomposition on the Illiac IV in [8], and systolic algorithms associated with this scheme have been presented in [2] and [1]. We now consider a few modifications to the scheme discussed in [11] for the determination of (3.1) on the Alliant FX/8.

Our main goal is to determine an orthogonal matrix $\tilde{V}$ as a product of plane rotations so that

$$A\tilde{V} = Q = (q_1, q_2, q_3, \cdots, q_n) \,, \qquad (3.2)$$

and

$$q_i^T q_j = \sigma_i^2 \delta_{ij} \,,$$

where the columns of $Q$, $q_i$, are orthogonal, and $\delta_{ij}$ is the Kronecker delta. We then may write $Q$ as

$$Q = \tilde{U}\Sigma \textit{ with } \tilde{U}^T\tilde{U} = I_n \,,$$

and hence

$$A = \tilde{U}\Sigma\tilde{V}^T \,.$$

Thus, we can obtain (3.1) if we can determine the matrix $\tilde{V}$ in (3.2).

We construct the matrix $\tilde{V}$ via the $(i,j)$ plane rotation

$$(a_i, a_j) \begin{bmatrix} c & -s \\ s & c \end{bmatrix} = (\tilde{a}_i, \tilde{a}_j) \quad i < j \,,$$

so that

$$\tilde{\mathbf{a}}_i^{\mathbf{T}} \tilde{\mathbf{a}}_j = 0, \text{ and } \|\tilde{\mathbf{a}}_i\| > \|\tilde{\mathbf{a}}_j\| \ , \qquad (3.3)$$

where $\mathbf{a}_i$ designates the $i$-*th* column of matrix **A**. This is accomplished by choosing

$$c = \left[\frac{\beta+\gamma}{2\gamma}\right]^{1/2} \text{ and } s = \left[\frac{\alpha}{2\gamma c}\right] \text{ if } \beta > 0 \ , \qquad (3.4)$$

or

$$s = \left[\frac{\gamma-\beta}{2\gamma}\right]^{1/2} \text{ and } c = \left[\frac{\alpha}{2\gamma s}\right] \text{ if } \beta < 0 \ , \qquad (3.5)$$

where $\alpha = 2\,\mathbf{a}_i^{\mathbf{T}}\mathbf{a}_j$, $\beta = \|\mathbf{a}_i\|^2 - \|\mathbf{a}_j\|^2$, and $\gamma = (\alpha^2+\beta^2)^{1/2}$.

Note that (3.3) requires the columns of **Q** to decrease in norm from left to right, and hence the resulting $\sigma_i$ to be in monotonic non-increasing order. To orthogonalize the columns of **A** there are certainly several schemes that can be used to select the order of the $(i,j)$ plane rotations. Following the annihilation pattern of the off-diagonal elements in the sequential Jacobi algorithm mentioned in Section 1, we could certainly orthogonalize the columns in the same cyclic fashion and thus perform the one-sided orthogonalization serially. This process is iterative since orthogonality between columns established in one rotation may be destroyed in subsequent rotations, and convergence is governed by the column norm ordering in (3.3). Each sweep consists of the $n(n-1)/2$ plane rotations selected in cyclic fashion. Due to the similarity with the sequential cyclic Jacobi algorithm for real symmetric matrices and the postmultiplication of matrix **A** only, we refer to this procedure as a "one-sided" Jacobi method.

By implementing the annihilation scheme of the Multiprocessor Jacobi Algorithm presented in Section 2 as the orthogonalization scheme for the one-sided Jacobi method discussed above, we obtain a parallel algorithm for computing the singular value decomposition on a multiprocessor. For example, let $n = 8$ and $m >> n$ so that in each sweep of our One-Sided Multiprocessor Jacobi Algorithm we simultaneously orthogonalize pairs of columns of **A** according to the diagram in Figure 2. In other words, for $n = 8$ we can orthogonalize the pairs (1,8), (2,7), (3,6), (4,5) simultaneously with the postmultiplication of matrix $\tilde{\mathbf{V}}_1$ which consists of the direct sum of 4 plane rotations. In general, each $\tilde{\mathbf{V}}_k$ will have the same form of $\mathbf{U}_k$ in Figure 1 so that at the end of any particular sweep $s_i$ we have

$$\tilde{\mathbf{V}}_{s_i} = \tilde{\mathbf{V}}_1 \tilde{\mathbf{V}}_2 \cdots \tilde{\mathbf{V}}_n \ ,$$

and hence

$$\tilde{\mathbf{V}} = \tilde{\mathbf{V}}_{s_1} \tilde{\mathbf{V}}_{s_2} \cdots \tilde{\mathbf{V}}_{s_t} \ , \qquad (3.6)$$

where $t$ is the number of sweeps required for convergence. We present a formal description of this algorithm in the next section.

## 4. A One-Sided Multiprocessor Jacobi Algorithm

This algorithm is an adaptation of the Multiprocessor Jacobi Algorithm from Section 2 for the singular value decomposition of real $m \times n$ matrices, **A**, where $m >> n$. Each $\tilde{\mathbf{V}}_k$ is the direct sum of either $\lfloor n/2 \rfloor$ or $\lfloor (n-1)/2 \rfloor$ plane rotations, depending on whether $k$ is odd or even, respectively.

### Algorithm 2.

**Step 1** (Postmultiply matrix **A** by orthogonal matrix $\tilde{\mathbf{V}}_k$ for current sweep)

**1.a** Initialize the convergence counter, *istop*, to zero.

**1.b** For $k = 1,2,3,\ldots,n-1$ (serial loop)
Simultaneously orthogonalize the column pairs $(i,j)$, where $i$ and $j$ are given by **1.a** in **Step 1** of **Algorithm 1.**,

provided that for each $(i,j)$ we have

$$\frac{(\mathbf{a}_i^{\mathbf{T}}\mathbf{a}_j)^2}{(\mathbf{a}_i^{\mathbf{T}}\mathbf{a}_i)(\mathbf{a}_j^{\mathbf{T}}\mathbf{a}_j)} > (\mathit{tolerance}) \ . \qquad (4.1)$$

Note: if (4.1) is not satisfied for any particular pair $(i,j)$, then *istop* is incremented by 1 and that rotation is not performed.

**1.c** For $k = n$
Simultaneously orthogonalize the column pairs $(i,j)$, where $i$ and $j$ are given by **1.b** in **Step 1** of **Algorithm 1.**

**Step 2** (Convergence test)

If $\mathit{istop} = n(n-1)/2$, then compute $\sigma_i = \sqrt{(\mathbf{A}^{\mathbf{T}}\mathbf{A})_{ii}}$ , $i = 1,2,\ldots,n$, and stop.

Otherwise, go to beginning of **Step 1** to start next sweep.

In the orthogonalization of columns in **Step 1** we are implementing the plane rotations specified by (3.4) and (3.5), and hence guaranteeing the ordering of column norms and singular values upon termination. Whereas the Jacobi algorithms of Sections 1 and 2 must update rows and columns following each similarity transformation, this one-sided scheme performs only postmultiplication of **A** by each $\tilde{\mathbf{V}}_k$ and hence the plane rotation $(i,j)$ changes only the elements in columns $i$ and $j$ of matrix **A**. The changed elements can be represented by

$$\mathbf{a}_i^{k+1} = c\,\mathbf{a}_i^k + s\,\mathbf{a}_j^k \ , \tag{4.2}$$

$$\mathbf{a}_j^{k+1} = -s\,\mathbf{a}_i^k + c\,\mathbf{a}_j^k \ , \tag{4.3}$$

where $\mathbf{a}_i$ denotes the *i-th* column of matrix **A**, and $c$, $s$ are determined by either (3.4) or (3.5). Since no row accesses are required and no columns are interchanged, one would expect good performance for this method on a machine such as the Alliant FX/8 which can apply vector operations to compute (4.2) and (4.3). As with the Multiprocessor Jacobi Algorithm in Section 2, no synchronization among processors is required for the implementation on multiprocessors. Each processor is assigned one rotation and hence orthogonalizes one pair of the $n$ columns of matrix **A**.

Following the convergence test used in [9], in **Step 2** we count the number of times the quantity

$$\frac{\mathbf{a}_i^T \mathbf{a}_j}{(\mathbf{a}_i^T \mathbf{a}_i)(\mathbf{a}_j^T \mathbf{a}_j)} \tag{4.4}$$

falls, in any sweep, below a given *tolerance*. The algorithm terminates when the counter *istop* reaches $n(n-1)/2$, the total number of column pairs, after any sweep. Upon termination, the matrix **A** has been overwritten by the matrix **Q** from (3.2) and hence the singular values $\sigma_i$ can be obtained via the $n$ square roots of the diagonal entries of $\mathbf{A}^T\mathbf{A}$. The matrix **U** in (3.1), which contains the left singular values of the original matrix **A**, is readily obtained by scaling the resulting matrix **A** (now overwritten by $\mathbf{Q} = \tilde{\mathbf{U}}\Sigma$) by the singular values $\sigma_i$, and the matrix **V**, which contains the right singular vectors of the original matrix **A**, is obtained as in (3.6) as the product of the orthogonal $\tilde{\mathbf{V}}_k$'s. This product is accumulated in a separate two-dimensional array by applying the rotations specified by (4.2) and (4.3) to the $n \times n$ identity matrix. It is important to note that the use of the ratio in (4.4) is preferable over the use of $\mathbf{a}_i^T\mathbf{a}_j$, since this dotproduct can be necessarily small for relatively small singular values. On the Alliant FX/8 computer, the number of sweeps required for convergence using (4.4) ranged between 3 to 8 for a *tolerance* of order $10^{-14}$.

Although we have restricted our discussion of the One-Sided Multiprocessor Jacobi Algorithm to the singular value decomposition, this method is certainly applicable for solving the eigenvalue problem (1.1) for real nonsingular symmetric matrices. If $m = n$, **A** is a positive definite matrix, and **Q** is given by (3.2), it is not difficult to show that

$$\begin{cases} \sigma_i^2 = \lambda_i^2 \\ \mathbf{x}_i = \dfrac{\mathbf{q}_i}{\lambda_i} \end{cases} \quad i = 1,2,\ldots,n \ ,$$

where $\lambda_i$ denotes the *i-th* eigenvalue of **A**, $\mathbf{x}_i$ the corresponding normalized eigenvector, and $\mathbf{q}_i$ the *i-th* column of matrix **Q**.

Two advantages of this one-sided Jacobi scheme over the "two-sided" Jacobi method discussed in Section 2 are that no row accesses are needed and that the matrix $\tilde{\mathbf{V}}$ need not be accumulated. Before discussing the performance of the Jacobi algorithms on the Alliant FX/8 computer, we present an overview of the architectural and software characteristics of the Alliant FX/8 computer in Section 5.

## 5. The Alliant FX/8

Both multiprocessor Jacobi algorithms described thus far have been implemented along with several new and existing EISPACK and LINPACK routines on an Alliant FX/8 computer at the Center for Supercomputing Research and Development, University of Illinois at Champaign-Urbana. On the FX/8 computer, 8 computational elements (CEs) deliver 94.4 MFLOPS (millions of floating point operations per second) peak single precision (32-bit) vector, 46 MFLOPS peak double precision (64-bit) vector, and 35 MIPS (millions of instructions per second) scalar performance. Each CE is a microprogrammed general purpose computer with a 5 stage pipelined instruction processor; a pipelined vector and floating-point unit; eight 64-bit, 32 element vector registers; a 16 KB (kilobyte) instruction cache and concurrency control hardware. Parallel processing is achieved by the application of all processors in the computational complex to the execution of a single program.

The memory of the Alliant FX/8 consists of a physical memory which is expandable to 64 MB (megabyte) in 8 MB modules, and 2 expandable cache systems that support the CEs. Four-way interleaving on each physical memory module permits any module to supply the full memory bus bandwidth of 188 MB-per-second on sequential read access (and 150 MB-per-second on sequential write access). The cache systems use a write-back architecture to reduce memory bus traffic, and the computational processor cache expands to a four-way interleaved, 128 KB physical memory buffer that allows up to eight simultaneous accesses in each 170 nanosecond cycle. A crossbar interconnect links the computational processor cache to the CEs and dynamically connects any CE to any cache port at 376 MB-per-second sustained bandwidth.

## 6. Performance On The Alliant FX/8

In this section we evaluate the performance of our two multiprocessor Jacobi algorithms on the Alliant FX/8. For comparison purposes, we refer to the

Multiprocessor Jacobi Algorithm from Section 2 as MUJAC, and the One-Sided Multiprocessor Jacobi Algorithm from Section 4 as OMJAC. All experiments on the Alliant FX/8 were performed using 64-bit double precision floating-point numbers. For Figures 3 and 4 we solve the dense symmetric eigenvalue problem

$$\mathbf{AX}=\mathbf{X\Lambda} \ , \qquad (6.1)$$

where $\mathbf{A} = [\,a_{ij}\,]$ is $n \times n$ and $a_{ij} = dfloat\,[\,max(i,j)\,]$.

In Figure 3 we plot the number of MFLOPS achieved by the Alliant FX/8 when MUJAC and OMJAC are used to compute eigenvalues and eigenvectors for matrices of order $n$. While MUJAC and OMJAC are implemented completely in FORTRAN, MUJAC(A) and OMJAC(A) use ASSEMBLER subroutines to compute the row and column updates as well as column inner products. The decrease in performance for MUJAC and OMJAC for matrix orders greater than 100 can be greatly attributed to the memory limitations of the computational processor cache described in Section 5, i.e., double precision two-dimensional arrays of order 100 or greater cannot be stored continguously in the 128 KB cache. Although peak performance of 12 and 17 MFLOPS for MUJAC and MUJAC(A) for $n = 50$ were much larger than the 11 and 14 MFLOPS for OMJAC and OMJAC(A), the variation from the peak performance for all $n$ was certainly much smaller for the latter pair. Since the number of multiplications required by MUJAC to determine and perform a rotation (on a full matrix) is twice that of OMJAC, we would expect that OMJAC would require only one-half the computational time that MUJAC does. This was usually the case when both algorithms were used to compute eigenvalues and eigenvectors for dense symmetric matrices. Although MUJAC is generally 50% slower than OMJAC, the potential for vectorization per rotation is much greater for MUJAC and thus we obtain the disparity in MFLOPS between the algorithms for $n \leq 200$.

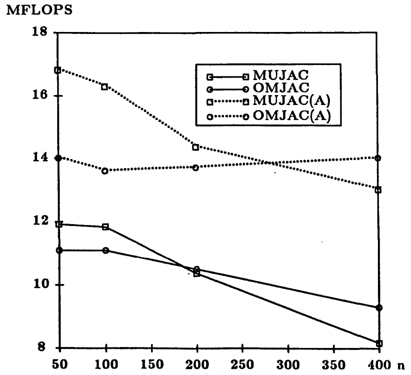

*Figure 3. Performance of Jacobi Schemes on Alliant FX/8.*

For Figure 4, let $t_8$, $t_v$, and $t_g$ represent the execution time on 8 processors with vectorization, 1 processor with vectorization, and 1 processor with only global optimization, respectively, and define

$$\sigma_{vc} = \frac{t_8}{t_g} \text{ and } \sigma_c = \frac{t_8}{t_v} \ ,$$

where $\sigma_{vc}$ represents speed-up for vectorization and concurrency, and $\sigma_c$ represents speed-up for concurrency only. From the graphs in Figure 4, we observe that MUJAC can maintain a larger $\sigma_{vc}$ than OMJAC for $n < 400$, and yet $\sigma_c$ for MUJAC decreases immediately from its peak of 5 at $n = 50$. Vectorization is the major reason for this result. Comparing the values of $\sigma_{vc}$ and $\sigma_c$ for MUJAC and MUJAC(A), we notice that $\sigma_{vc} \approx 2 \times \sigma_c$, and so we can increase the speed-up of MUJAC and MUJAC(A) by a factor of 2 if we use vectorization. However, for $n > 100$ we observe the memory limitation of the computational processor cache by the sharp declines in $\sigma_{vc}$ and $\sigma_c$ for both MUJAC and MUJAC(A). These declines are due not only to the cache memory limitiations incurred by large $n$, but also to the row accessing that must be done by MUJAC. OMJAC and OMJAC(A), on the other hand, do not show such sharp declines in $\sigma_{vc}$ and $\sigma_c$, and so the cache effect is not nearly as great when only column accesses are required. For OMJAC and OMJAC(A) we note that the graphs of $\sigma_{vc}$ and $\sigma_c$ are very similar, and so the vectorization effect is not as substantial as it was for MUJAC. However, where in the case of MUJAC and MUJAC(A) we can expect the speed-ups $\sigma_{vc}$ and $\sigma_c$ to significantly drop for large $n$, OMJAC and OMJAC(A) show little variation from their peak performance for large $n$. In fact, OMJAC(A) is nearly ideal in that it maintains a speed-up close to 8, the number of processors, for all $n$.

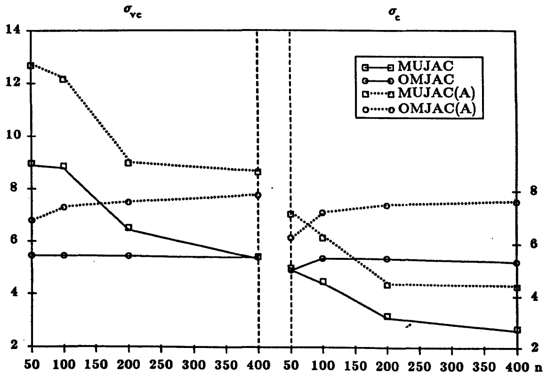

*Figure 4. Speed-ups for concurrency with and without vectorization on Alliant FX/8.*

## 7. Comparisons With EISPACK and LINPACK

We now compare the performance in speed and accuracy of MUJAC and OMJAC with that of new and existing EISPACK and LINPACK routines on the Alliant FX/8. For the dense symmetric eigenvalue problem we first compare MUJAC, OMJAC, and TRED2+TQL2 from EISPACK [12]. In order to compare a set of highly efficient subroutines that are optimized for vector as well as parallel processing, we compare MUJAC(A) and OMJAC(A) which use ASSEMBLER routines for applying rotations and computing dotproducts, with TQL2 and the new matrix-vector implementation of TRED2, TRED2V, developed by Dongarra et al. in [4]. On the Alliant FX/8, MUJAC(A) and OMJAC(A) are 30% faster than MUJAC and OMJAC, and TRED2V is on average 40% faster than TRED2. In Figure 5, we compare the timing of these three algorithms on 8 CEs with full optimization (global and vector) for

$$\mathbf{AX} = \mathbf{X\Lambda} \ ,$$

where $\mathbf{A} = [\, a_{ij} \,]$ is $n \times n$ and $a_{ij} = dfloat\,[\,(i+j-1)/n\,]$.

The largest $n$ for which MUJAC(A) executed faster than TRED2+TQL2 was 90, while OMJAC(A) consistently out-performed the other two algorithms and required only one-half the execution time of the EISPACK routines for each $n$. For $n \geq 100$ we exceed the Alliant FX/8's cache memory capability and consequently obtain sharper increases in time especially for MUJAC(A). Convergence for both MUJAC(A) and OMJAC(A) occurred after 3 to 4 sweeps, and for each $n$ the order of accuracy in the eigenvalues and eigenvectors computed by these Jacobi algorithms was identical to that obtained by TRED2V+TQL2.

For any symmetric matrix of order greater than 100, the advantage of using MUJAC (and OMJAC) rather then TRED2+TQL2 will primarily depend on whether or not convergence can be obtained within 2 to 3 sweeps. This rate of convergence is more prevalent not only in the more diagonally dominant matrices but also in symmetric matrices with a large number of multiple eigenvalues (see [16]).

For the singular value decomposition of a real $m \times n$ matrix $\mathbf{A}$ $(m >> n)$

$$\mathbf{A} = \mathbf{U\Sigma V^T} \ ,$$

where $\mathbf{U^TU} = \mathbf{V^TV} = \mathbf{I_n}$, and $\Sigma = diag(\sigma_1, \cdots, \sigma_N)$, we compare the speed and accuracy of OMJAC and OMJAC(A) with that of the appropriate routines from EISPACK and LINPACK, SVD and DSVDC. Recall that both routines SVD and DSVDC reduce the matrix $\mathbf{A}$ to bidiagonal form via Householder transformations and then diagonalize this reduced form using plane rotations. We will also compare our results with OMJAC and OMJAC(A) with the new matrix-vector implementation of SVD, SVDV, developed by Dongarra et al. in [4], which has been demonstrated to achieve 50% speed-up in execution time over SVD on machines such as the CRAY-1.

Suppose that the elements of the $m \times 32$ matrix $\mathbf{A} = [\, a_{ij} \,]$ are given by

$$a_{ij} = dfloat\,[\,(i+j-1)/n\,]$$

for $m >> 32$, and that we wish to determine all the singular values and singular vectors of the matrix $\mathbf{A}$. In Figure 6, we present the speed-ups for OMJAC(A) over each routine used to compute the singular values and singular vectors of the matrix $\mathbf{A}$ on the Alliant FX/8 with 8 CEs and vectorization for each $m$. With regard to accuracy, OMJAC(A) was somewhat less accurate than SVDV and .DSVDC for the smaller values of $m$, but very competitive for $m > 512$.

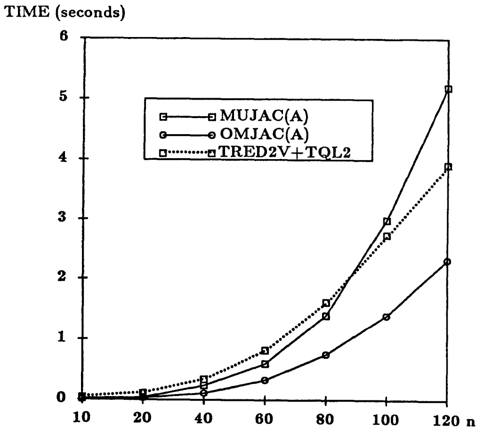

*Figure 5. Execution Times for Highly Optimized Routines.*

| m | $\frac{t_s}{t_o}$ | $\frac{t_d}{t_o}$ | $\frac{t_{sv}}{t_o}$ |
|---|---|---|---|
| 64 | 3.57 | 8.33 | 1.78 |
| 96 | 3.57 | 7.14 | 1.67 |
| 128 | 3.33 | 5.88 | 1.69 |

## 8. Conclusions

For solving the dense symmetric eigenvalue problem on multiprocessors such as the Alliant FX/8, we have presented a parallel algorithm (based on Jacobi's method for symmetric matrices), MUJAC, that can produce accurate eigenvalues and eigenvectors significantly faster than the popular EISPACK routines, TRED2+TQL2, for matrices of order less than 100. We have also presented a Jacobi-like one-sided multiprocessor algorithm, OMJAC, that can be used to solve not only the symmetric eigenvalue problem but also the singular value decomposition of $m \times n$ matrices with $m >> n$. When used to determine eigenvalues and eigenvectors (though somewhat less accurate) on the Alliant FX/8, a highly efficient implementation of OMJAC using FORTRAN and ASSEMBLER, OMJAC(A), executes not only 50% faster than MUJAC but also substantially faster than the most efficient EISPACK routines, TRED2V+TQL2, for all matrix orders considered. When compared with the new and existing EISPACK and LINPACK routines for computing the singular value decomposition, OMJAC(A) is at least 2 to 3 times faster.

Future work with the Jacobi algorithms presented in this paper will involve the use of blocking schemes to optimize MUJAC and OMJAC for better cache management of the Alliant FX/8 as the order of the matrix gets large.

## 1. Introduction

The problem of solving a real, symmetric and positive definite matrix of size n, on vector computers of type Cray-1 and Cyber-205 is considered. Three parallel algorithms based on simple Gaussian elimination (hereafter refered to as GE algorithm), Gaussian elimination with scaled partial pivoting (PGE algorithm) and the Cholesky decompositon (LDLT algorithm) are analyzed and compared in terms of their speedup and efficiency. Actual performance of these three algorithms on Cray-1 and Cyber-205 is also included.

A study based on these algorithms for MIMD (multiple-instruction multiple-data) type machines is presented by Kumar and Kowalik [4]. Details about Cray-1 and Cyber-205 architecture can be found in Hockney and Jessehope [2], Kascic [3] and Gentzsch [1].

## 2. The algorithms

Six algorithms to solve a randomaly generated symmetric positive definite matrix (diagonally dominant) in the vector computers Cray-1 and Cyber-205 are analyzed. These 6 programs are the scalar and vectorized version of the GE, PGE and LDLT algorithms. The algorithms are arranged in a way so that the vectors are contiguous in the memory. Thus, 'identical' codes are compared on the two machines.

The first algorithm is the Gaussian elimination method (GE) without pivoting. The factorization part of the algorithm is as follows:

```
For  k=1,-----,n-1 do;
   For  i=k+1,-----,n do;
      a(i,k):=a(i,k)/a(k,k)
   For  j=k+1,-----,n do;
      For  i=k+1,-----,n do;
        a(i,j):=a(i,j) -a(i,k)*a(i,j)
```

Note that the i loops of the above algorithm are the vectorized loops in both machines because of parallel computations and contiguous memory locations involved. The backward and forward substitution in this code are vectorized according to the "column sweep" method. It is noticed in the results that the factor, whether the substitution is vectorized or not, does not affect the CPU time much. This is because the $O(n^3)$ operation counts in the factorization dominates the $O(n^2)$ operation counts in the substitutions.

The second algorithm is essentially the same as GE algorithm except we introduce the "scaled partial pivoting" strategy. In general, the pivoting should give us a more accurate solutions. Thus, it is useful to investigate the price of a pivoting strategy on the vector machines. In this "scaled partial pivoting" strategy, the bookkeeping is stored in a vector and used later on in the forward substitution. The pivoting is a scalar process, therefore in the PGE program only the factorization and the backward substitution can be vectorized.

The final algorithm is the Cholesky method (LDLT). In this decompositon, $A = LDL^T$ where L is a lower triangular with unit elements and the D is a diagonal matrix with positive elements. To avoid the square root computation is the reason for introducing D matrix. The algorithm is as follows:

```
d(1) = a(1,1)
For  i = 2,-----,n do;
L(i,1) = a(i,1)/d(1)
For  k = 2,-----,n-1 do;
                   k-1
d(k) = a(k,k) -  Σ  d(p)*L(k,p)**2
                   p=1
For  i = k+1,-----,n do;
                      k-1
L(i,k) = (a(i,k) -  Σ  L(i,p)*d(p)*L(k,p))/d(k)
                      p=1
                   k-1
d(n) = a(n,n) -  Σ  L(n,p)**2*d(p)
                   p=1
```

The i loops are again the vectorized loops for both computers.

The operation counts for sequential GE is $n^3/3$ while it is roughly $n^3/6$ for the Cholesky method.

## 3. Computational Results

The speed up of an algorithm is defined here

0190-3918/86/0000/0441 $01.00 © 1986 IEEE

as its the sequential CPU time divided by its vectorized CPU time. The normalized CPU time is defined as the CPU time divided by the order of operation counts (here is $N^3$). All programs were tested on a randomly generated positive definite matrix. Table 1 gives the CPU time (in seconds) for the GE, LDLT and PGE programs on the Cyber-205 and the Cray-1 for different values of N. From Table 1 we can see there is not much difference in the CPU time for the scalar PGE program and the scalar GE program(within 10% difference). The speed up values on the Cray-1 never exceed 10 while the speed up values on the Cyber-205 can be greater than 20 (e.g. the GE algorithm for N = 200).

The speed up factors as functions of the matrix size N for all three algorithms on both vector machines are shown in Figure 1. The GE algorithm has larger speed up compare to the other two algorithms on both computers. This may imply that the GE algorithm has more parallelism in the computations. The GE algorithm in the Cyber-205 especially has the largest speed up values (e.g. maximum speed up of 22.3 for N = 200) except when N is very small. On the Cyber-205, the LDLT has better speed up than the PGE algorithm due to the fact that certain percentage of the code in PGE can not be vectorized. The speed up of the LDLT algorithm is about the same as the speed up of the PGE algorithm in the Cray-1( it ranges from 2 to 5 from small N to large N ). This probably is due to the Cray-1 has better scalar process to handle the pivoting. In general, the Cyber-205 has better speed up than the Cray-1 especially for large N. This means there is a substantial difference in program performance as one change from the scalar environment to the vectorized environment on the Cyber-205. The results are reasonalbe since Cyber-205 favors long vector length for peak performance and its scalar codes do not run as fast as their counterparts on the Cray-1.

Table 1. The CPU time (in seconds) for the vectorized and scalar versions of the GE, PGE and LDLT algorithms on both vector computers. The S columns are the speed up values for the particular algorithm.

| 200 | 1.381 | 0.215 | 6.4 | 0.74 | 0.11 | 6.7 | 1.278 | 0.178 | 7.2 |

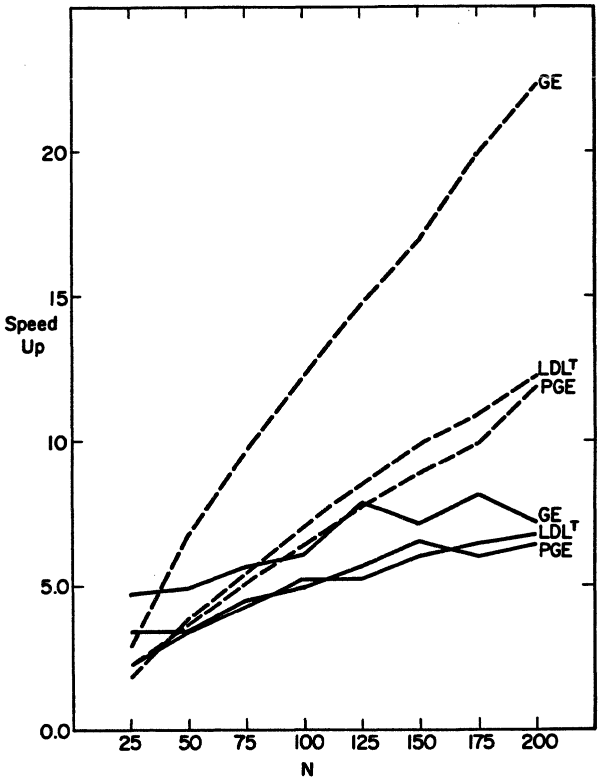

Figure 1. The speed up values as a function of the matrix size N for the GE, PGE and LDLT algorithms on both vector computers. The solid lines are the results from the Cray-1. The dashed lines are the results from the Cyber-205.

Figure 2 illustrtes the normalized CPU time as a function of the matrix size N. The upper four curves are the results of the scalar codes on both computers. The PGE results are so close to the GE results thus not shown here. The scalar LDLT and GE programs run faster on the Cray-1 than on the Cyber-205. The scalar LDLT program runs faster than scalar GE program in both machines. These results are due to better scalar process on the Cray-1 and less operations involed in scalar LDLT program. We also observe from these scalar curves that the Cyber-205 curves reach their asymptotic performance with smaller N compare to the Cray-1 curves. This can be interpreted as the faster reach of Cyber-205's scalar optimal efficiency than the Cray-1.

The bottom six curves the Figure 2 are the results of the normalized CPU time for the vectorized codes on both computers. Non of the testing codes reached its asymptotic performance for the experimental values of N. The vectorized LDLT program runs faster than the vectorized GE program on the Cray-1. On the other hand, the vectorized GE program performs better than vectorized LDLT program on the Cyber-205. Actually the vectorized GE performs best on the Cyber-205 for N greater than 100. The PGE program performs better on Cyber-205 than the PGE program on the Cray-1 only when N is somewhat greater than 100. The bigger size of matrix A provides long length vectors, therefore the performance is increased on the Cyber-205.

In all cases, the computed error norms do not show significance difference from algorithms to algorithms and from machine to machine. If we are to solve a positive definite matrix that is not diagonally dominant, the accuracy then becomes a big concern, and we should use the vectorized PGE program. The pivoting stragtegy is cheap in the scalar environment (shown in Table 1), but is as expensive as the factorization part of the program for larger N in the vectorized environments. The PGE is not recommended to solve a diagonally dominant matrix on the vector machines.

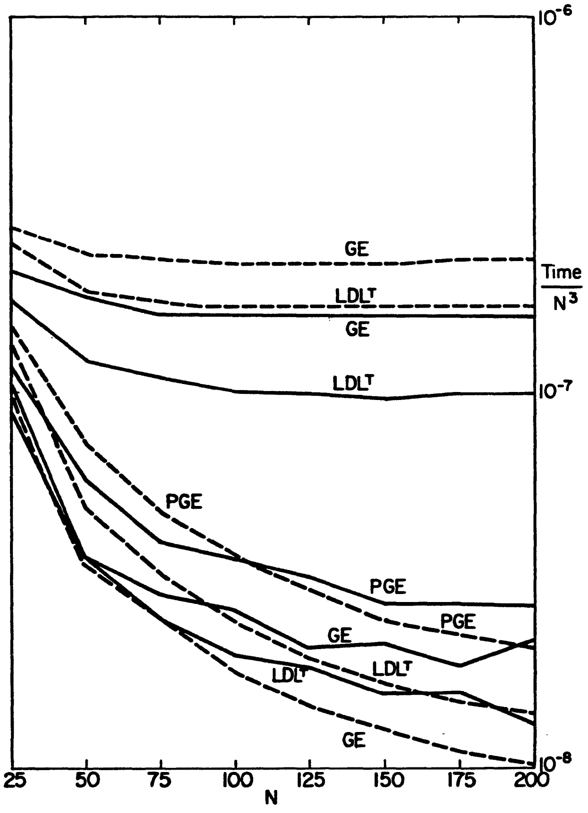

Figure 2. The normalized CPU time (in seconds) as a function of matrix size N on both vector computers. The solid curves are from the Cray-1 while the dashed curves are from the Cyber-205. The upper 4 curves are scalar results while the lower 6 curves are vector results.

## 4. Conclusions

A comparative performance analysis of three different algorithms to solve a positive definite system of linear equations on two vector computers is presented. Our experimental results for vector computers show that the vectorized Gaussian elimination performs best of the three methods on Cyber-205 vector computer, whereas the vectorized Cholesky method is best suited to Cray-1. All the corresponding scalar codes ran faster on Cray-1 than on Cyber-205. On the other hand, the scalar codes reach their optimal asymptotic efficiency with smaller matrix size N on the Cyber-205. In general,the Cyber-205 has better speed up than the Cray-1. The difference in CPU time for scalar PGE and GE programs on both machines were negligible. The price of the pivoting in PGE program can be as expensive as the factorization part of the GE program in the vectorized environment.

# Parallel Approximate Algorithms for the 0-1 Knapsack Problem

**P.S. Gopalakrishnan** †

Department of Computer Science
University of Maryland
College Park, MD. 20742

**Abstract**

Several combinatorial optimization problems are known to be NP-complete. As a consequence, fast parallel algorithms for finding optimal solutions for such problems using a polynomial number of processors are unlikely. An important practical approach to solving such problems on parallel machines is to seek approximate algorithms for them. In this paper, we present an approximate algorithm for the 0-1 knapsack problem on the parallel random access machine model. Our algorithm takes an $\epsilon$, $0 < \epsilon < 1$, as an input parameter and finds a solution such that the ratio of its deviation from the optimal solution is at most $\epsilon$. Our algorithm requires $O(\log^3 n + \log^2 n \log \frac{1}{\epsilon})$ time and uses at most $\frac{n^{2.5}}{\epsilon^{1.5}}$ processors. In contrast to a naive algorithm that requires significantly more processors, our algorithm exploits the relationship among the sets of solutions to the problem generated in the intermediate steps to reduce the number of solutions considered. This in turn results in a reduction in the processor requirements.

## 1. Introduction

There is a growing interest in the design of parallel algorithms for SIMD machines. In particular, the design of SIMD computer algorithms for problems such as sorting, matrix computations, and graph and network computations has received widespread attention. In contrast, very little attention has been paid to designing SIMD computer algorithms for such combinatorially hard problems as knapsack problems, vertex covering, and set covering. In this paper we will describe an approach to the design of parallel algorithms for one such problem, namely, the 0-1 knapsack problem (see Section 2 for definition). This problem is known to be NP-complete [GJ79] and as a consequence, a polynomial time parallel algorithm that finds an optimal solution using a polynomial number of processors is unlikely. An important practical approach to solving such problems has been to design fast algorithms that find approximate instead of optimal solutions. Here we present parallel algorithms for finding approximate solutions to the knapsack problem.

Several approximate algorithms on sequential machines for various NP-complete problems have been reported (see [GJ76] for a bibliography of some early work). Many of these algorithms use a greedy strategy [HS78, Chapter 4]. It has been shown by Anderson and Mayr [AM84] that greedy algorithms for several graph problems are inherently sequential and hence, fast parallel implementations of these sequential algorithms are unlikely. Several approximate algorithms currently known appear to be highly sequential and hence, there is a need to develop new techniques for finding approximate solutions to some of these NP-complete problems on parallel computers.

The model of parallel computation we use here is a parallel random access machine (PRAM) [FW78]. We allow several processors to read from the same location simultaneously. However, simultaneous writing into the same memory location is disallowed. Such a model is usually known as a concurrent read exclusive write (CREW) PRAM. An important goal of research on algorithms for this model has been to design poly-logarithmic time (that is, $O(\log^k n)$ for some k) algorithms. The algorithm reported in this paper finds an approximate solution to the knapsack problem in poly-logarithmic time using a polynomial number of processors. The solution found by our algorithm will be worse than the optimal solution by at most a factor of $\epsilon$, for any given $\epsilon$, $0 < \epsilon < 1$. Our algorithm requires $O(\log^3 n + \log^2 n \log \frac{1}{\epsilon})$ time and at most $\frac{n^{2.5}}{\epsilon^{1.5}}$ processors. A naive algorithm would generate several partial solutions and merge them to obtain the final solution. As explained in Section 3.3, our algorithm exploits the relationship among these partial solutions in order to reduce the number of such solutions to be generated. This leads to a reduction in the processor requirements of our algorithm. The processor bound is established using an interesting combinatorial result.

The only known parallel algorithm for this problem is by Peters and Rudolph [PR84]. Their algorithms achieve speedups using a limited number of processors by exploiting the explicit parallelism in the inner loop of the sequential algorithm of Lawler [LE79]. The divide-and-conquer algorithm presented there uses a simple merging procedure and hence requires substantially more processors compared to our algorithm. Our attempt has been to explore new properties of the problem that can be exploited in the parallel algorithm.

‡ Present Address - Department of Computer Science, SUNY at Stony Brook, Stony Brook, NY. 11794. The work of the second author supported in part by the National Science Foundation under grant number ECS-84-04399 and by the Office of Naval Research under contract N00014-84-K-0530.

The rest of the paper is organized as follows. In the next section we introduce the knapsack problem. In Section 3, we present a parallel approximate algorithm for the 0-1 knapsack problem. The combinatorial result that is made use of in proving the processor bound is also presented in that section. Some concluding remarks are given in section 4. Several implementation details as well as proofs of some theorems are omitted in this preliminary report for the sake of brevity. Proofs of other theorems are sketched briefly. Complete proofs and other implementation details will appear in a forthcoming paper [GRK86]

## 2. The 0-1 Knapsack Problem

The 0-1 knapsack problem is defined as follows. We are given n elements having positive integer valued profits $p_1, p_2, \cdots, p_n$ and positive integer valued weights $w_1, w_2, \cdots, w_n$. We are also given a positive integer valued knapsack capacity K and the optimization problem is to find a set $S \subseteq \{1, 2, ..., n\}$ that maximizes $\sum_{i \in S} p_i$ subject to the constraint $\sum_{i \in S} w_i \leq K$.

We can assume that all the weights are at most equal to the capacity K. Any solution to the knapsack problem is a set of integers which is a subset of the set $\{ 1, 2, ..., n \}$. We will denote the profit of a solution S by P(S) and accumulated weight by W(S). Thus, $P(S) = \sum_{i \in S} p_i$, and $W(S) = \sum_{i \in S} w_i$. S is a *feasible solution* if $W(S) \leq K$. A feasible solution $S^*$ is an optimal solution if $P(S^*) \geq P(S)$ for any other feasible solution S. We denote the profit of an optimal solution by $P^*$. In the rest of the paper the term solution will stand for a feasible solution unless explicitly stated.

An approximate solution to the 0-1 knapsack problem takes as its input a real number $\epsilon$, $0 < \epsilon < 1$, and finds a solution with profit P such that $P^* - P \leq \epsilon P^*$. Several such algorithms on sequential machines have been reported in the past [IK75, LE79, MO81, SS75]. Our aim in this paper is to design such an approximate algorithm on the PRAM model.

## 3. Parallel Approximate Algorithm

In this section we first present a simple parallel algorithm that finds an optimal solution to the problem. However, this algorithm would require an exponential number of processors to find an optimal solution in polynomial time. We then outline a scheme for obtaining an approximate solution in poly logarithmic time using polynomial number of processors. This approximate algorithm is further refined to obtain a more efficient algorithm with reduced processor requirements.

We will use the following notation in the description of the algorithms below. $R_i$, $S_i$, $T_i$, and $U_i$ ($i = 1, 2, ...$) will denote solutions to the knapsack problem and $G_i$, $H_i$ ($i = 1, 2, ...$) will denote sets of solutions. We will also assume, for the sake of simplicity that n is a power of 2.

All our algorithms use the following dominance relation between solutions in order to discard partial solutions.

*Definition*

Let $S_1$ and $S_2$ be two solutions. Then $S_1 < S_2$ ($S_2$ dominates $S_1$) if $P(S_1) \leq P(S_2)$ and $W(S_1) \geq W(S_2)$.

●

Observe that if $S_i < S_j$ and $S_k$ is a solution that is disjoint from both $S_i$ and $S_j$ then $S_i \cup S_k$ will be dominated by $S_j \cup S_k$. Thus, for every feasible solution that can be obtained from $S_i$ by adding more elements, there is another feasible solution that can be obtained from $S_j$ having possibly greater profit. Hence, given any set of feasible solutions, we can remove all solutions from this set that are dominated by other solutions in the same set.

Note that the dominance relation is transitive. Using this property, it is easy to show the following.

**Lemma 3.1:** Let I be a subset of $\{1, 2, ..., n\}$ and let $G_i$ be the set of all feasible solutions that are subsets of I and are not dominated by any other subset of I. Let $S_j$ be any feasible solution that is also a subset of I. Then, either $S_j \in G_i$ or there is a solution $S_k \in G_i$ such that $S_j < S_k$.

●

Let F(i,j) denote the set of all feasible solutions that are subsets of the set $\{i, i+1, ..., j\}$ and are not dominated by any other feasible solution in the same set.

### 3.1. A Simple Exact Parallel Algorithm

Algorithm 1 below is a simple parallel algorithm for finding an exact solution to the 0-1 knapsack problem.

**Algorithm 1**

```
[1]  Call FEASIBLE(1,n) (given below) to find the set F(1,n).

●

**Analysis**

The correctness of the procedure FEASIBLE(i,j) is easy to establish using induction on j–i. Clearly, F(i,j) is correctly set up when i–j = 0. Assume now that FEASIBLE(i,j) returns the set F(i,j) for all values of i–j < n–1. Now, let i–j = n–1. Consider any solution S that is a subset of {i, i+1, ..., j}. Let the intersection of S with {i,..., (i+j)/2} be $S_1$ and its intersection with {(i+j)/2 + 1, ..., j} be $S_2$. Since F(i, ..., (i+j)/2) and F((i+j)/2 + 1, ..., j) are assumed to be correctly computed by the recursive calls, by lemma 3.1, $S_1$ is either present in F(i, ..., (i+j)/2) or there is some solution $S_i$ in that set that dominates $S_1$. In the latter case S will be dominated by $S_i \cup S_2$. A similar argument can be applied to $S_2$. We can thus show that a feasible solution is in the set returned by FEASIBLE(1,n) if and only if it is not dominated by any other solution.

Observe that if two solutions have the same profit value, one of them will be discarded because it will be dominated by the other. Similarly, if two solutions have the same weight, one will be discarded. Thus, there will be at most one solution for each integer value of the profit and for each value of the weight in the set of solutions returned by procedure FEASIBLE. Therefore, there will be at most $c$ solutions in these sets, where $c = \min\{P^*, K\}$.

The recursive procedure FEASIBLE goes through log n stages of recursion. In each stage, step [5] requires O(1) time and $c^2$ processors as we require one processor for each pair of solutions $S_i$, $S_j$ and there are at most $c^2$ such pairs. Step [6] can be executed in O(log $c$) time using $c^2$ processors as removing the dominated solution involves finding the minimum among at most $c^2$ values (details are omitted here). Since the two recursive calls in procedure FEASIBLE are executed in parallel, at most O(n) sets of solutions will be constructed simultaneously. Hence, the total processor requirement for generating the set F(1,n) is n$c^2$ and the time required is O(log nlog $c$). Finding the maximum profit solution from F(1,n) will require O(log $c$) time and $c$ processors and hence the time complexity of Algorithm 1 is O(log nlog $c$) and the processor requirement is n$c^2$.

## 3.2. Approximation Scheme

Since $c$ can be arbitrarily large, the time complexity of Algorithm 1 is not a true logarithmic function of n and the processor requirement is not a true polynomial of n. However, we can scale down the profits [IK75, LE79, SS75] to obtain a bound on $c$ that is a polynomial in n. We divide all the profit values by a scale factor $\lambda$. For the problem with these scaled down profits, the optimal profit cannot be more than $\frac{P^*}{\lambda}$. The scale factor $\lambda$ is chosen to obtain an upper bound on $\frac{P^*}{\lambda}$ that is a polynomial in n. The scale factor is derived as follows.

Let the profits and weights be arranged such that $\frac{p_1}{w_1} \geq \frac{p_2}{w_2} \geq \cdots \geq \frac{p_n}{w_n}$. Now, choose j such that $(w_1 + w_2 + \cdots + w_j) \leq K < (w_1 + w_2 + \cdots + w_j + w_{j+1})$ Let

$$P_0 = \max\{p_1 + p_2 + \cdots + p_j\ ,\ p_m\}, \text{ where } p_m = \max_i\{p_i\}$$

Let $\epsilon$ be the allowed deviation from the optimal solution, $0 < \epsilon < 1$. That is, we are required to find a solution with profit P such that $P^* - P \leq \epsilon P^*$.

**Theorem 3.1:** If the profits are scaled down using a scale factor $\lambda = \epsilon P_0/n$ then an optimal solution to the problem with the scaled profits will be an approximate solution to the original problem satisfying the desired bounds. Moreover, the profit of any solution to the scaled problem will not exceed $2n/\epsilon$.

**Proof:** See [LE79].

A parallel algorithm based on the above derivation is given below.

**Algorithm 2**

[1] Sort the weights and profits into non-increasing order of the ratio $p_i/w_i$.

[2] Compute $P_0$ and scale factor $\lambda$ using the expression given above.

[3] Scale all profits $p_i$ to obtain $r_i = \lfloor p_i/\lambda \rfloor$.

[4] Use Algorithm 1 on the modified problem with profits $(r_1, r_2, \ldots, r_n)$, weights $(w_1, \ldots, w_n)$ and capacity K. Let $P_1$ be the profit of the solution to the modified problem found by Algorithm 1.

[5] The approximate solution to the original problem is the solution found above and its profit P is $\lambda P_1$.

**Complexity**

The sorting step [1] in the above algorithm will require O(log n) time and n processors using the algorithm in [AK83]. To compute $P_0$, we need to find out the integer j such that $w_1 + w_2 + \cdots + w_j \leq K < w_1 + w_2 + \cdots + w_j + w_{j+1}$. Such a j can be found in O(log n) time with n processors. Step [3] requires O(1) time and n processors. Thus the time and processor requirements of Algorithm 2 are dominated by the requirements of step [4]. From the analysis of the complexity of Algorithm 1, it follows that Algorithm 2 requires O(log n.log c) time and n$c^2$ processors. Since $c$ is O(n/$\epsilon$) for the approximate algorithm, the time complexity is $O(\log^2 n + \log n . \log \frac{1}{\epsilon})$ and the number of processors required is $\frac{n^3}{\epsilon^2}$ †.

### 3.3. An Improved Algorithm

We can obtain a more efficient parallel algorithm (in terms of the processor time product) by modifying the merging step used in procedure FEASIBLE of Algorithm 1. This modification, as we shall see later, will increase the time by another factor of (log n) and decrease the worst case processor requirement to $\frac{n^2}{\epsilon}\sqrt{\frac{n}{\epsilon}}$. The processor-time product of the resulting algorithm is significantly smaller. This reduction in the number of processors is significant since the value of $\epsilon$ is usually very small.

Notice that the merging step of procedure FEASIBLE is highly wasteful since, out of the $c^2$ solutions that are generated, at most $c$ are retained. We need not generate several of these solutions if we make effective use of the information from previous stages of the procedure FEASIBLE. Recall that in procedure FEASIBLE(i,j), F(i,j) is computed by first computing F(i,(i+j)/2) and F((i+j)/2 + 1, j) and then merging them. Let $G_1$ denote F(i,(i+j)/2) and let $G_2$ denote F((i+j)/2 + 1, j). Instead of merging $G_1$ and $G_2$ directly by taking the union of every solution from $G_1$ with every solution from $G_2$, we first merge $G_1$ with the two sets that were merged to obtain $G_2$, namely, F((i+j)/2 + 1, 3(i+j)/4) and F(3(i+j)/4 + 1, j). Let $G_3$ and $G_4$ denote F((i+j)/2 + 1, 3(i+j)/4) and F(3(i+j)/4 + 1, j) respectively. Let $H_1$ and $H_2$ denote the result of merging $G_1$ with $G_3$ and $G_4$ respectively. That is, $H_1$ is the set of all feasible solutions that are subsets of the set {i, i+1, ..., (i+j)/2}∪{(i+j)/2 + 1, ..., 3(i+j)/4} and are not dominated by any other feasible solution in the same set. Similarly, $H_2$ is the set of all non-dominated feasible solutions that are subsets of the set {i, i+1, ..., (i+j)/2}∪{3(i+j)/4 + 1, ..., j}. Figure 3.1 shows the relationship among these sets. The reduction in the number of solutions follows from the fact that when $G_1$ is merged with $G_3$ and all dominated solutions are removed, any solution that is discarded will not form part of a non-dominated solution in the set obtained by merging $G_1$ and $G_2$. The same is the case with the solutions that are discarded when merging $G_1$ and $G_4$. This result is proved below.

Each non-empty solution $S_i$ in $G_2$ is either a solution $U_i$ in $G_3$, or a solution $V_j$ from $G_4$, or the solution $U_i \cup V_j$ (where $U_i$ and $V_j$ are non-empty). If $S_i$ is $U_i$, its union with solutions in $G_1$ would already have been determined while computing $H_1$. Similarly, if $S_i$ is $V_j$, its union with the solutions in $G_1$ will be present in $H_2$. So, we need now consider only the solutions $U_i \cup V_j$ in $G_2$.

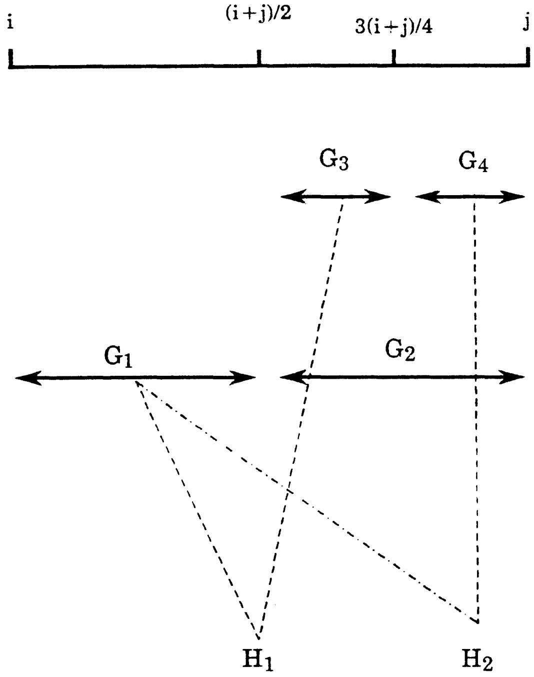

Figure 3.1. Broken lines indicate merging.

Let $f(U_i)$ be the set of solutions from $G_1$ whose union with $U_i$ occurs in $H_1$. That is,

$$f(U_i) = \{R_k \mid R_k \in G_1 \text{ and } U_i \cup R_k \in H_1\} \qquad (3.7)$$

Similarly, let $f(V_j)$ be the set of all solutions from $G_1$ whose union with $V_j$ occurs in $H_2$. That is,

$$f(V_j) = \{R_k \mid R_k \in G_1 \text{ and } V_j \cup R_k \in H_2\} \qquad (3.8)$$

The following lemma is the key to the reduction in the number of solutions generated.

**Lemma 3.2:** Let $S_i$ be $U_i \cup V_j$ and let $R_1$ be a solution in $G_1$ that is not in $f(U_i) \cap f(V_j)$. Then one of the following is true - (1) $S_i \cup R_1 < U_i \cup T_1$ for some $T_1$ in $H_2$, or (2) $S_i \cup R_1 < V_j \cup T_2$ for some $T_2$ in $H_1$.

**Proof:** Let $R_1$ be in $f(U_i)$ and not in $f(V_j)$. This implies that $R_1 \cup V_j$ does not occur in $H_2$. By Lemma 3.1, there is a solution $T_1$ in $H_2$ such that $R_1 \cup V_j < T_1$. Now, $S_i \cup R_1 = U_i \cup V_j \cup R_1 < U_i \cup T_1$, since $T_1$ and $U_i$ are disjoint.

If $S_i \cup R_1$ is a feasible solution then $U_i \cup T_1$ is also a feasible solution. Similarly, if $R_1$ is in $f(V_j)$ and not in $f(U_i)$ then there is a solution $T_2$ in $H_1$ such that $U_i \cup R_1 < T_2$.

†Here we use the property that any algorithm that can be executed in time T(n) using O(p) processor can be executed in O(T(n)) time using p processors.

This implies that $S_i \cup R_1 < V_j \cup T_2$. If $R_1$ belongs to neither $f(U_i)$ nor $f(V_j)$, then both conditions (1) and (2) hold.

●

Lemma 3.2 shows that the union of certain pairs of solutions from $G_1$ and $G_2$ need not be generated. In particular, for every solution $U_i \cup V_j$ in $G_2$, we need generate only its union with every solution in $f(U_i) \cap f(V_j)$. This is implemented by replacing the merging step in procedure FEASIBLE of Algorithm 1 (step [4]) with the following procedure :

```
*procedure* MERGE($G_1$,$G_2$,i,j)
    (* Here $G_2$ is F(i,j) *)
[1] If i=j then merge $G_1$ and $G_2$ by taking the union of
    each element in $G_2$ with every element of $G_1$ in parallel.
    Compute the union of the resulting set with $G_1$ and $G_2$
    and remove all dominated solutions. Return the set thus
    obtained. (* There will be only two solutions in $G_2$ if i=j
    and hence, this step can be executed in O(1) time using
    $c$ processors. *)
    **otherwise**
[2] Let $G_3$ = F(i,(i+j)/2) and $G_4$ = F((i+j)/2 + 1, j). (*
    These are available from the previous stage of procedure
    FEASIBLE. *)
    Call MERGE($G_1$,$G_3$,i,(i+j)/2) to obtain $H_1$
    and in parallel call MERGE($G_1$,$G_4$,(i+j)/2 + 1, j) to
    obtain $H_2$.
[3] For each non-empty solution $S_i \in G_2$ that is of the
    form $U_i \cup V_j$, where $U_i \in G_3$ and $V_j \in G_4$ and $U_i$, $V_j$
    are non-empty, do in parallel -
    Identify the set of solutions $f(U_i) \cap f(V_j)$. Generate the
    solution $S_i \cup R_k$ for each $R_k$ in $f(U_i) \cap f(V_j)$ in parallel.
    If $W(S_i \cup R_k) > K$ then discard this solution, else add
    it to the set of solutions $H_3$
[4] Compute the union of $H_1$, $H_2$, and $H_3$ and remove all
    dominated solutions to obtain $H_4$.
[5] Compute the union of $H_4$, $G_1$, and $G_2$ and remove all
    dominated solutions. Return the resulting set.
```

●

We prove the correctness of the MERGE procedure below.

**Theorem 3.1:** Let $G_1$ be F(k,l) and $G_2$ be F(i,j), where $k \leq l < i \leq j$. Let $H_5$ be the set of solutions generated in step [5] of the procedure call MERGE($G_1$,$G_2$,i,j). Then $H_5$ is the set of all feasible solutions that are subsets of the set $\{k, ..., l\} \cup \{i, ..., j\}$ and are not dominated by any other solution in the same set.

**Sketch of Proof:** We prove the result using induction on (j–i). The base case is correctly handled by step [1]. Let us assume that the recursive calls in step [2] return sets $H_1$ and $H_2$ which contain all the feasible non-dominated solutions that are subsets of the set $\{k, ..., l\} \cup \{i, ..., (i+j)/2\}$ and the set $\{k, ..., l\} \cup \{(i+j)/2 + 1, ..., j\}$ respectively. To show that $H_5$ is the set of all non-dominated solutions that are subsets of $\{k, ..., l\} \cup \{i, ..., j\}$, we have to show that for any feasible solution $S \subseteq \{k, ..., l\} \cup \{i, ..., j\}$, S is in $H_5$ if and only if it is not dominated by some solution $S_1$ in $H_5$.

Since $G_1$ is F(k,l) and $G_2$ is F(i,j), we need concern ourselves only with solutions S of the form $R_1 \cup T_1$, where $R_1$ is in $G_1$ and $T_1$ is in $G_2$.

(I) Sufficiency: We need to show that if $S \notin H_5$ then $S < S_1$ for some $S_1$ in $H_5$.

If $S \notin H_5$ then either S was generated in step [3] and eliminated in steps [4] or [5], or S was not generated in step [3]. If S was generated and eliminated then obviously $S < S_1$ for some $S_1 \in H_5$. Assume now that S was not generated at all. If S is of the form $R_1 \cup T_1$ and $T_1$ is either equal to $U_1$ for some $U_1 \in G_3$, or equal to $V_1$ for some $V_1 \in G_4$ then by the induction hypothesis and lemma 3.1, either S is present in $H_1$ or $H_2$, or $S < S_1$ for some $S_1$ in $H_1$ or $H_2$. Since $H_1$ and $H_2$ are used in step [4], there must be some solution in $H_5$ that dominates S. Now, if S is of the form $T_1 \cup R_1$, and $T_1 = U_1 \cup V_1$ for some $U_1 \in G_3$, $V_1 \in G_4$ then we can show, using Lemma 3.2 that S would be dominated by some solution that is already in $G_2$, $G_1$, $H_1$, or $H_2$, or is generated in step [3].

(II) Necessity: We want to show that if $S < S_1$ for some $S_1$ in $H_5$ then $S \notin H_5$.

This is trivial since all dominated solutions from the solutions that are generated are eliminated in steps [4] and [5].

Thus, the set $H_5$ generated in step [5] is the set of all feasible solutions that are subsets of $\{k, ..., l\} \cup \{i, ..., j\}$ and are not dominated by any other solution in the same set.

●

From Theorem 3.1 it is clear that if procedure MERGE is called with $G_1$ = F(1,n/2) and $G_2$ = F(n/2 + 1, n), then the set of solutions returned would be F(1,n).

**Complexity**

Any call to procedure MERGE will go through (log n) stages at most. Step [1], where the recursion halts, will require O(1) time and $c$ processors. At any instant, at most n/2 simultaneous executions of step [1] may be going on. Thus, this step contributes O(n$c$) to the overall processor requirement. We implement step [3] as follows.

After the sets $H_1$ and $H_2$ have been generated we construct, for each $U_i \in G_3$, the set $f(U_i)$ defined by equation (3.7) using $c$ processors in O(log $c$) time. Also, the total number of solutions in this set is stored along with each $U_i$. A similar computation is done for each $V_j$ in $G_4$. Now, for each $S_i$ in $G_2$ we assign one processor. If $S_i$ is of the form $U_i \cup V_j$ then the processor checks the number of solutions in the sets $f(U_i)$ and $f(V_j)$. The minimum of these two numbers is found and these many processors are assigned to $S_i$. We can use these processors to identify the solutions that are common to $f(U_i)$ and $f(V_j)$ in O(1) time. The solutions $S_i \cup R_k$ are generated for each solution $R_k$ that is in this common set in O(1) time.

The number of processors required for the computation of the solutions $S_i \cup R_k$ is thus $p = \sum_{U_i \cup V_j \in G_2} \min\{$number of solutions in $f(U_i)$, number of solutions in $f(V_j)\}$. Taking into account the number of processors needed for the initial computations on $H_1$ and $H_2$, the total number of processors required for step [3] is $\max(p,c)$ and the time required is $O(\log c)$. Since the two recursive calls in step [2] are executed in parallel, the overall processor requirement of procedure MERGE would be $n(\max\{p,c\})$ and the time required would be $O(\log n . \log c)$.

●

Now, Algorithm 1 is modified by replacing the merging step in procedure FEASIBLE with a call to procedure MERGE. We can now use this modified algorithm to find a solution to the scaled problem and get an approximate solution. The time required by the modified algorithm is given by Theorem 3.2 below.

**Theorem 3.2:** An approximate solution having relative error at most $\epsilon$ can be found using the modified parallel algorithm in time $O(\log^3 n + \log^2 n \log \frac{1}{\epsilon})$.

**Sketch of Proof:** The procedure FEASIBLE goes through (log n) recursive stages. In each stage, the MERGE procedure requires $O(\log n . \log c)$ time. Thus, the time required by procedure FEASIBLE is $O(\log^2 n \log c)$ and this is greater than the time required for the rest of the steps in Algorithm 2. Since $c$ is $O(\frac{n}{\epsilon})$ for the approximate algorithm, the time required is $O(\log^2 n \log \frac{n}{\epsilon})$ which is $O(\log^3 n + \log^2 n \log \frac{1}{\epsilon})$.

●

The worst case processor bound for the modified algorithm is obtained using the following combinatorial result.

Let G be an undirected bipartite graph (A,B,E) where A and B are the sets of vertices and E is the set of undirected edges. Let $a_i$ be a non-negative integer weight associated with each vertex i in A and $b_j$ be a non-negative integer weight associated with each vertex j in B. The edges and weights satisfy the following constraints -

$$|E| \leq c \tag{3.9}$$

$$\sum_{i \in A} a_i \leq c \tag{3.10}$$

$$\sum_{j \in B} b_j \leq c \tag{3.11}$$

**Theorem 3.3:** For any bipartite graph G and set of weights satisfying constraints (3.9), (3.10), and (3.11), the sum $M = \sum_{(i,j) \in E} \min\{a_i, b_j\}$ is at most $c\sqrt{c}$.

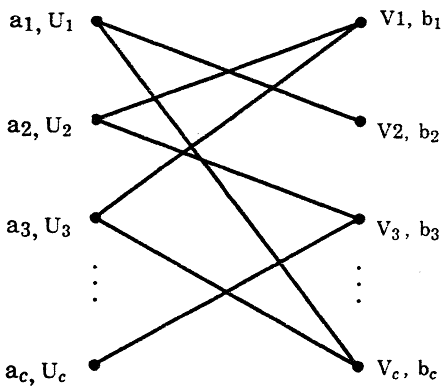
**Sketch of Proof:** The result is proved by showing that given any bipartite graph and set of weights satisfying constraints (3.9) - (3.11), we can transform the graph into a standard graph by applying a series of transformations, each of which increases the value M, or at worst, leaves M unchanged. This standard structure will be an almost complete bipartite graph having close to $\sqrt{c}$ vertices on both sides and nearly equal weights on the vertices. The value of M cannot be increased above the value obtained for this structure. The value of M for this graph can be shown to be at most $c\sqrt{c}$.

●

**Theorem 3.4:** Algorithm 2 using the modified merging procedure requires $\frac{n^{2.5}}{\epsilon^{1.5}}$ processpors.

**Proof:** From the complexity analysis of procedure MERGE, we see that this procedure requires $n.(\max\{p,c\})$ processors, where $p = \sum_{U_i \cup V_j \in G_2} \min\{$number of solutions in $f(U_i)$, number of solutions in $f(V_j)\}$, and $c$ is $O(\frac{n}{\epsilon})$. The processor requirement of Algorithm 2 is dominated by the requirement of procedure MERGE. Theorem 3.3 can be used to determine p. We define a bipartite graph associated with the set $G_2$. The vertices of this graph correspond to each $U_i$ in $G_3$ and each $V_j$ in $G_4$. An edge between vertices $U_i$ and $V_j$ is present in this graph if the solution $U_i \cup V_j$ is present in $G_2$. The weight associated with $U_i$ is the number of solutions in $f(U_i)$, where $f(U_i)$ is defined by equation (3.7). Similarly, the weight associated with $V_j$ is the number of solution in $f(V_j)$, where $f(V_j)$ is defined by equation (3.8) (see Fig 3.2). There are at most $c$ elements in $G_2$ and hence the number of edges in this graph is at most $c$. This satisfies constraint (3.9). The sum of weights on all the $U_i$ is at most equal to the number of solutions in the set $H_1$ which is less than or equal to $c$. This shows that constraint (3.10) is satisfied. The sum of weights on all the $V_j$ is at most equal to the number of solutions in $H_2$ which is at most $c$. Thus all three constraints are satisfied. Applying Theorem 3.3, we see that p, which is $\sum_{U_i \cup V_j \in G_2} \min\{$number of solutions in $f(U_i)$, number of solutions in $f(V_j)\}$, is at most $c\sqrt{c}$.

Thus, the total processor requirement is at most $nc\sqrt{c}$. Since $c$ is at most $2n/\epsilon$ for the approximate algorithm, the total processor requirement is $O(\frac{n^{2.5}}{\epsilon^{1.5}})$. Using the property that any algorithm that runs in time t using O(p) processors can be executed in O(t) time using p processors, we see that the processor requirement for Algorithm 2 is at most $\frac{n^{2.5}}{\epsilon^{1.5}}$.



Edge $(U_i, V_j)$ => $U_i \cup V_j$ occurs in $G_2$

$a_i = \| f(U_i) \|$

$b_j = \| f(V_j) \|$

Fig 3.2. Construction for proof of processor bound.

●

We have thus shown that using a parallel algorithm we can find an approximate solution to the given knapsack problem whose profit P is related to the profit $P^*$ of the optimal solution by the inequality $P^* - P \leq \epsilon P^*$. The time required by the parallel algorithm is $O(\log^3 n + \log^2 n \log \frac{1}{\epsilon})$ and the number of processors required is at most $\frac{n^{2.5}}{\epsilon^{1.5}}$.

## 4. Conclusions

In this paper, we have presented an approximate algorithm for the 0-1 knapsack problem on the CREW PRAM model. Our algorithm takes an $\epsilon$, $0 < \epsilon < 1$, as an input parameter and finds a solution such that the ratio of its deviation from the optimal solution is at most $\epsilon$. Our algorithm requires $O(\log^3 n + \log^2 n \log \frac{1}{\epsilon})$ time and uses at most $\frac{n^{2.5}}{\epsilon^{1.5}}$ processors. In contrast to a naive algorithm that requires significantly more processors, our algorithm exploits the relationship among the partial solutions to reduce the number of such solutions to be generated. This in turn results in reductions in the processor requirements. (Notice that the divide-and-conquer algorithm presented in [PR84] has, in fact, the same processor and time bounds as the algorithm described in section 3.2 and hence is less efficient compared to the algorithm presented in section 3.3.)

Although the worst case processor requirement of our algorithm is $\frac{n^{2.5}}{\epsilon^{1.5}}$, we strongly conjecture that on an average our algorithm would only require $O(\frac{n^2}{\epsilon})$ processors. It will be interesting to analytically establish an average case processor bound.

The approach we have adopted in our algorithm is general enough to solve several other problems that can be formulated along similar lines as the knapsack problem (details will appear in a forthcoming paper [GRK86]).

## ABSTRACT

Parallel architectures, based on the *two dimensional shuffle exchange (2DSE) network*, to solve a class of quadtree problems are presented. The quadtree problems are those can be solved by using quadtree as data structure. The 2DSE approach enables us to have a spectrum of functionally equivalent configurations, which use different number of processors and have different time complexities. The various configurations give us more choices to best-fit to the constraints of real world applications.

## 1. INTRODUCTION

The quadtree is a well known data structure in the areas of computer vision and image processing. It has been used for the algorithms for computing geometric properties such as areas and moment [1], perimeter [2], Euler number [3], and distance transform [4]. In addition, it has been used in digital image processing applications such as edge enhancement [5], image segmentation [6], smoothing [7], shape approximation [8] *et al.* For a tutorial on quadtree, see [9]. However, the quadtree approach we adopt, is how the quadtree manipulates data rather than a data compression scheme for image storing. Hardware architectures for solving similar problem can be found in the papers [10,11,12,13]. The distinctions between our approach and the previous ones are listed as follows.

(1) Versatility of the architecture: The architectures, which are used to solve the quadtree problems in this paper, can also be applied to tackle a class of two dimensional problems such as 2DFFT. For more details see [14]. The versatility of the architecture give us valuable tools to investigate more complicated vision functions, and construct more advanced vision systems.

(2) Various configurations for real world applications: The 2DSE approach enables us to have a spectrum of functionally equivalent configurations, which use different number of processors and have different time complexities. The various configurations give us more choices to best-fit to the constraints of real world applications.

(3) Common communication lines: All of the algorithms in this paper, plus a class of two dimensional algorithms, utilize the same set of lines among processors. This makes the 2DSE approach more economically feasible.

## 2. 1DSE AND 2DSE NETWORK

One-dimensional shuffle exchange (1DSE) network can perform the shuffle, unshuffle, exchange, and broadcast operations. A shuffle operation moves the data at the address **x** to the output address $\mathbf{S_1(x)}$, where $\mathbf{S_1(x)}$ is defined as follows:

$$\mathbf{S_1(x)} =$$
$$(2x \text{ MOD } N) + 1 \qquad \text{if } x \ge \frac{N}{2}$$
$$2x \text{ MOD } N \qquad \text{if } 0 \le x < \frac{N}{2}.$$

An unshuffle operation $U_1$ perform the function inverse to the shuffle operation. Where $\mathbf{U_1(x)}$ is defined as follows:

$$\mathbf{U_1(x)} =$$
$$\frac{x}{2} \qquad \text{if x is an even number.}$$
$$\frac{x+N-1}{2} \qquad \text{if x is an odd number.}$$

The exchange operation is defined by $\mathbf{E(x)}$ as follows:

$$\mathbf{E_1(x)} = x_{n-1}\,2^{n-1} + \ldots.. + x_1 2 + \bar{x}_0.$$

The broadcast operation is defined by $\mathbf{B_1(x)}$ as a mapping from **x** to two positions $x_{n-1}\,2^{n-1} + \ldots.. + x_1 2 + x_0$ and $x_{n-1}\,2^{n-1} + \ldots.. + x_1 2 + \bar{x}_0$.

A two-dimensional shuffle exchange network can perform the two dimensional shuffle, unshuffle, exchange, and broadcast operations. A two-dimensional (2D) shuffle operation $S_2$ and unshuffle operation $U_2$ move the data at the address **(x,y)** to the output address $\mathbf{S_2(x,y)}$, and $\mathbf{U_2(x,y)}$. Where $S_2(x,y)$ is defined as follows:

$$\mathbf{S_2(x,y)} = (\mathbf{S_1(x)}, \mathbf{S_1(y)}) \tag{2.1}$$

$$\mathbf{U_2(x,y)} = (\mathbf{U_1(x)}, \mathbf{U_1(y)}) \tag{2.2}$$

An 2D exchange element is a switch, with four inputs and four outputs, which can perform all kinds of interchanges of four inputs (*i.e.* it is equivalent to a 4x4 crossbar network).

The 2D broadcast operation is defined by $\mathbf{B_2(x,y)}$ as a mapping from **x** to four positions, which are the same as the inputs of the 2D exchange elements.

## 3. MATHEMATICAL DERIVATION

Due to the space limitation, we use two examples, area and centroid computation, to demonstrate the applicability of 2DSE architectures on the quadtree problems.

### 3.1. Area Calculation

The area of a image is defined as

$$A = \sum_{x=0}^{N-1}\sum_{y=0}^{N-1} f(x,y) \tag{3.1}$$

where f(x,y)=1 if the pixel at (x,y) is black.
=0 otherwise, $0 \le x,y \le$ N-1.

$$x = x_{m-1}2^{m-1} + x_{m-2}2^{m-2} + \ldots\, x_1 2 + x_0$$

$$y = y_{m-1}2^{m-1} + y_{m-2}2^{m-2} + \ldots\, y_1 2 + y_0$$

The equation (3.1) can be denoted by the following binary representation:

$$A = \sum_{x_{m-1}}\sum_{y_{m-1}} \cdots \sum_{x_0}\sum_{y_0} f(x_{m-1}, y_{m-1}, \ldots, x_0, y_0) \tag{3.2}$$

The area can be computed in m steps, where m is equal to logN. The area computation results of the first stage can be calculated by equation (3.3) and saved in buffers $B_1$. $B_i$, which saves the computation results of the *i-th* stage, is a two dimensional array of registers denoted by indices x and y. $B_0$ saves the digitized image at the initial state.

$$B_1(x_{m-1}, y_{m-1}, x_{m-2}, y_{m-2}, \ldots x_1, y_1, 0, 0) =$$

0190-3918/86/0000/0452 $01.00 © 1986 IEEE

$$\sum_{x_0}\sum_{y_0} f(x_{m-1},y_{m-1},\dots,x_0,y_0) \tag{3.3}$$

Similarly, the area in the s-th stage is computed by the equation (3.4) and saved in buffer $B_s$.

$$B_s(x_{m-1},y_{m-1},\dots x_s,y_s,0,0,\dots,0,0,0.0) =$$

$$\sum_{x_{s-1}}\sum_{y_{s-1}} B_{s-1}(x_{m-1},y_{m-1},\dots x_{s\ 1},y_{s\ 1},0,0,\dots,0,0)$$

$$\text{for } s = 2, 3\dots. m. \tag{3.4}$$

The m-th stage area computations, which represent the total area of the image, are saved in the buffer $B_m(0,0)$.

### 3.2. Centroid Computation

The centroid of a image is defined as

$$(x_{center}\hat{\imath}+y_{center}\hat{\jmath}) = \frac{1}{A}\sum_x\sum_y(xf(x,y)\hat{\imath}+yf(x,y)\hat{\jmath}) \tag{3.5}$$

where A is equal to the area of the image.

The results in the s-th stage is computed by the equation (3.6), and saved in buffers, $A_s$, $B_{x,s}$, and $B_{y,s}$.

$$B_{x,s}\ (\ x_{m-1},y_{m-1},\dots x_{s-2},y_{s-2},x_{s-1},y_{s-1},0,0,0,0,\dots,0,0\ ) =$$

$$\sum_{x_{s-1}}\sum_{y_{s-1}} B_{x,s-1}\ (\ x_{m-1},y_{m-1},\dots x_{s-1},y_{s-1},0,0,\dots,0,0\ ) +$$

$$\sum_{x_{s-1}}\sum_{y_{s-1}} x_{s-1}2^{s-1}A_{s-1}\ (\ x_{m-1},y_{m-1},\dots x_{s-1},y_{s-1},0,0,\dots,0,0\ ) \tag{3.6}$$

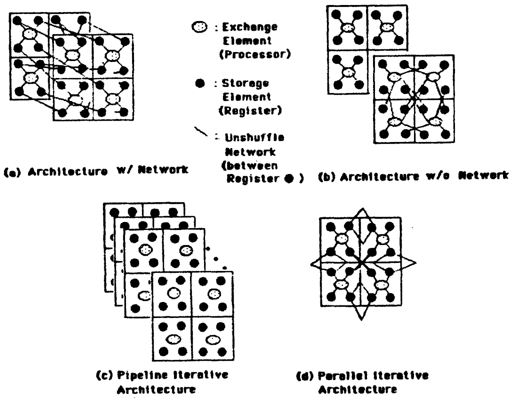
Where A are functionally the same as B, which are defined in equations (3.3) and (3.4). The $B_{y,s}$ can be obtained by changing the the variable x to y in equation (3.6).

The centroid of an image can be obtained by equation (3.7) and (3.8).

$$x_{center} = \frac{B_{x,m}(0,0)}{A_m(0,0)} \tag{3.7}$$

$$y_{center} = \frac{B_{y,m}(0,0)}{A_m(0,0)} \tag{3.8}$$

## 4. ARCHITECTURES AND ALGORITHMS



: Exchange Element (Processor)
: Storage Element (Register)
: Unshuffle Network (between Register ● )
(a) Architecture w/ Network
(b) Architecture w/o Network
(c) Pipeline Iterative Architecture
(d) Parallel Iterative Architecture

Figure 1: 2D Architectures

Figure 1 illustrate the architectures that can solve the quadtree problems with maximal parallelism based on 2DSE network. The black nodes in Figure 1 represent storage elements. Use centroid computation as example, these nodes stand for the places where the values of $B_x$, $B_y$, and A are stored. The dotted nodes represent exchange elements (*i. e.* processors) where all the computations are executed. In the case of centroid computation, these nodes executed the operations shown in equation (3.6).

Part (c) and (d) of Figure 1 show the two different ways: iteratively pipeline and iteratively parallel, to integrate processors into a working system.

Architectures in part (a) and (b) are functionally equivalent. The only difference is: in part (a), the window size of exchange elements is a constant one, but the size doubles when stage advances in part (b). Where the window size of exchange elements are defined as the index distance between any accessed data inputed to the exchange elements. The role of the 2DSE network is to unshuffle the data so that the window size of exchange elements can remain the same. Two dimensional input and output is the common characteristics and necessary requirement of the 2D architecture shown in the Figure 1.

The summation mechanism $SUM_2^i$, are exchange elements difined to executed the operations in the equation (3.3), with window size $2^i$, where i is the stage number. The function sums up the value from four subdived quadrants, is used in both the area calculation and centroid computation.

The centroid computation mechanism $CENX_2^i$, and $CENY_2^i$, are exchange elements defined to execute the operations shown in the equation (3.6) with window size $2^i$. Thus, the centroid of the image can be computed with time complexity of O(logN) by the architecture shown in Figure (1.b). Where N is equal to the number $2^m$, which is the number of pixels in the x or y direction.

We have the following algorithm:

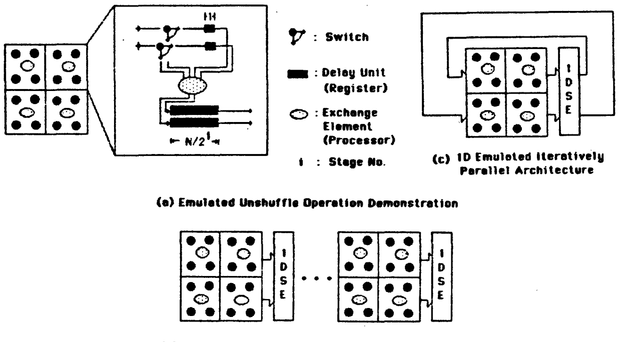
```
line Procedure CENTROID-b (A,$B_x$, $B_y$)
     //centroid computation in architecture (1.b)//
     for i = 1 to logN do
       begin
         for n1, n2 = 0 to N-1
           cobegin
             A[n1,n2] = ($SUM_2^i$A[n1,n2])
             //do summation with window size $2^i$ /
             $B_x$[n1,n2] = ($CENX_2^i B_x$[n1,n2,)
             //do center-x with window size $2^i$/,
             $B_y$[n1,n2] = ($CENY_2^i B_y$[n1,n2])
             //do center-y with window size $2^i$//
           coend
        end.
```

The role of 2DSE network (*i.e. unshuffle*) can be used to access data that have the window size doubled when stage advances. Thus the centroid computation can be mapped into a 2DSE architecture (*i.e.* Figure (1.a)) with time complexity O(logN). The mechanism $SUM_2$, $CENX_2$, and $CENY_2$ are exchange elements with widow size fixed as *two*.

The following procedure CENTROID-a is a parallel algorithm based on the architecture in Figure (1.a).

```
line Procedure CENTROID-a (A,$B_x$, $B_y$)
     //centroid computation in architecture (1.a)//
     for i = 1 to logN do
       begin
         for n1, n2 = 0 to N-1
           cobegin
             A[n1,n2] = {$U_2$($SUM_2$A[n1,n2])}
             //do summation and unshuffle the results//
             $B_x$[n1,n2] = {$U_2$($CENX_2${$B_x$[n1,n2]})}
             //do center-x and unshuffle the results//
             $B_y$[n1,n2] = {$U_2$($CENY_2${$B_y$[n1,n2]})}
             //do center-y and unshuffle the results//
           coend
        end.
```

In 1983, Liu proposed a way to emulate the 2DSE network so that he can implement the 2DFFT computation in VLSI [15]. His scheme takes advantage of the separability property formulated in the equation (2.1) of the 2D shuffle operation. The delay units, in his paper, are used to emulate the x direction of the shuffle operation. By modifying of his scheme, the emulated 2D architectures, which are shown in Figure 2, are obtained.



(c) 1D Emulated Iteratively Parallel Architecture

(a) Emulated Unshuffle Operation Demonstration

(b) 1D Emulated Iteratively Pipeline Architecture

Figure 2: 1D emulated Architectures

Part (a) of Figure 2 illustrates the architecture that emulates the 2D unshuffle operation. Part (b) and (c) show the iteratively pipeline and parallel fashion of the 1D emulated architecture.

Table 1 summarizes the results of the quadtree problems we solved by using 2DSE pipelined (*i.e* part (c) in Figure 1) and 2D emulated architecture (*i.e.* part (b) in Figure 2).

The detail algorithms for all these quadtree problems can be found in [16].

| | ARCHITECTURE 1<br>2DSE PIPELINE | | ARCHTECTURE 2<br>1D PIPELINE | |

Table 1 Summarized Results

The various functionally equivalent architectures enable us to best-fit to the requirements of real world constraints.

## 5. CONCLUSIONS

In this paper, parallel processing for quadtree problems based on 2DSE network is discussed. Various architectures such as 2D iteratively pipelined, iteratively parallel, 1D pipelined *et al* can be used to solve the quadtree problems with different performance constraints (*i.e.* processor numbers and time complexity). The results of the 2DSE approach toward the quadtree problems are listed in Table 1. It includes many primitive operations of computer vision. Besides the quadtree problems, the 2DSE network had been applied to efficiently solve a class of two dimensional problems such as 2DFFT, 2D Walsh/Hadamard transform, and 2D sorting [14]. Thus, the same architectures can be used for a broad range of applications. This makes the 2DSE approach more economical feasible.

# A Feasibility Study and Simulation of the Circulating Context Multiprocessor (CCMP)

Clinton A. Staley    Steven E. Butner

**Department of Electrical & Computer Engineering**
**University of California – Santa Barbara**
**Santa Barbara, CA 93106**

## Abstract

This paper discusses the design and preliminary performance evaluation of the Circulating Context Multiprocessor (CCMP) -- a novel form of tightly coupled multiprocessor that combines significant positive features of modern computer structures and organizations while avoiding many of the negative ones. The CCMP consists of banks of special-purpose processors joined by full interconnection nets with queue-buffering. Each bank contains processors which perform one portion of the traditional Von Neumann cycle. Processes are represented by packets of information circulating among these banks and being modified by them. Many processes are active at once, being executed in an instruction-interleaved fashion. The structure inherently supports load balancing, high degrees of pipelining, efficient context switching, and modular reconfiguration. It appears to the software designer, however, to be simply a parallel computer with many Von Neumann processors sharing a memory.

**Keywords:** MIMD computer architecture, parallel computers, interleaved instruction streams.

## I. Introduction

The circulating context machine organization was first proposed in 1984 [1]. Since that time a great deal of feasibility study, simulation, and further development of the architecture has occurred. This paper reports on our current circulating context multi-processor (CCMP) architecture, its basis, strengths, weaknesses, and simulated performance. Additional material on the CCMP architecture can be found in [2].

The origins of CCMP are based on a collection of existing modern computer structures. The CCMP organization pulls together and adapts known successful concepts and structures from other designs while carefully avoiding most of the observed weaknesses of these concepts. Overall, it is an adaptation of ideas that make sense together. The list below capsulizes the design concepts and their origins.

- **Packets of executable context** --- from the dataflow (activation by availability) model [3]. The use of such packets facilitates streaming-type high throughput ... high-efficiency use of processing resources. Other problematical areas of dataflow, such as the need for a different model of computation, are avoided.

- **Von Neumann model** --- By utilizing this well-known computational model we do not require major investments for development in languages, compilers, linkers, debuggers and the like. Non-Von Neumann systems (such as data flow) will certainly require major development in these areas.

- **Queues with multiple server processors** --- from transaction systems (e.g. Pluribus [4]). The use of first-in, first-out queues as front-end staging for multiple identical servers (processing units) decouples hard synchronization, provides smoothed packet flow, and facilitates higher system availability.

- **Interleaved instruction streams** --- from modern pipelined systems [5,6,7]. By circulating process packets for many independent processes simultaneously, we can ensure (given sufficient workload) that processing units are kept busy, thus achieving very high utilization.

- **Redundancy management and reconfiguration** --- from fault-tolerant systems [8,9]. The presence of multiple copies of identical processing units within a system with full interconnection implemented among them allows immediate replacement of failing units --- giving a very robust and highly available organization.

The architectural concepts above are brought together to form the circulating context multiprocessor. The system makes a deliberate trade-off of increased instruction execution time for each individual process in exchange for overall system throughput and flexibility in adapting the machine to many differing types of parallel processing.

The motivations for the latency-for-throughput trade-off are several. In order to implement Von Neumann style computing, pipelining, and transaction-style dataflow in the same machine, a ring of processing stages is used. When parallel units are added, along with queueing to decouple and smooth packet flow, the trade-off becomes clear. The trade-off is necessary in order to get a clean, unidirectional processing loop structure with scalability, high-availability and other positive properties. The structure and connectivity of the resulting system inherently support "hot sparing", a type of redundancy that is among the quickest and easiest to reconfigure. The CCMP does not really treat "spares" as extra units --- instead such units are actively used to increase throughput. When failures occur and some units start to stand-in for downed companions, the system gracefully degrades in performance.

0190-3918/86/0000/0455 $01.00 © 1986 IEEE

By using queues to stage work packets for each set of processor servers, high utilization of pipelines is possible. The use of instruction stream interleaving guarantees that no dependencies will exist within pipelines and hence that no pipeline breaks will occur. Full pipelines imply maximized throughput. In a heavily pipelined system, throughput is directly linked to system clock rate. With the latency-for-throughput trade-off in effect, we will expand (within reason) the number of pipeline stages that are used to accomplish a given bit of processing if it helps in increasing the main clock rate.

The programming of CCMP is not vastly different from the programming of a conventional uni-processor. The CCMP offers flexible parallelism providing a high-throughput easily-sharable computing resource. For appropriately decomposable problems, the CCMP can take advantage of a significant degree of parallelism, particularly if the problem can be subdivided into co-operating but largely independent processes.

The machine does not have hard architectural size limits as are typical of SIMD machines with fixed vector lengths. The CCMP is first and foremost a throughput engine. The more it is loaded, the more it will deliver. Section 4 presents detailed simulation results which show linear throughput per process until roughly 80% efficiency is achieved. The CCMP can achieve streaming mode execution as is the goal of activation-by-availability (dataflow). However, the CCMP requires no changes to the model of computation.

On the negative side, the trade-off of per-process latency for system throughput implies that single stream performance will never be much better than that of a microcomputer. Thus, tasks will little parallelism will run relatively slowly. This roughly corresponds to non-vectorized segments of programs on SIMD machines. One important difference in the CCMP case, however, is that the unused portion of the machine (corresponding to the wasted vector register lengths in an SIMD machine) is available for use by other simultaneously-executing processes. The CCMP architecture allows full sharing of all resources so that users with low parallelism tasks get fixed, but relatively low performance while highly parallel ones can simultaneously get a significant percentage of system resources.

### Previous Work

As is apparent from the introduction, the ideas upon which the CCMP is based are not new. What is new is the combination and adaptation of those ideas in the present form ... culminating in a feasible, scalable, flexible multiprocessing system. There are several descriptions in the literature that document both proposed and constructed systems using some of the same ideas. In the area of interleaved instruction streams, the work of Miller [10] and of Kaminsky & Davidson [6] must be acknowledged. Other important related work is [5]. The positive effect of queued decoupling between various parts of a processor was discussed in [11].

The closest system to the CCMP is unquestionably the heterogeneous element processor (HEP) [7] [16]. This machine bears a resemblance to the CCMP although some of the CCMP's most important features are not present in the HEP. CCMP processes may visit any execution processor, a property that aids in systemwide load balancing. Interconnection networks in the CCMP are global and buffered, making the organization more homogeneous and thus both more flexible and more available. The CCMP memory is variably interleaved (as seen by the home module). This allows programs to create special memory layouts so that they can efficiently fit special meshes or algorithms to get added parallelism.

## II. Current CCMP Design

Here we discuss a refined CCMP design based on the concepts already discussed.

### Stage Division

The CCMP divides the Von Neumann cycle into portions, with a stage of processors handling each portion. The exact division used is a design parameter. Our current design uses three stages. Each of them is discussed below. Figure 1 provides an overview of the structure of the design, with the three stages linked by several interconnection networks through which packets of process context flow from stage to stage.

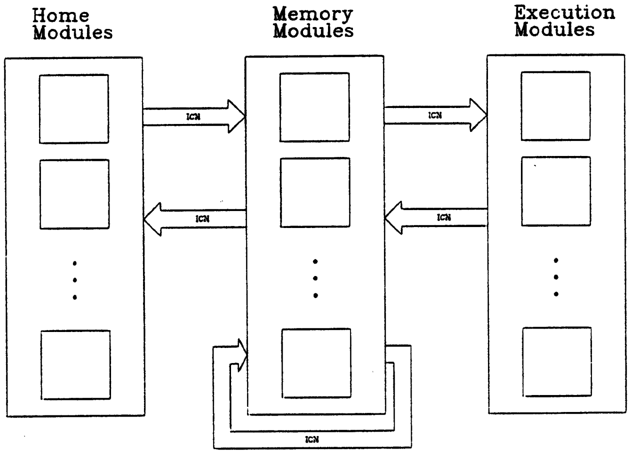

**Figure 1: Overview of the CCMP**

The first stage is the "home" stage which performs process specific functions such as updating the PC, delivering interrupts to a process, performing register fetch/store operations, and using segmentation registers to translate virtual addresses to physical addresses. The home processors in this stage are so called because a given process is always served by the same home processor -- it "returns home" to the same point in this stage. Note that we have departed from the pure CCMP concept here in that a good deal of the process' context remains in the home stage, instead of being transmitted about via the process packet. This was deemed necessary to avoid an unacceptable overhead in transmission costs, especially since most of this data is used only occasionally. The current instruction, the data on which we are immediately working, and a unique process ID number are the only contents of the process packet in our current design. Given the decision to hold some of the process context in a fixed stage, the necessity for that stage to have the "return home" property is obvious, since replicating each process' context in each processor of the stage would restrict the degree of parallelism possible, and result in data concurrency problems among the processors in the stage.

The next stage is the memory stage, "smart memory banks" capable of performing variable length instruction fetches, executing synchronization primitives like test-and-set and possibly maintaining private caches. Note that the memory stage to memory stage interconnect shown in figure 1 allows processes to visit several memory processors in sequence to fetch or store data without going to any other stage in the interim.

The memory stage constitutes a shared global memory accessible to all processes, but has no inherent interleaving policy. Memory segmentation is performed in the home stage, since performing it in the memory stage would require replication of segmentation information for each process in every memory processor. A few extra bits in the home processor segmentation registers can allow variable specification of interleave on a per-segment basis without any action on the part of the memory processors. The memory processors will use a standard physical address, the bits of which can be derived in any manner from the virtual address by the home processor to cause a segment to be low, high or even mid-order interleaved. This allows for more flexibility in load balancing of the memories and is essential to the high availability schemes discussed later. Variable interleaving can cause complex overlap problems between segments in physical memory -- it is assumed that any operating system for the CCMP will either plan for and prevent such overlaps (unless they are desired), or simply use a standard interleave policy for all segments.

The final stage in the design is the execution stage, which performs all arithmetic or logical operations demanded by the instructions. Each processor in the stage is identical -- we chose not to specialize them to avoid problems with tasks that make skewed use of operations and might load only a subset of the processors. Any process, then, may visit any execution processor to have an operation performed on data that it has fetched. Processes are sent to non-overloaded processors in a round robin fashion. Overloaded processors receive no new processes until they become free; then they join the round-robin.

As an example to clarify the above, we trace a process packet through a typical instruction. The instruction begins with the packet at its home processor, where its PC is fetched and translated to a physical address that is placed in the process packet. The packet then goes to the appropriate memory processor where the contents of the instruction are fetched. It returns to the home processor, where any register fetches required by the instruction are performed. If memory data fetches are required, the home processor determines the physical addresses involved and the process packet returns to the memory stage, travelling to the memory(ies) where the data to be fetched resides. Data stores can be done at this point also. For instance, a memory-to-memory data transfer can be done without returning to the home. If arithmetic or logical operations are required, the process travels from the memory stage to the execution stage. If memory stores are required after an execution processor completes the operation, the process returns to the memory stage, and then finally returns home where any register stores needed are performed and the next instruction begins.

## Interconnection Networks

We have said nothing in detail thus far about the interconnection networks. ~~There are a lot of them as the reader~~ can see from Figure 1. This set of networks was derived from an examination of the likely stage-to-stage transfers in a typical instruction set. As one would expect, the design of these interconnects is critical to the success of the CCMP. For large scale parallelism --- more than around 40 processors per stage --- we currently intend to use a single stage cube connection (see [14]). We feel that the cube connection is superior to the shuffle exchange or one of its relatives for this application. The cube connection allows for fewer transfers between nodes on the average. This is generally offset by the cost of a larger number of interconnections per node. In our case, however, we are designing to optimize the use of the hardware, coming as close as feasible to saturating the network with a continuous flow of data, rather than attempting to guarantee some short delivery time to occasional individual messages. For this discussion, let us assume that the clock speeds of sending and receiving modules are the same as that of the interconnection lines, and that bandwidth is measured in bits per clock. Assuming full utilization of bandwidth, (with $n$ the bandwidth per incoming line and $p$ the degree of parallelism) our choice is between shuffle nodes with internode bandwidths of $n \log_2 p$ on each of two internode lines and cube nodes with internode bandwidths of $n$ on each of $\log_2 p$ internode lines. We obtain a 50% reduction in internode bandwidth with the cube interconnect, paying only the price of dividing the internode lines more finely. This comparison is discussed in more detail in [12].

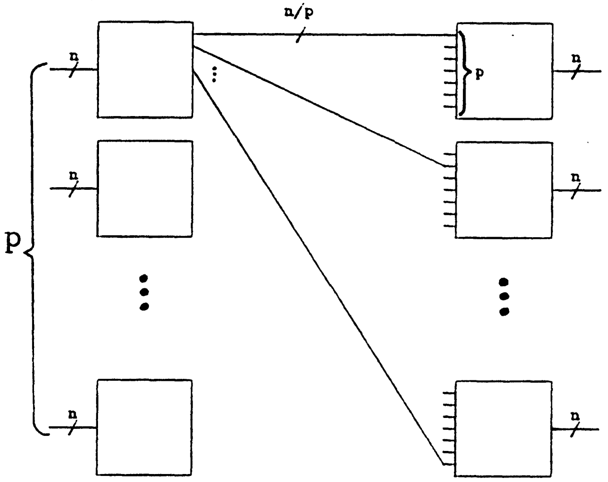

**Figure 2: Modified Crossbar Interconnection Network**

Let us assume that the transmission time of an individual packet is not at issue, and concern ourselves only with meeting the overall bandwidth requirements of the stage-to-stage interconnection with a minimum of physical interconnect. Assuming a packet has $n$ bits and that a fully utilized module delivers one packet per clock, we see that the actual bandwidth required is only $np$ and that both of the above networks use a factor of $\log_2 p$ too much bandwidth. We can remove this factor by using a modified crossbar interconnect as shown in Figure 2. Each sending node has an outgoing bandwidth divided evenly among all receiving nodes (simultaneous transmission is assumed). The same bandwidth can be divided more finely for higher degrees of parallelism, serializing the transmission of individual processes to accommodate the lower individual bandwidths. The cost of such division is that each packet is delivered more slowly, and somewhat more queueing is required to buffer packets prior to delivery. More complex switching is also required in the sending and receiving units. The tradeoffs between this approach and the cube interconnect are shown in the complexity analyses of table 1.

Two terms that may require elaboration are the $O(p^2)$ and $O(\frac{1}{p})$ figures for number of processes and per-process throughput in the bipartite (crossbar) case. Although the overall throughput of the modified crossbar is equal to that of the cube interconnect, the speed of transmission through the interconnect drops for an individual process in inverse

**Table 1: Complexity Analysis of Candidate ICNs for the CCMP**

| Resource | Modified Crossbar Interconnect | Cube Interconnect |
|---|---|---|
| Throughput | $O(p)$ | $O(p)$ |
| Interconnect Bandwidth | $O(p)$ | $O(p\log_2 p)$ |
| Number of Processes | $O(p^2)$ | $O(p\log_2 p)$ |
| Per Process Throughput | $O(\frac{1}{p})$ | $O(\frac{1}{\log_2 p})$ |
| Number of Queues | $O(p^2)$ | $O(p\log_2 p)$ |
| Interconnect Node Complexity | $O(p)$ | $O(log_2 p)$ |

proportion to the degree of parallelism. This is due to the increased serialization needed to maintain the same bandwidth as the number of processors increases. $O(p)$ processes per sending processor will be tied up in transmission across the net. Thus, $O(p^2)$ processes will be needed to maintain an $O(p)$ increase in throughput. The constant factors in the $p^2$ terms for number of processes and queue sizes are expected to be small enough to make the modified crossbar connection preferred for low orders of parallelism. Note that number of processes, or more precisely, degree of parallelism is viewed as a resource here, and the modified crossbar scheme requires a higher order of parallelism to deliver the same performance with all other factors held constant. A number of changes in parameters for the CCMP will result in higher consumption of parallelism but no significant drop in throughput. This is true, for instance, when the number of pipeline stages in the various processors is increased.

**Software and System Details**

The current synchronization primitive in the CCMP simulator is a standard test and set instruction. We expect to change this, however, to an atomic swap operation. This requires about the same extra logic in the memory processors and is more powerful. In particular, it can be made to emulate the full/empty flags that were attached to registers by the HEP [7] designers and which work so elegantly in that architecture. All that is required is a designated "empty" value. The two pieces of code in table 2 demonstrate one use of this. A group of processes running the sending segment can synchronously pass one value at a time through memory location $x$ to a group of processes running the receiving segment.

**Table 2: Synchronization via Atomic Swap**

| Sending Segment | Receiving Segment |
|---|---|
| while data to send {<br>   place data in d;<br>   while d ≠ "empty" value {<br>      atomic swap d and x;<br>   }<br>} | while data to be received {<br>   place "empty" value in d;<br>   while d equals "empty" {<br>      atomic swap d and x;<br>   }<br>} |

Control of process creation and segmentation is through special instructions. There is a set of (privileged) instructions to allow one process to set another's segmentation registers. There is also a "*create*" instruction that allows one process to create another by instructing the new process' home processor to start a packet circulating for that process and to set its PC to a designated value. Home processors keep track of whether a process is currently active (has a packet circulating) or not. If a *create* is done on an already circulating process, the *create* becomes an interrupt, which is implemented by altering the affected process' PC so that it will go elsewhere next time it comes around. This same mechanism allows an I/O device to interrupt a given process.

The I/O system is memory mapped, so connections between it and the CCMP hardware are via the memory processors. Low bandwidth devices are linked to memory processors in a conventional manner, with devices evenly spread across processors to prevent any one processor from being overloaded by process packets attempting to fetch data from devices. Disk or other mass storage devices are somewhat more problematic, since they are required to deliver block transfers in various interleaved fashions to the memory processors. To accommodate this, we place another interconnection network between disks and memories, with buffering at the disks. This allows each disk to deliver data to and from each memory and permits a block load, even to a low-order interleaved segment, to be delivered from a single disk.

A simple approach to delivering interrupts to a process when an I/O operation is complete would be to run a bus through the home processors to allow devices to signal for interrupts. This might become a bottleneck in a highly parallel system, however. As mentioned above, internal interrupts may be delivered to a process by means of a *create* instruction. A more general approach to I/O interrupts, then, would be to allow an I/O device to signal a memory processor to create a dummy packet with a *create* instruction in it, destined for the desired process. The dummy packet would be given a special process ID number that would cause it to vanish after completing its task. In this way, the capacity to deliver interrupts would increase proportionally to the parallelism.

We are currently looking into the design of a distributed microcode system, in which each type of processor would have its own set of micro-operations, and would fetch microinstructions from a private microinstruction memory which would tell it what to do for a packet with a given instruction at a given point in its completion (instruction and state of completion are part of the process' packet). This would allow a more flexible instruction set and simpler hardware, as with other microcoded machines. Dynamic downloading of microcode would, of course, also be a possibility.

One somewhat tricky problem with the CCMP is the possibility of what we refer to as "ring deadlock", a situation in which a ring of modules and interconnect lines in the architecture have become mutually deadlocked. This situation will not abate by itself, and will quickly deadlock the remaining processes as they attempt to enter modules on the deadlocked ring. The solution to this problem is fairly straightforward. As figure 1 shows, the topology of the interconnections is such that the memory processors have a number of choices of where to send packets, and any deadlock loop must include a memory processor. Any time a memory processor becomes blocked, it sends the offending packet to another memory processor with an indication that the packet has been deferred. The receiving processor will try to send the process to its proper destination, or failing that will defer it once again. To obtain ring deadlock in this case it would be necessary to fill all the memory-to-memory queues. This is arranged to be more space than there can be process packets so deadlock becomes impossible. The existence of ring deadlock was predicted and then confirmed by simulation. The solution described has also been tested in simulation and found to be highly effective -- keeping the machine running smoothly when it would quickly deadlock without the avoidance mechanism.

## III. Simulation Results

We have developed a detailed simulation written in 'C' and running on a SUN work-station (or VAX) under UNIX 4.2. The simulation is at the register-transfer level, accounting for single-clock events. We believe that our simulations are conservative and very realistic, modeling virtually all significant aspects of the CCMP.

Several configurations of a particular CCMP machine have been modeled. Because of the detailed nature of our simulator, however, we have not extensively studied *large* configurations. We have instead concentrated on investigating relatively small systems, particularly studying the behavior under heavy process and memory loads. The system loads well (according to our studies so far) and we have reason to expect that because of its load-balanced, bottleneck-free structure, the CCMP will scale-up to large configurations well.

Our simulations assume representative levels of pipelining such as would be achievable and typical in conventional NMOS or CMOS VLSI (refer to table 3). We have assumed 18-25 MHz clock rates† (depending on stage type). Instruction processing may involve as many as several hundred single-clock pipeline stages including queue waiting times. This still would provide per-process instruction speeds of around 100,000 operations per second.

**Table 3: Pipeline Stages per Module Type**
(queue lengths excluded)

| Module Type | Simulated Stages |
|---|---|
| Home module | 16 |
| Memory module | 8 |
| Execution unit | 32 |

In the simulation results that follow, we have modeled a 4/4/2 CCMP system, i.e. one with 4 home modules, 4 memories, and 2 execution units. Note that because of our extensive use of queues these modules need not be synchronized, nor must they execute at similar clock rates. If the clock rates of different banks of resources are not roughly equal, then it will be necessary to balance the overall system by selecting the number of units in each resource bank so that their average throughputs match.

### Matrix Multiply (Saturation Load) — MMSAT

The first test program written for our simulator was a matrix multiply. In this program, we use one process for each entry in the output matrix. Since the matrix size chosen was 15×15, we used 225 processes. In this problem the parallelism is immediate, predictable, and constant. This is shown by the processes versus time plot (figure 3); the corresponding instructions per second versus process count plot (figure 4) shows that linear throughput is delivered as a function of the number of concurrent processes. Instead of terminating execution upon completion of the matrix multiply, we simply continue computing the elements over and over so that the program can be used as a type of system load.

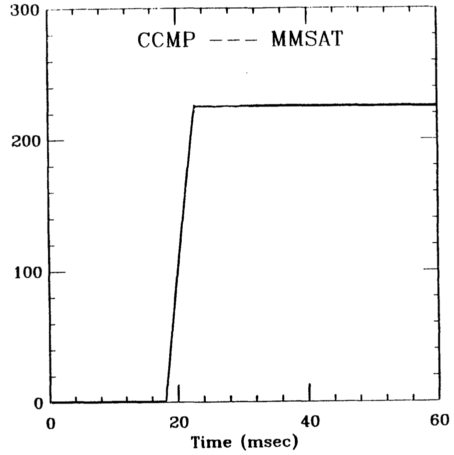

**Figure 3: MMSAT — Processes vs. Time**

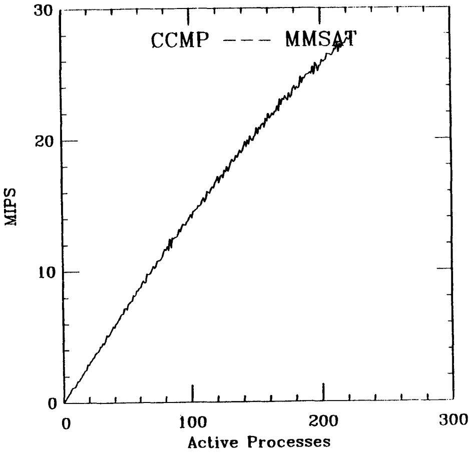

**Figure 4: MMSAT — Throughput vs. Offered Load**

### Recursive Quick Sort — QSORT

The quicksort algorithm [13] has also been coded and run on our simulator. Three distinct experiments were performed with qsort. In the first one, the pivot element was chosen arbitrarily (the first element in the array) as specified in Knuth's description. Figure 5 gives the parallel behavior for a sort of 10,000 integer elements in memory. Note that the maximum parallelism achieved is in the neighborhood of 30 processes. The corresponding throughput graph (figure 6) gives the observed MIPS rate, again very linear with respect to process count.

The second experiment with qsort was an attempt to intelligently choose better pivot points, ones that tend to divide the remaining elements into more or less equal groups. To do this, a simple pivot-choosing loop was added. The resulting behavior is shown in Figures 7 and 8. In this case parallelism of over 200 processes was observed, but at

† Note that we may freely trade additional pipeline stages in exchange for higher clock rates since an overall per-process latency trade-off has already been made.

the cost of a long-running initial pivot choice. The algorithm used for choosing the pivot point samples every $32^{nd}$ data element throughout the entire array. For the full 10,000 element array (the first pivot point chosen), this requires the inspection of over 300 items. Clearly, we could adjust this number and get vastly improved behavior with a much smaller number of probes.

The final experiment with qsort involved running the previous case in the presence of the matrix multiply saturation load. This was done to see how the two parallel programs interacted (i.e. whether they interfered with one another) on the machine. As expected, the CCMP allowed smooth sharing of resources. Neither program significantly impacted the resource utilization of the other. Figures 9 and 10 show the observed behavior from the mmsat + qsort experiment.

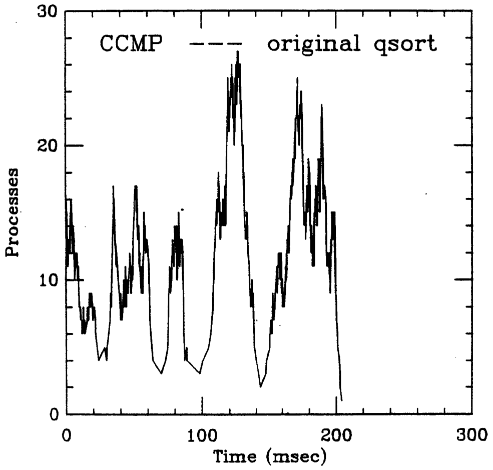

**Figure 5: QSORT — Processes vs. Time**

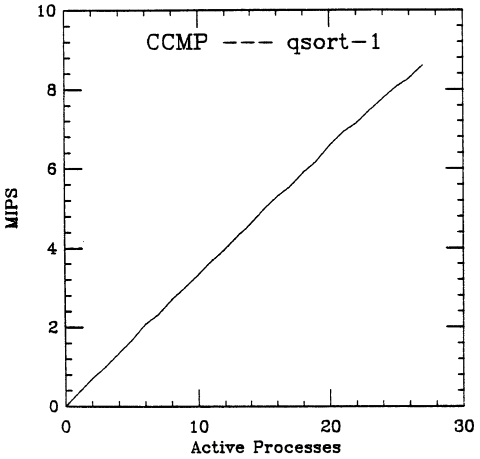

**Figure 6: QSORT — Throughput vs. Offered Load**

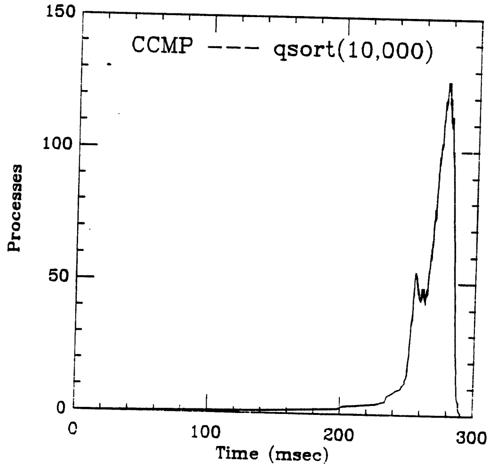

**Figure 7: QSORT w/ Pivot Selection — Processes vs. Time**

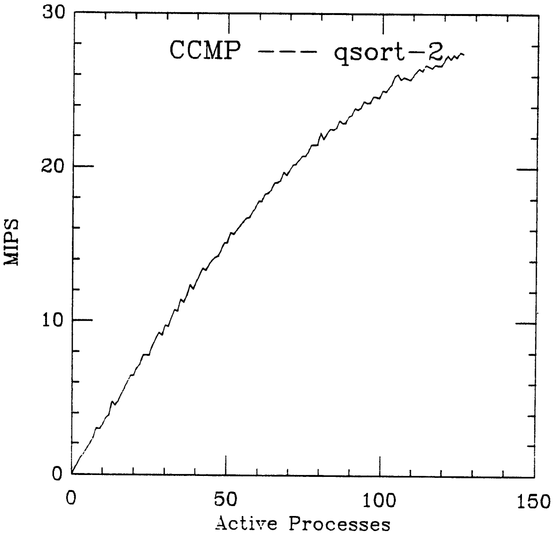

**Figure 8: QSORT w/ Pivot Selection — Throughput vs. Load**

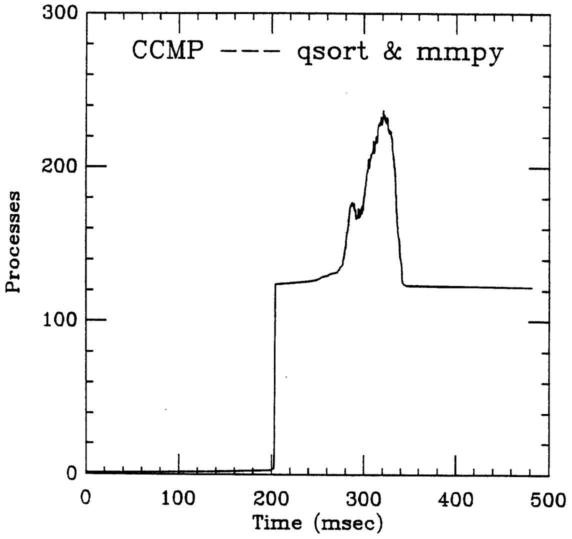

**Figure 9: QSORT w/ MMSAT — Processes vs. Time**

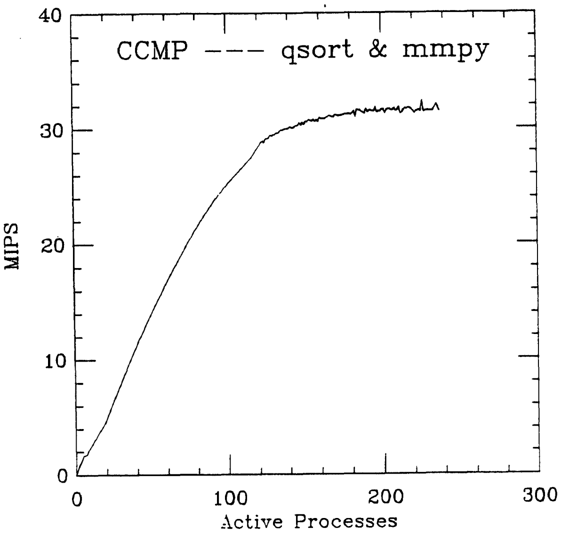

**Figure 10: QSORT w/ MMSAT — Throughput vs. Offered Load**

**Relaxation Algorithm — RL**

This program implements a simple 2-dimensional relaxation algorithm. We used a fast process generation technique, with each process creating four others, to rapidly build parallelism. Even though the program begins with only a single process, it is clear from figure 11 that after a segment set-up time, included for ease of coding, the full parallelism is acheived almost instantaneously. The simulation uses 256 cells (each with its own process) without synchronization. Each cell accesses the data elements associated with its neighboring cells, i.e. neighboring cells' data areas overlap. Like the matrix multiply (saturation) test, this program never terminates. It is the fully-loaded behavior of the CCMP that we wish to study. Figures 11 and 12 present the observed performance. The throughput graph appears jagged because of transient effects during the rapid increase in parallelism. The final dip in performance is caused by transient contentions for the same instructions by many newly-created processes. As can be seen from the two figures, this cluster of processes rapidly spreads out to permit 77% utilization of the machine (maximum performance achievable in this configuration is 36.36 MIPS). The relaxation algorithm provides so much parallelism that very little time is spent (hence, relatively few sample points) with less than the full number of processes.

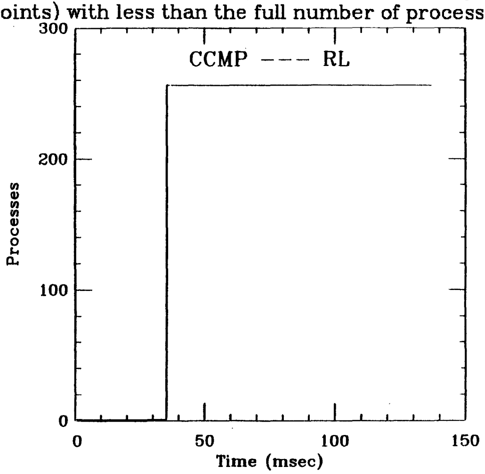

**Figure 11: RL — Processes vs. Time**

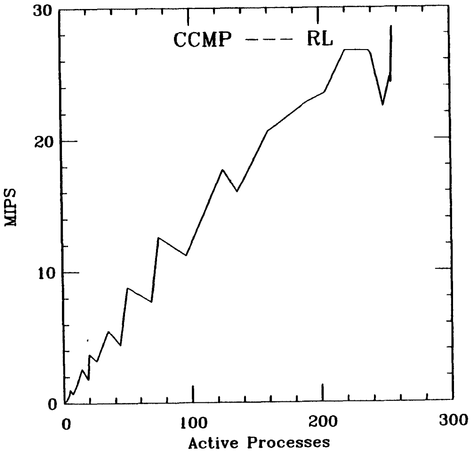

**Figure 12: RL — Throughput vs. Offered Load**

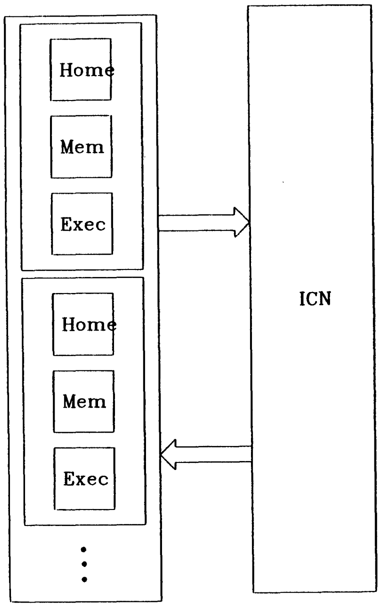

**Figure 13: Grouped Module CCMP Configuration (not yet simulated)**

## IV. Ongoing Work

We are currently engaged in simulation of larger models of the CCMP. Indications have so far shown no serious problems with expanding the degree of parallelism. One difficulty is that small, highly iterative loops in a low-order interleaved segment should be unrolled to span the entire set of memory processors to avoid overloading only a few processors with instruction fetches.

We are currently planning a major re-structuring of the simulator to allow us to test the effects of different instruction sets, varying numbers of registers, various queue designs, and other CCMP configurations, especially that shown in figure 13, where the various stages have been stacked one atop the other and share a common, higher-bandwidth interconnection network.

Implementation of high availability for the CCMP is another area for further research. Coding can be added to the process packets to allow detection of faults in networks or processors. Once a faulty processor has been detected it can be set offline while the others continue functioning. In the case of the execution units this is trivial since they are all identical. A faulty home can be offlined by not using the process ID's that report to it. Offlining a memory processor can be accomplished by using the flexible interleaving capability described earlier to interleave segments across subsets of the memory processors, avoiding the faulty one(s). Offlining a network link in the case of the crossbar arrangment can be accomplished by offlining the processors at either end of it or by using the deferral mechanism already installed for deadlock avoidance. All stages can send to the memory stage, and a bad link can be circumvented by sending the process, with an indication that it has been deferred, to an accessible memory processor which can then send the packet to the desired location.

In the case of a cube interconnect, there are well-established means for avoiding a bad link. A bad node, however, would require the offlining of the two processors to which it is connected.

## V. Conclusions

We have presented a novel multiprocessor architecture and the results of a recent study of its feasibility and performance. The CCMP machine is a general MIMD computer that trades individual process performance for high overall system throughput. For maximum speed on a given (parallel) problem, the goal is to express the overall computation in terms of many (perhaps thousands) of co-operating, but largely independent, processes.

We have carefully modeled a particular instruction set at essentially the register-transfer level and studied the performance on several important and typical problems. The system can deliver 80% efficiency quite routinely (i.e. without significant optimization) and can get near-100% utilization on selected problems.

Since the system in pipelined and uses instruction stream interleaving to preclude pipeline breaks, pipelines can be longer than typical. This can allow higher than typical clock rates, since large-delay circuitry can be broken down into multiple simpler (i.e. faster) pipeline stages. The CCMP makes sense for VLSI, particularly as technology moves toward wafer-level interconnect [15] and multi-chip hybrids.

Another strength of the architecture (which has not been stressed in this report) is its excellent support for error-detection, reconfiguration, and re-try. With adjustments made to the home modules (primarily in the number and type of registers) and with the addition of error detection (at either the register-transfer, single module, or single instruction loop level), the CCMP could be made to support fault-tolerant applications.

# Shared Memory Versus Message-Passing in a Tightly-Coupled Multiprocessor: A Case Study

Thomas J. LeBlanc
Computer Science Department
University of Rochester

**Abstract** - The BBN Butterfly Parallel Processor can support a user model of computation based on either shared memory or message-passing. In this paper we describe the results of our experiments with the message-passing model. The goal of the experiments was to analyze the tradeoffs between the shared memory model, as exemplified by the BBN Uniform System package, and a simple message-passing model. We compare the two models with respect to performance, scalability, and ease of programming. We conclude that the particular model of computation used is less important than how well it is matched to the application.

## Introduction

The hardware architecture of the BBN Butterfly™ Parallel Processor supports message-passing between processors using an FFT network of 4x4 switch elements. The memory architecture, implemented by the operating system in conjunction with a micro-coded co-processor, provides the illusion of shared memory. As yet, there are no additional software levels that distort this illusion, so the user-level view of the architecture is that of a shared memory multiprocessor. This paper describes a series of experiments designed to explore the ramifications of a user-level view of the Butterfly architecture based on message-passing.

Both shared memory and message-passing models have been advocated for parallel computation. Shared memory is usually found in tightly-coupled architectures that support remote memory operations in hardware or firmware. Message-passing is typically employed in loosely-coupled systems (*e.g.*, local-area networks). Early work on the Butterfly, the Voice Funnel application in particular, used message-passing. Recently, Butterfly applications, including finite element analysis and computer vision algorithms, have assumed the shared memory model of computation. The only programming environment available on the Butterfly that masks the low-level details from the programmer is the Uniform System package from BBN, which implements a shared memory model. Programmers find it easier to use the Uniform System than to build the program from scratch, *regardless* of how well the application fits the shared memory model.

Before proceeding with our implementation of an environment supporting message-passing [3], we conducted a series of experiments using Gaussian elimination as a sample application. The goal of the experiments was to explore the tradeoffs between the shared memory model, as exemplified by the Uniform System package, and a simple message-passing model based on asynchronous send and receive. Important factors to be considered were ease of programming, performance, and scalability. In this paper, we present the results of our experiments.

## The BBN Butterfly Parallel Processor

The Butterfly multiprocessor at the University of Rochester consists of 128 processing nodes connected by a switching network. Each processor is an 8 MHz MC68000 with 24 bit virtual addresses. A 2901-based bit-slice co-processor interprets every memory reference issued by the 68000 and is used to communicate with other nodes across the switching network. All of the memory in the system resides on individual nodes, but any processor can address any memory through the switch. A remote memory reference (read) takes about 3.75 *us.*, roughly 6 times as long as a local reference.

Each switch node in the switching network is a 4-input, 4-output crossbar switch with a bandwidth of 32 megabits/sec. An N processor system uses $(N \log_4 N)/4$ switches arranged in $\log_4 N$ columns. The 128-node Butterfly contains 256 switch nodes; the extra switch capacity is used to provide an alternate communication path between all processors for reliability and improved efficiency. The alternate paths can be enabled or disabled by the user, making it possible to indirectly measure the effect of switch contention.

## Case Study: Gaussian Elimination

The sample application chosen for the experiments was the solution of a set of linear equations using Gaussian elimination (without pivoting). The reason for this choice was that several experiments using shared memory to implement Gaussian elimination had been performed at BBN Laboratories [2,5]. Our experiments with message-passing were designed for comparison with their results. In addition, Gaussian elimination is representative of a large class of problems in finite element analysis. While it is fairly easy to develop parallel algorithms for Gaussian elimination, the problem does have important synchronization constraints.

In solving a set of linear equations using Gaussian elimination, the coefficient matrix M is diagonalized, producing a modified vector of unknowns, and the unknowns are determined using backsubstitution. (Since backsubstitution is a small percentage of the total time required to solve the equations, it is not performed in any of the experiments.) To eliminate an entry M[i,j], we replace row M[i] with M[i] - (M[j] * M[i,j]/M[j,j]), where M[j] is known as the pivot row. However, this operation cannot be performed until row M[j] has stabilized, *i.e.*, $M[j,k] = 0, \forall k < j$. In addition, all previous entries in row i must already be eliminated, *i.e.*, $M[i,k] = 0, \forall k < j$. These two synchronization constraints limit the amount of parallelism that we can expect to achieve.

Floating point arithmetic is required to solve a set of linear equations. Unfortunately, our Butterfly does not have floating point hardware. All floating point arithmetic is performed by costly subroutines. This makes it difficult to analyze the communication costs of an application because the execution time is dominated by floating point software. To alleviate this problem, our experiments were performed with *simulated floating point* arithmetic, using the same approach as that used in the shared memory implementation [2]. All floating point variables were replaced with integer variables, and addition and subtraction were used in place of multiplication and division. Such a computation does not give the correct answers, but does accurately simulate the performance of the computation on a Butterfly with floating point hardware. Each experiment was performed using software floating point to ensure the correctness of the results, but all reported performance figures refer to the results of experiments using simulated floating point. By using simulated floating point, we not only can make predictions about the performance of the Butterfly with floating point hardware, we also reduce the execution time of the computation and thereby increase the significance of communication costs.

### Shared Memory Implementation

The shared memory version of Gaussian elimination was implemented at BBN Laboratories using the Uniform System (US) package [1]. US provides a set of calls to create a global shared memory, accessible to all US processes. Within the shared memory, pointers may be shared between processors. US also creates a manager process on each processor that is responsible for allocating the processor to a series of tasks, light-weight processes that operate on the shared memory. Usually, a task is some small procedure to be applied to a subset of the shared memory. A task, therefore, can be represented as simply an index, or a range of indices, into the shared memory and an operation to be performed on that memory. Atomic operations in micro-code are used to efficiently allocate tasks to processors.

The strength of the Uniform System is that it supports a user-level view of the architecture consisting of light-weight tasks and shared memory. To reduce memory contention, US encourages a globally-shared memory and the scattering of data uniformly throughout the machine. (This may even include putting data in memory associated with a processor that is not involved in the computation.) To reduce process management overhead, only one real process is allocated per node; all tasks are light-weight.

Several experiments were performed at BBN Laboratories to see how well applications that use US, including Gaussian elimination, perform on large Butterfly configurations [2, 5]. In these experiments, the problem matrix was uniformly distributed throughout available memory. A task was created to eliminate a single entry in the matrix, M[i,j]. Both row M[i] and row M[j] were transferred to local memory before performing the computation, rather than perform a remote reference for each individual entry in a row. (Block transfers amortize overhead associated with remote references and can significantly improve performance.) Since M[i] is modified by the operation, an additional transfer of the modified row back to the shared memory location for M[i] was also necessary.

The main result of these experiments was to show that the 128-node Butterfly could achieve nearly linear speedup when performing Gaussian elimination using US. Both switch contention and memory contention were shown to be insignificant (2% and 3%, respectively). However, those results used an early version of the program which had not been tuned. An optimized version was later developed, which greatly reduced the time spent in the inner loop of the program. Tuning the inner loop not only lowers the total time required for the computation, but increases both memory and switch contention during the computation. Therefore, we performed several experiments to examine the effects of contention on the optimized shared memory implementation.

The first experiment we performed was designed to examine the effect of memory contention on the performance of the optimized shared memory implementation. In the US implementation, all memories in the system are used to store the problem matrix, even when only a few processors are involved in the computation. This has the effect of improving the overall performance by decreasing memory contention. Since the message-passing implementation can not take advantage of memories in unused processors, it is important to quantify this effect before comparing the two implementations.

In order to determine the effect extra memories have on the performance of a computation (and to indirectly measure memory contention), the optimized shared memory implementation of Gaussian elimination was executed on various numbers of processors and memories. The test results show that the extra memories can have a substantial impact on performance, which in turn suggests that memory contention can be a significant factor. On a problem matrix of size 400x400, a Butterfly configuration with 4 columns of switches, 16 processors, and 96 memories performed 15% better than 16 processors and 16 memories. On a problem matrix of size 200x200 and a Butterfly configuration with 2 columns of switches, 4 processors and 16 memories performed 30% better than 4 processors and 4 memories. The greatest effect occurs when roughly 1/4 to 1/2 of the total number of processors are in use. When a larger fraction of processors are performing computation, most of the memory is already in use, *i.e.*, there is no other extra memory. When too few processors are used, they are insufficient to generate enough load on the memory to make memory contention significant.

The second experiment we performed was designed to examine the effect of switch contention on the performance of the optimized shared memory implementation. The 128-node machine has a switch configuration capable of supporting 256 nodes. The excess switch capacity increases the total amount of potential bandwidth in the switch, which will improve the overall performance of a computation whenever there are enough processors involved to cause switch contention.

The results of this experiment show that the effect of alternate switch paths can be dramatic (as a percentage of total execution time) when a large number of processors are in use. A 35% improvement in execution speed was attained using alternate paths for 94 processors on a problem of size 400x400; 64 processors achieved a speedup of more than 20% on the same problem using alternate paths. Since the shared memory implementation does not exploit locality of data (two problem rows must be copied into local memory before an operation can proceed), it is not surprising that the shared memory implementation introduces significant switch contention once the inner loop has been tuned to the point where the program is communication intensive.

### Message-Passing Implementation

In order to explore fully the potential of message-passing in the context of the case study, it was important to provide a general-purpose message-passing system. Communication primitives too closely associated with the application would demonstrate little about the message-passing model. Therefore, the following primitives were provided:

**Send**(destination, buffer address, byte count);
**Broadcast**(buffer address, byte count);
**Receive**(source) : buffer address:

Communication is asynchronous between a sender and receiver. **Send** is nonblocking; the sender may continue to execute before the destination receives the message. However, the implementation may block the sending process for a short period of time necessary to buffer the message. **Receive** will block until a message from the source arrives. A wildcard value is available so that messages from any source may be received. **Broadcast** is included because it can be implemented more efficiently by the system than if it is simulated using point-to-point communication. These primitives are very general since minor variants have been used as the basis for communication in distributed operating systems.

Several versions of the message-passing system were implemented in an attempt to explore efficient implementation techniques. In the first, and simplest, implementation, an object was created for each message, using the object management facilities of Chrysalis, the Butterfly operating system [4]. Each time a broadcast took place, the message system would create a remote object for each recipient and copy the message into the object. This approach yielded a very clean implementation, but the overhead of using the object management system for each message was too great. In addition, remote object creation requires the cooperation of a remote daemon process, which introduces contention on the remote processor. Later versions used preallocated objects for buffers and placed responsibility for copying a message with the receiver rather than the sender. The final implementation has the following properties: (1) buffers are preallocated on each processor and are eventually reused, (2) each sender copies the message from local memory into a local buffer object and updates the local ring buffer pointers, (3) each broadcast recipient copies a message from a remote buffer into local memory when a corresponding **Receive** is issued, and decrements a use count in the remote buffer using an atomic operation, and (4) synchronization for access to buffers uses primitive atomic operations implemented in micro-code.

In the implementation of Gaussian elimination, a coordinator process is responsible for creating worker processes on each processor. All workers initialize the local message handler, which requires global synchronization, and then create a local partition of the problem. When N processors are used, each processor P is assigned the task of diagonalizing all rows R for which R mod N = P. To do so, each processor must request each row of the problem matrix in sequence and use it to eliminate entries in the corresponding column of the local partition. A percentage of these requests, 1/P, will be satisfied locally and, therefore, do not require a message. Local rows are broadcast to the other processors when they have been diagonalized. When all local rows are completely diagonalized, the worker process signals the coordinator, which is responsible for termination of the computation.

### Implementation Comparison

In this section, we compare the two implementations of Gaussian elimination with respect to performance, scalability, and ease of programming. Where possible, quirks in the implementation of a model are ignored, in order to concentrate on the methodology suggested by the model.

Figure 1 shows the performance of the two implementations on a problem matrix of size 800x800. With four processors, the message-passing implementation is about 30% faster than the shared memory implementation. The relative performance is consistent across different problem sizes and, in each case, the message-passing implementation is more efficient. The disparity decreases as additional processors are used until the "knee" in the performance curve of the message-passing system is reached.

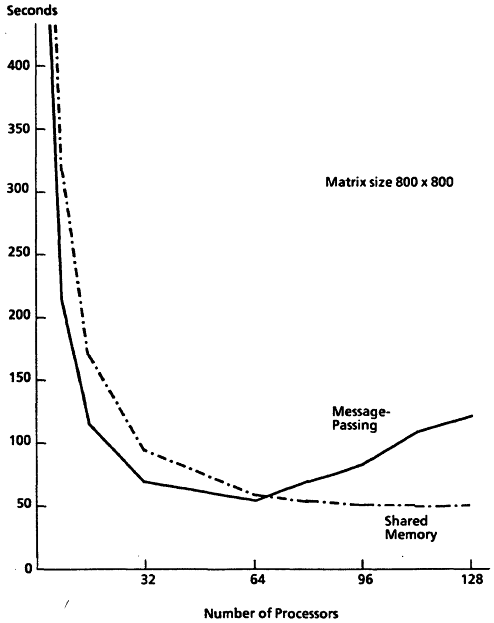
The improved performance of the message-passing implementation can be directly attributed to data locality. Nearly every data access in the shared memory implementation requires a remote reference. Even when the data physically resides in local memory, all data conceptually resides in shared memory and must be copied into the local workspace. Very few remote references are needed in the message-passing implementation (none, if only one processor is in use), and a copy takes place only when a remote reference is made.

Exploiting locality of data also minimizes switch contention. Unlike the shared memory implementation, the message-passing implementation for Gaussian elimination showed no significant switch contention. A problem of size 800x800 was able to execute on 32 processors without alternate paths at roughly the same speed as with the alternate paths. Over the entire range of experiments, the effect of alternate communication paths improved the execution time of the message-passing implementation by at most 3%.

Another measure of an application's performance is how well the implementation is able to use additional processors. Ideally, if a problem of size NxN using P processors requires time T, the same problem can be solved on 2P processors in time T/2. The extent to which the ideal is realized depends, in part, on the number of sequential operations in the implementation that depend on P.

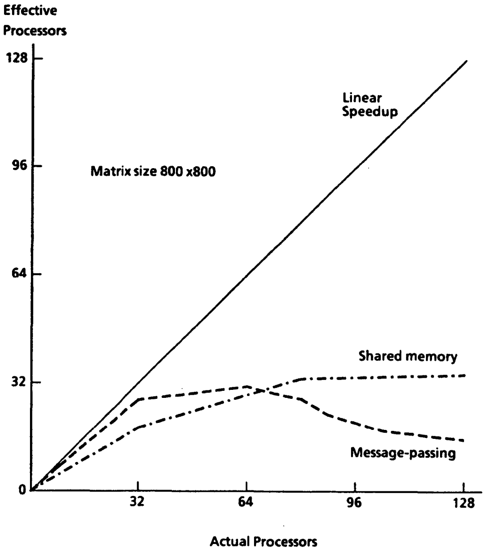
Figure 2 illustrates the scalability of the two implementations. The computation time for a program designed for a single processor is divided by the time required by the parallel version to yield the number of *effective* processors. With linear speedup, P actual processors yields P effective processors. As Figure 2 demonstrates, the message-passing implementation has nearly linear speedup with 16 processors, and a slight deviation from linear speedup with 32 processors. Speedup reaches a turning-point at 64 processors (31 effective processors) and additional processors only serve to *increase the execution time of the computation.*

The shared memory implementation, on the other hand, has a speedup factor that is less than linear, even for a small number of processors. For example, 4 real processors shows a speedup of 2.8 and 16 processors shows a speedup of 10.6. Speedup reaches a plateau when 64 processors are in use (30 effective processors). Additional processors do not have much impact and, at best, were able to yield 34 effective processors with 116 actual processors.



Shared Memory vs. Message-Passing: Performance

Figure 1



Shared Memory vs. Message-Passing: Speedup

Figure 2

In order to explain the "knee" in the performance curve for message-passing, we have to look at the implementation for operations that depend on P, the number of processors involved. Each broadcast operation requires time O(P). Since all data is local to some process, each process is responsible for modifying its local rows and broadcasting the results. Each processor that is to receive a broadcast must copy the message into local memory, so a broadcast requires P-1 processors to sequentially access a single remote memory. A total of N messages are broadcast to P-1 processors. Since each message is buffered locally before it is copied, the total number of copies is P*N. As P increases and N remains fixed, we reach a point of diminishing returns. Eventually, the time to copy an additional row in the presence of broadcast contention is not justified by the gain in parallelism.

The shared memory implementation does not exhibit a "knee" because, after initialization, there are no operations in the shared memory implementation that depend on P. The Uniform System encourages the programmer to avoid memory contention by distributing the data uniformly throughout the available memory. Tasks are allocated to processors independently of the data to be accessed. This means that while contention for a particular memory is reduced, overall switch contention is increased because practically all data references are remote. $N^2$ remote data copies, involving the non-zero portion of a whole row, are required, so the total number of copies is independent of the number of processors. Thus, if P is significantly smaller than N, as it should be to achieve high processor efficiency, the message-passing implementation will make many fewer copies than the shared memory implementation, although each copy (message) will take longer. Fewer copies will reduce both switch and memory contention, and improve performance, until the "knee" in the curve is reached. Beyond that point, additional copy operations cannot be justified by a significant gain in parallelism.

Our third criterion for comparison is ease of programming. Programming models are employed so that each application can be written without the knowledge of too many underlying details. Thus, an important criterion of any model is that it facilitate program construction. One concrete measure is the amount of user code that needs to be written. For Gaussian elimination, the amount of user code is comparable in both implementations. The Uniform System implementation contains 426 lines of user code, including comments, compared with 368 lines of user code in the message-passing implementation.

A related measure is the amount of user code unrelated to the specific application. That is, to what extent does the user code have to deal with the details of communication and synchronization? In the message-passing implementation, there is one call to **Broadcast** and another to **Receive**. There is no explicit synchronization in the user code. The shared memory implementation uses primitive atomic operations for synchronization and several calls to transfer blocks of memory. There are also spin locks that are sensitive to the amount of time delay between attempts to set the lock.

## Conclusions

The original intention of this work was to show that message-passing could play an important role in the design of a programming environment for a tightly-coupled multiprocessor. This exercise was designed to provide some empirical data that suggests how best to structure communication between processes in a tightly-coupled multiprocessor. We offer the following conclusions.

*The particular model of computation in use is less important than how well it is matched to the application.* Gaussian elimination is an appropriate application for a multiprocessor, however, this does not mean that the shared memory model is the best fit for this application. Since Gaussian elimination is essentially *value-oriented* (no addresses are communicated and rows are not used until they have stabilized), message-passing is a better model of the communication that takes place. There are other applications for which message-passing would not be appropriate. Any programming environment that offers a single model of communication will not be well-matched to a large class of applications.

*A high-level interface, efficiently implemented, leaves the programmer fewer opportunities to introduce inefficiency.* Of course this assumes that the high-level interface provides a *useful* abstraction. The Uniform System offers no high-level synchronization primitives; the two primitives provided are a busy wait LOCK and an UNLOCK primitive. Each programmer must use these to implement the appropriate synchronization. Spin locks are commonly used, but the resultant program can be especially sensitive to the amount of time spent between attempts to set the lock [5]. The only process synchronization in the message-passing implementation occurs during access to message buffers, which is implemented very efficiently using micro-coded atomic operations. The user does not need to be concerned with low-level synchronization; it is implicit in the message-passing primitives.

*The performance of an application depends not only on the efficiency of communication, but also on the extent to which the underlying model of computation encourages or discourages communication.* The Uniform System model does not encourage the programmer to exploit locality. Data is assumed to reside in one large, uniform address space and the boundaries between processors are ignored. Thus, in Gaussian elimination, each task must copy two rows into local memory to eliminate a single entry and then copy the result back. (Pivot rows were cached to avoid one of these copies.) This is not the case with the message-passing model, since all data is local to some process in the computation. Locality makes it possible to avoid copying any row to be modified (since only local rows are ever modified) and also to avoid copying any pivot row that happens to be local. Thus, an implementation based on very efficient communication (*e.g.*, shared memory) may perform worse than one based on a less efficient mechanism (*e.g.*, message-passing), if such efficiency encourages too much communication.

## Acknowledgements

I would like to thank Lawrence Crowl, Neal Gafter, and Thomas Olson for their help in performing the experiments. Liud Bukys, Stuart Friedberg, Walter Milliken (BBN), and Bob Thomas (BBN) provided technical assistance and several helpful suggestions. ## ABSTRACT

Experimental hierarchical multiprocessor systems, such as the Cm* [1],[2], EGPA [3] machine and the Cedar [4], show that hierarchical systems encompass a range of processor configurations and interprocessor communication links. Cost and performance models are developed for the components of a hierarchical system where all processors share a global memory and processors are grouped into clusters that share a cluster memory. With these models, it is shown that a unique combination of processor speeds and numbers best achieves a given performance goal. Given the distribution of interprocessor communication, the cluster size is chosen to minimize average communication delay. When the patterns of communication correspond directly to some parallel architecture, the analysis indicates the effectiveness of the hierarchical system in emulating that architecture. Our primary objective is to compare various processor configurations in large systems. Thus, the models we have developed ignore factors that tend to have a similar effect on a wide range of configurations.

## 1. INTRODUCTION

The shared memory model, in which all $p$ processors access a common memory in constant time, has been widely used in parallel processing research. Crossbar switches are too expensive to construct for large $p$. Multi-stage interconnection networks have order $lg\ p$ stages and a direct realization of the shared memory model results in an order $lg\ p$ increase in delay as $p$ increases. Local memory for each processor can decrease memory latency to some extent because a large fraction of all references are to variables that are private to each processor. An extension of this approach is to organize processors in groups (*clusters*) with a local *cluster memory* shared by each group of processors. Communication between processors in the same cluster is done through the cluster memory. Access to *global memories* is required primarily to communicate among processors in different clusters. Such a two-level hierarchical system may be extended to several levels. In this paper, we focus on two-level hierarchies.

As in uniprocessor systems, a large proportion of all references are to a small set of storage locations. The development of methods to ensure that the highest level in the hierarchy is populated mainly by this set has led to the success of cache-based systems. Furthermore, for many applications, it is possible to assign tasks so that interprocessor communication occurs mainly within small groups of processors. It is for these applications that providing a faster set of communication links within groups of processors results in improved performance. The models that we use here are similar in some respects to those in Welch [5] and in Vrsalovic et al [6].

We briefly describe three hierarchical systems. The Cm* is a two-level hierarchical multiprocessor system [1]. The Cm* hardware is made up of 50 processor-memory pairs called Computer Modules or Cm's [2]. These are grouped to form clusters containing up to 14 Cm's. Communication within the cluster is via a parallel bus controlled by a *Kmap*, which is an address mapping processor. There are five clusters and these communicate via intercluster buses. The Cm* is extensible, either by adding processors to each cluster (up to 14) or by increasing the number of clusters. The Cedar [4] uses a crossbar interconnection between the processors within a cluster and the cluster memory they share, and a multistage interconnection network between all processors and a global memory shared among all clusters. At present there are up to 8 processors per cluster and the number of clusters is extensible.

The Erlangen general purpose array, EGPA [3], is extensible only in the number of levels. Each processor except for the ones at the lowest level is connected to the memories of four subordinate processors. Data transfer is done on the EGPA via the common memories. Processors and memories in the same level are connected by additional links. Although hierarchical and tree are often used interchangeably, we assume that a ***hierarchical machine*** has processors at the leaf nodes and communicating nodes or memories at the internal nodes, whereas a ***tree machine*** has processors at internal as well as leaf nodes. We thus classify the EGPA as a tree machine. The models we develop are directly applicable only to hierarchical systems.

Several design decisions involve specifying gross system parameters. For instance, a mesh architecture can be specified by the size of the mesh, the speed of the individual processors, and the communication bandwidth and delay of the links. In a hierarchical (cluster) system, parameters include the number of processors and their speed, the number of levels in the hierarchy, the type of interconnection at each level, and the number of clusters. We have developed cost and performance

models and techniques that use them to make some of these decisions, given knowledge of the workload as input.

The efficient utilization of the resources in a multiprocessor system requires a match between the architecture and the application. Inter-task and interprocessor communication are determined by the algorithms used. Structured programming with hierarchical design may improve the mapping to a hierarchical multiprocessor. The importance of reducing interprocessor communication is well described in [7]. In order to examine the general suitability of hierarchical systems, we evaluate their ability to emulate the patterns of communication encountered in typical code for some important applications. We develop some methods to choose a processor configuration that is best suited for the patterns considered.

We present models for the components of a hierarchical system in section 2. In section 3, we show how these models help to obtain an optimum distribution of costs among the components. In section 4, we are concerned with the choice of cluster size. For some patterns of communication commonly encountered, we show that the cluster size can be optimized with respect to average communication delay. In section 5, we determine the cluster sizes that will minimize interprocessor communication delay for emulating certain processor networks.

## 2. COST AND PERFORMANCE MODELS

### 2.1. Parameters

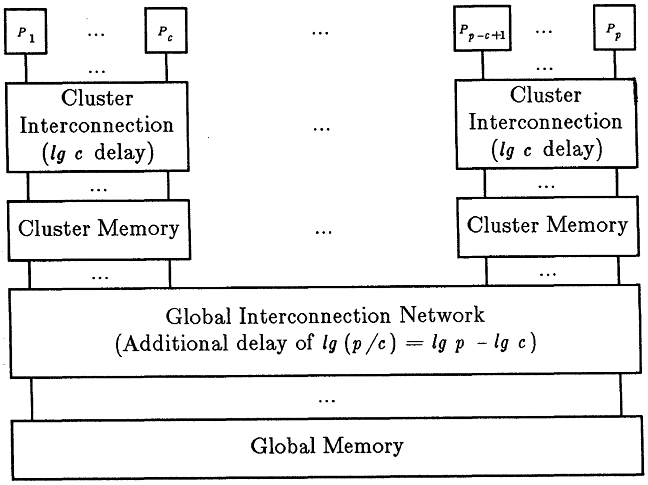
We list some of the parameters that characterize a two-level hierarchical system (Fig. 2.1).

$p$ - number of processors in the system.
$s$ - speed of a single processor.
$c$ - number of processors in a cluster.
$p/c$ - number of clusters in a two-level system.

For a single application with a uniform pattern of communication, a uniform cluster size, $c$, is the best choice.

### 2.2. Cost and Access Times

We propose models for the three major components in a two-level hierarchical system, viz. the processors, the cluster interconnection, the global interconnection. These models are simple since the primary purpose is to develop quantitative methods to obtain a better understanding of some tradeoffs in large systems [8]. For example, we show a tradeoff between processor cost and communication structure cost. Other models can be substituted for the ones used here, but the basic analysis technique remains unchanged.



$P_1$
...
$P_c$
...
$P_{p-c+1}$

Cluster Interconnection ($lg\ c$ delay)
Cluster Memory
Cluster Memory
Global Interconnection Network
(Additional delay of $lg\ (p/c) = lg\ p\ - lg\ c$)
Global Memory

Fig. 2.1. Model of Communication Delay for a Hierarchical Multiprocessor.

### 2.2.1. Processors

In order to focus on the configuration issues of concern here, a processor is characterized by only a single parameter, speed. All processors are required to have the same speed.

One model for the individual processor cost as a function of speed is the power function $c(s) = s_0 . s^{\alpha}$. With this model, multiprocessing is a cost-effective option only if $\alpha \geq 1$. If $\alpha < 1$, the performance of a uniprocessor system can be improved at sublinear cost, while a multiprocessor system with additional processors can result in at most linear speedup. Such a power function is fairly commonly used [5] and is mathematically tractable. The boundary beyond which multiprocessing is undesirable can be stated concisely.

### 2.2.2. Global Interconnection

There are several strategies for interconnecting a large number of processors [9]. The ring and the mesh networks (Figs. 5.1 and 5.2) are good for certain applications, but they have a large diameter. For general purpose multiprocessors, multi-stage packet switched networks are usually most suitable for global interconnection and we model such networks here.

In such a network, there are $p$ requesters and a similar number of memory banks serving these requesters. The memory banks together constitute the global memory (Fig. 2.1). The number of switches in each stage is proportional to $p$. There are $lg\ p$ stages in the network. The total number of switches and the number of wires connecting switches are thus proportional to $p\ lg\ p$ and the cost of the global interconnection is modeled as $p\ lg\ p$. We assume that each switch operates in unit time. Processor speed, $s$, may thus be viewed as being relative to switch speed.

Since the number of switches that have to be traversed to reach the server is $lg\ p$, the model access time is proportional to $lg\ p$. Another rationale for modeling the access time or communication delay as $lg\ p$ is the following. Since the number of possible destinations is $p$ and the switches are binary in nature, the data should be switched through at least $lg\ p$ switches. Accordingly, the model delay of a link in a mesh is two, since there are four possible destinations. To obtain a fair comparison, it is necessary to penalize, with a larger delay, those parallel architectures with many communication links per processor.

### 2.2.3. Cluster interconnection

At the cluster level, a wider range of interconnection schemes is possible, since the number of processors is small [10]. We show that a crossbar for the cluster interconnection is not feasible if the cluster size is to be larger than $lg\ p$ and we may be constrained to multi-stage interconnection networks within such a large cluster.

A desirable if not essential characteristic of a large multiprocessor architecture is scalability. Scalability as it pertains to cost requires that the cost of a system should not increase much faster than the number of processors. We have seen that the cost of the global interconnection increases as $p\ lg\ p$. We require that the total cost of all cluster interconnections be similarly bounded.

Consider the choice of a crossbar for the cluster interconnection. Since there are $c^2$ switches in a crossbar of size $c$, the cost of the crossbar increases as $c^2$. Since there are $p/c$ crossbars, the total cost of the cluster crossbars is proportional to $p.c$. Since this cost must be bounded by $p\ lg\ p$, the size of a cluster, $c$, should not increase faster than $lg\ p$, as $p$ increases.

As we shall see for some cluster communication patterns, cluster size should increase faster than $lg\ p$ to ensure minimum communication delay. A multi-stage interconnection network within the cluster may then be more suitable. We assume a delay of $lg\ c$ for a cluster interconnection.

## 3. COST TRADEOFFS BETWEEN PROCESSORS AND THE COMMUNICATION NETWORK

The wide disparity in the cost of microprocessors and large scientific computers often evokes the suggestion of generating supercomputing power from a multi-microprocessor system. In a large multiprocessor, the interprocessor communication links can account for a significant fraction of the total cost. In our model, the cost of the interconnection network increases faster than the number of processors. Even if the choice of cheaper and slower, but more processors to attain a required system performance reduces the total processor cost, the larger interconnection network might increase total cost. Additionally, as the number of processors increases the utilization of the processors decreases, where utilization is the fraction of the total number of processors that can be effectively used. As a result of these factors, higher levels of performance are best achieved by using sufficiently fast processors as system components. In this section, we develop quantitative methods for evaluating such tradeoffs, e.g. to determine the number and speed of the processors.

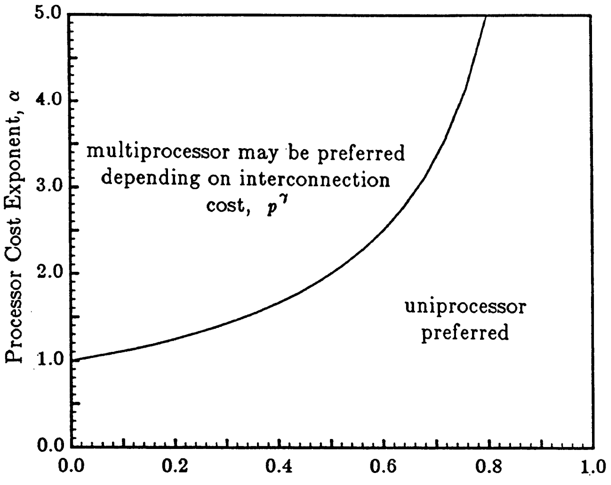

Fig. 3.1. Region in which a Uniprocessor is Cost-Effective. ($\alpha(1 - \beta) < 1$)

A combined analysis of the factors affecting cluster size, $c$, and system size (the number of processors), $p$, is difficult. Although the cluster size can affect the cluster interconnection cost, we approximate the total cluster interconnection cost to be a function of system size, $p$. This enables us to find the system size, $p$ without a knowledge of the cluster size. Further, we approximate the interconnection cost to be $p^\gamma$. Here $\gamma$ is chosen so that $p^\gamma$ approximates the model cost of $p\ lg\ p$ for the range of system sizes under consideration. This enables us to develop closed form expressions. Iterative solutions can be obtained without this additional assumption.

The parameters of the model are listed below.

$P_0$ - desired performance level.
$s$ - individual processor speed.
$s_0 s^\alpha$ - individual processor cost.
$p^\gamma$ - communication structure cost.
$p^{-\beta}$ - processor utilization factor.
$C$ - total cost of the system.

We model the utilization factor as $p^{-\beta}$, because the utilization factor is generally observed to decrease as the number of processors increases. If we obtain linear speedup, $\beta=0$ and the processor utilization factor is one. If there is no speedup, $\beta=1$ and this factor is $1/p$. Ordinarily, $\beta$ lies between 0 and 1, where smaller values imply better utilization.

The objective is to attain performance $P_0$ with minimum total cost, $C$. The total processing capacity is $s.p$, of which a fraction $p^{-\beta}$ is used. Therefore,

$$P_0 = s.p.p^{-\beta} = s.p^{(1-\beta)} \qquad (3.1)$$

The cost $C$ is the sum of processor and the communication structure costs, namely

$$C = p.s_0.s^\alpha + p^\gamma \qquad (3.2)$$

From (3.1)

$$s = P_0/p^{(1-\beta)} \qquad (3.3)$$

Substituting (3.3) in (3.2),

$$C = s_0.P_0^\alpha.p^{1-\alpha(1-\beta)} + p^\gamma \qquad (3.4)$$

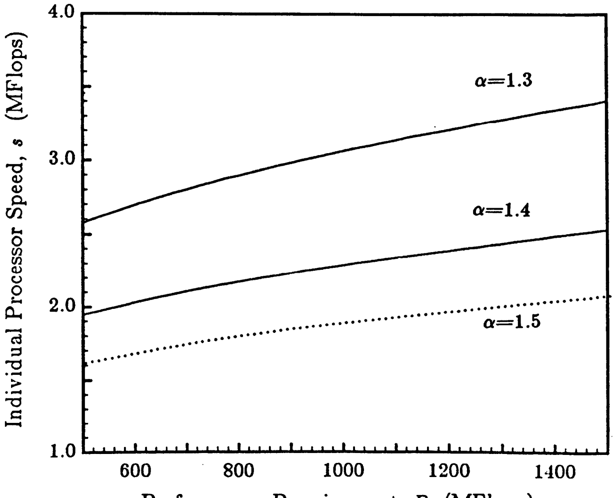

Fig. 3.2. Plot of Individual Processor Speed, $s$ vs. Performance Requirement, $P_0$. (from (3.7) in (3.3) with $\beta$=0.1, $\gamma$=1.4, $s_0$=25.0)

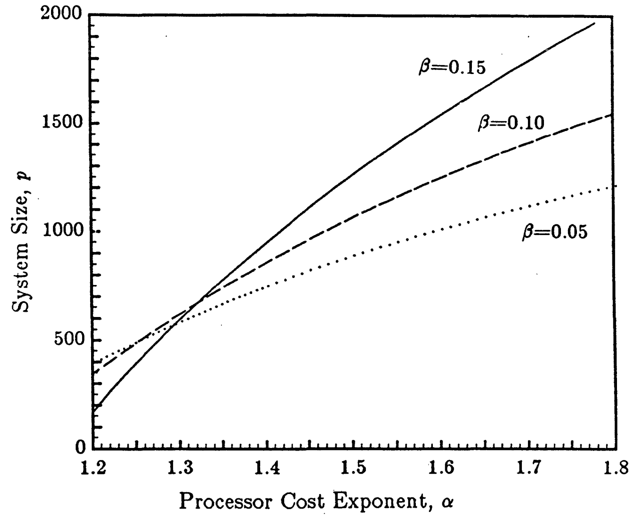

Fig. 3.3. Plot of System Size, $p$, vs. Processor Cost Exponent, $\alpha$. (from (3.7) with $\gamma$=1.4, $s_0$=25.0, $P_0$=1000)

Differentiating (3.4),

$$\frac{dC}{dp} = [1 - \alpha(1 - \beta)].s_0.P_0^{\alpha}.p^{-\alpha(1 - \beta)} + \gamma.p^{\gamma-1} \tag{3.5}$$

Setting (3.5) to zero, we note that there is a solution only if

$$\alpha(1-\beta) \geq 1 \tag{3.6}$$

In Fig. 3.1 a uniprocessor solution is best in the region below the curve. Within this region, if a uniprocessor system with cost $C$ achieves performance $P_1$ and a two-processor system with individual processor cost $C/2$ achieves performance $P_2$, then $P_1 > P_2$. This can be shown by substituting for $s$ from (3.2) in (3.1), assuming that the interconnection cost is zero.

If (3.6) holds, we can set (3.5) to zero and solve for $p$. We obtain the following closed form solution for $p$.

$$p = [P_0^{\alpha} s_0 (\frac{\alpha(1 - \beta) - 1}{\gamma})]^{\frac{1}{[\gamma - 1 + \alpha(1 - \beta)]}} \tag{3.7}$$

From (3.3) we can now find the processor speeds (Fig. 3.2).

In Fig. 3.2, we see that higher performance is best achieved by increasing processor speeds in addition to increasing the number of processors. For higher processor cost exponents, $\alpha$, corresponding to rapidly increasing processor cost versus speed, the same performance is best achieved by a greater number of slower processors (Figs. 3.2 and 3.3). If the cost of interconnecting processors is larger (larger $\gamma$), it is more economical to use fewer and therefore faster, more expensive processors to reduce the interconnection cost at the expense of processor cost (Fig. 3.4).

## 4. CLUSTER SIZES FOR VARIOUS APPLICATIONS

In the previous section, we developed techniques to determine the number of processors and their speeds. In a two-level cluster system, specifying the cluster size completes the processor configuration. If the cluster interconnection has nearly a linear cost-size relationship, the choice of cluster size has little effect on the cost of the system. The choice of cluster size does, however, have a significant effect on interprocessor communication delay. If the cluster interconnection is a multi-stage interconnection network, a cluster size is best determined from performance considerations. Though otherwise identical two-level systems with different cluster sizes may not appreciably differ in cost, there may be a significant cost difference between such a system and a similar system, like the NYU Ultracomputer [11], with a single global memory and no cluster memories. In this section, we propose some methods for determining the best cluster size.

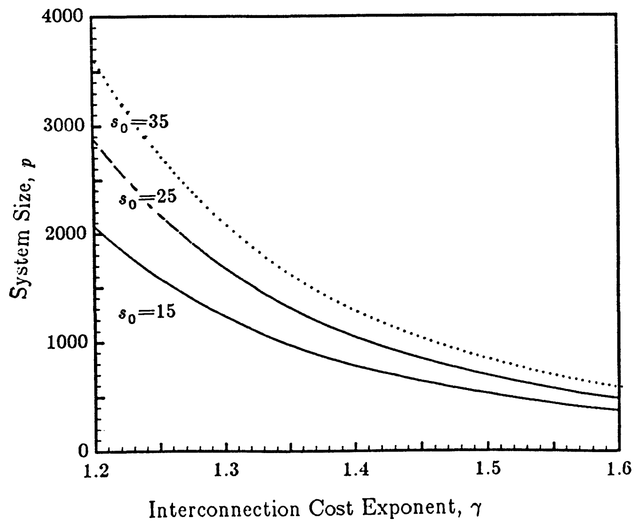

Fig. 3.4. Plot of System Size, $p$, vs. Interconnection Cost Exponent, $\gamma$. (from (3.7) with $\alpha$=1.5, $\beta$=0.1, $P_0$=1000)

### 4.1. Cluster Size from Probability Distribution

We first propose a model for the distribution of references between processors. We assume that all references to cluster and global memory are to communicate between processors in the same cluster and in distinct clusters, respectively. This assumption is not perfectly correct since the cluster and even the global memory may be used to avoid duplication of variables among local memories, which are private to each processor. We choose any processor $p_j$ and determine the distribution of interprocessor communication $c_j(p_i)$ between processor $p_j$ and the other processors $p_i$ in the system. The $c_j(p_i)$ are scaled so that $\sum_i c_j(p_i) = 1$. We assign an integer rank $r_j(p_k)$ to a processor $p_k$ so that $r_j(p_k) = l$ if there are $l$ processors, $p_i$, with $c_j(p_i) \geq c_j(p_k)$. We plot the communication $c_j(p_i)$ versus the rank $r_j(c_i)$ of each processor. We call this the *communication distribution curve* and by definition it is a monotonically non-increasing curve. We assume that such plots for all the processors are identical, i.e. all processors have similar patterns of communication. Additionally, we assume that if we choose a cluster size of $c$, we can obtain a *compatible assignment* of processors to disjoint clusters. In a compatible assignment, for each processor, $p_j$, processors, $p_i$ with rank, $r_j(p_i)$ less than $c$ belong to the cluster containing $p_j$. With such a model, we show that there is an optimum cluster size which minimizes average communication delay.

*Example :* Consider a system of four processors, $p_1$ through $p_4$. Let the fraction of communication between any two processors be specified by the following table.

| **Communication between Processors** (total communication of each processor normalized to 1) | | | | |
|---|---|---|---|---|
| | $p_1$ | $p_2$ | $p_3$ | $p_4$ |
| $p_1$ | | 0.7 | 0.2 | 0.1 |
| $p_2$ | 0.7 | | 0.1 | 0.2 |
| $p_3$ | 0.2 | 0.1 | | 0.7 |
| $p_4$ | 0.1 | 0.2 | 0.7 | |

Table 4.1. Distribution of Interprocessor Communication.

The first step involves selecting a processor, say $p_3$. The next step involves ranking the remaining processors. Since the processor communicating the most with $p_3$ is $p_4$, the rank of $p_4$, $r_3(p_4)$, is 1. The ranks $r_3(p_1)$, $r_3(p_2)$ of $p_1$ and $p_2$ are 2 and 3 respectively. We can now plot the curve of fraction of communication versus rank through the points (1,0.7), (2,0.2) and (3,0.1). Such curves for the other processors are identical to the one for $p_3$. Choosing a cluster size of 2 and assigning $\{p_1, p_2\}$ to one cluster and $\{p_3, p_4\}$ to the second cluster forms a compatible assignment. We note that, by our model, the average communication delay with no cluster memory is $lg\ 4 = 2$. With a cluster size of 2, the average communication delay is $0.7\ lg\ 2 + (0.2 + 0.1)\ lg\ 4 = 0.7 + 0.6 = 1.3$.

Given a continuous communication distribution curve $f(q)$, we can find an optimum cluster size. With cluster size, $c$, the average communication delay, $D_c$ is given by

$$D_c = lg\ c. \int_0^{c-1} f(q).dq + lg\ p. \int_c^{p-1} f(q).dq \qquad (4.1)$$

From the definition of the communication distribution curve, it follows that

$$\int_0^{p-1} f(q).dq = 1 \qquad (4.2)$$

Eqn. (4.1) can thus be rewritten as

$$D_c = lg\ p - (lg\ p\ - lg\ c). \int_0^{c-1} f(q).dq \qquad (4.3)$$

The original objective of $\underset{c}{Min}\ D_c$, given $p$, is equivalent to

$$\underset{c}{Max}\ [(lg\ p\ - lg\ c). \int_0^{c-1} f(q).dq] \qquad (4.4)$$

If $f(q)$ is known, we can determine the cluster size that minimizes average communication delay from (4.4).

We examine the changes in optimum cluster size for a class of communication distribution curves of the form $f(q) = f_0.2^{-\lambda q}$ where $\lambda$ is a parameter and $f_0$ is chosen to normalize $f(q)$. Solving

$$\int_0^{p-1} f_0.2^{-\lambda q}\ dq = 1 \qquad (4.5)$$

we obtain

$$f_0 = \frac{\lambda\, ln\ 2}{1 - 2^{-\lambda(p\ -1)}} \qquad (4.6)$$

Substituting for $f(q)$ in (4.4), the objective is to maximize

$$(lg\ p\ - lg\ c)(\frac{\lambda \ln 2}{1 - 2^{-\lambda(p\ -1)}} \int_0^{c-1} 2^{-\lambda q} dq) \qquad (4.7)$$

Differentiating (4.7) with respect to c, simplifying and setting to zero we obtain the following implicit relationship.

$$lg\ c + \frac{1}{\lambda c. \ln^2 2}(2^{\lambda(c-1)} - 1) = lg\ p \qquad (4.8)$$

Once $p$ and $\lambda$ are known, we can solve (4.8) iteratively for the optimum cluster size, $c$.

Since the choice of cluster size, $c$ is ordinarily constrained to powers of 2, we plot the logarithm of cluster size, $lg\ c$ against the communication exponent, $\lambda$ (Fig. 4.1). When the communication exponent, $\lambda$ is large, a large proportion of the interprocessor communication is to a few processors. In this case, it is best to choose a small cluster size, $c$. A larger cluster size will slow down all references and will not sufficiently increase the fraction of total interprocessor communication satisfied directly by the clusters.

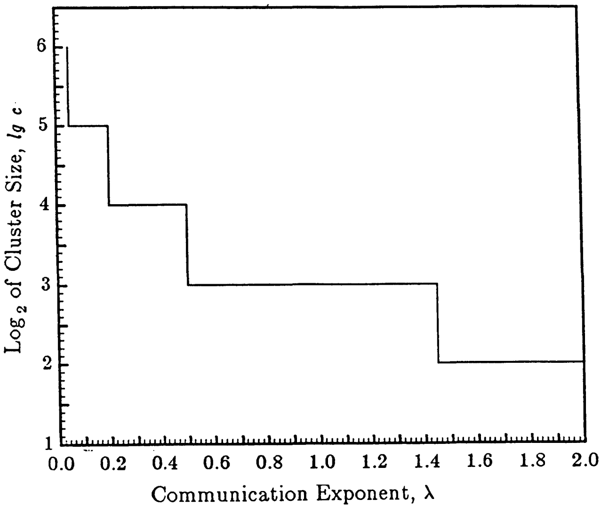

Fig. 4.1. Plot of Cluster Size, $c$ vs. Communication Exponent, $\lambda$ (p = 512).

### 4.2. Cluster Sizes for Fixed Degree Networks

A hierarchical multiprocessor has been proposed as a general purpose multiprocessor, with respectable efficiency over a range of applications. We consider a class of applications, which is frequently encountered, namely problems having a pattern of communication in which each node communicates to a fixed number of neighboring nodes. The communication graph for this class of problems is regular with a fixed degree, $d$. Additionally, we require that a network of size $p$ be reducible to a network of size $p/c$, so that $c$ nodes in the original network are mapped onto a single node in the reduced network and the reduced network belongs to the same class of networks. In [12], the computation factor, $f_c$, is defined to be the number of nodes mapped onto a single node and the exchange factor, $f_e$, is defined to be the number of links that map onto a single link. For the restricted class of networks and reductions under consideration, the computation factor, $f_c$ is always $c$ since we map networks of size $p$ to $p/c$ clusters, each with $c$ processors. For fixed degree networks, the exchange factor, $f_e$, lies between 1 and $c$. This technique is described further in [12].

Many common networks satisfy these requirements. For instance, each node in a mesh (Fig. 5.2) has four neighbors regardless of the size of the mesh. A mesh can be reduced to a smaller mesh, by coalescing square meshes of size $\sqrt{c}$ by $\sqrt{c}$. The computation factor $f_c$ is $c$ and the exchange factor $f_e$ is $\sqrt{c}$. For a mesh, the degree of reduction, $c$, changes the compute/communication balance at the global level by a factor of $f_e/f_e = \sqrt{c}$. In general, the improvement of a hierarchical system over a multiprocessor system with a single global memory depends on this ratio for the application. There are many applications and algorithms having a mesh-like pattern of communication. It may be best to execute such an application on a mesh, but a mesh may not be adequate for other algorithms that have other patterns of communication. A single hierarchical multiprocessor may adequately support a broad range of other patterns.

A multiprocessor system with a single global memory has a communication delay of $lg\ p$. Adding a cluster interconnection to such a system for faster communication between processors within a cluster involves an additional cost which must be justified by performance improvement. We require that a hierarchical system with the same number of processors have an average delay of $(lg\ p)/k$, where the $k$ divisor is intended to compensate for the additional cost of the cluster interconnection and memory. With such a requirement, we show that some range of cluster sizes can be excluded from further consideration for the class of applications described in the first paragraph of this section. We are able to exclude both very small and very large cluster sizes, by making a few assumptions on the workload.

We can now measure average communication delay for a hierarchical system with clusters of size $c$ as

$$D_c = \frac{a_c.lg\ c + a_g.lg\ p}{a_c + a_g} \tag{4.9}$$

where $a_c$ and $a_g$ are the number of cluster and global accesses respectively. We require

$$D_c \leq (lg\ p)/k \tag{4.10}$$

The nodes within a cluster of size $c$ make a total of $d.c$ accesses, since the communication graph has degree $d$. Since the reduced communication graph has degree $d$ with $f_e$ links of the original graph mapped onto each link in the reduced graph, the mapping of nodes onto clusters causes each cluster to make $d.f_e$ global accesses to other clusters. The number of accesses that are served within a particular cluster is $d.c - d.f_e$. From (4.9) and (4.10),

$$D_c = \frac{(d(c - f_e).lg\ c + d.f_e.lg\ p)}{d.c} \leq \frac{lg\ p}{k} \tag{4.11}$$

Solving for $lg\ c$ in (4.11),

$$lg\ c \leq (\frac{c - k.f_e}{k(c - f_e)})lg\ p \tag{4.12}$$

This relationship is always satisfied if $k = 1$, because the average communication delay can be no worse than $lg\ p$. For $k > 1$, it cannot be satisfied when $c > p^{1/k}$. With a cluster size larger than $p^{1/k}$, an average delay greater than $(lg\ p)/k$ is to be expected, because even cluster reference delay is more than $(lg\ p)/k$. Since $c > f_e$, if $c < k.f_e$ the right hand side in (4.12) is negative, requiring the cluster size to be less than one (an impossibility). So a lower bound on cluster size is $k.f_e$. In general, $f_e$ is a function of $c$. For a mesh, $f_e$ is $\sqrt{c}$ and the lower bound on cluster size is $k^2$. These results can be summarized as

$$k.f_e \leq c < p^{1/k} \tag{4.13}$$

Tighter upper bounds on the cluster size, $c$ can be developed if the exchange factor is known. In Fig. 4.2, we plot upper and lower bounds on $c$ obtained by an iterative solution of (4.11) with $f_e = \sqrt{c}$ and $k = 1.5$. For system sizes smaller than 64, no choice of cluster size can yield the desired improvement factor.

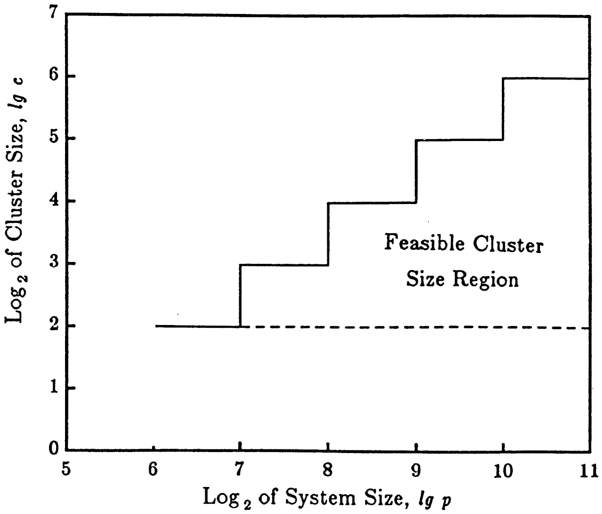

Fig. 4.2. Feasible Cluster Size Region vs. System Size, $p$ for a Mesh with Improvement Factor, $k = 1.5$.

We note that these bounds are independent of the degree of the network. In this section, we have been concerned with the efficiency with which a hierarchical multiprocessor can support the communication requirements of algorithms and the extent to which this can be improved by using clusters. A related problem is to determine how well such a system can emulate the communication links of other processor networks. The results in section 4.2 are equally applicable to processor networks and essentially state that very small and very large cluster sizes can be excluded from consideration.

## 5. EMULATION OF PROCESSOR NETWORKS

In this section, we consider the emulation of some common processor interconnections on a hierarchical system. We show that the average communication delay is minimized by an appropriate cluster size.

We outline the general technique used in the subsequent subsections on specific processor networks. In each case, we consider a processor network with $p$ processors and a two-level hierarchical system of the same size. For some scheme of mapping the processors in the network onto the clusters in the two-level system, we find the ratio of cluster to global accesses as a function of the cluster size. We then use (4.9) to find the best cluster size and its average communication delay. In general, it is difficult to find the best mapping from a network to a two-level system. However, since the networks considered are regular, the best quotient mappings are obvious.

### 5.1. Ring Network

Consider the emulation of a ring of size $p$ on a two-level hierarchy. We divide a ring into $p/c$ segments each containing $c$ processors. We map the processors in each segment of length $c$ onto the processors in a single cluster of size $c$. Consider a typical communication pattern in which each processor in the ring accesses its left neighbor. There are then $c$-1 cluster accesses for each global access (Fig. 5.1). It is easy to see that no other mapping scheme can result in a larger ratio of cluster to global accesses.

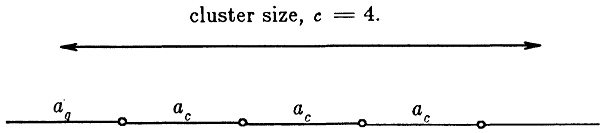

Fig. 5.1. Mapping a Ring Segment onto a Cluster of Size, $c$ = 4.

Substituting for cluster and global accesses in (4.9),

$$D_c = \frac{(c - 1)lg\ c + lg\ p}{c} \qquad (5.1)$$

Differentiating (5.1) with respect to $c$, setting to zero, and solving for $lg\ p$,

$$lg\ c + \frac{c - 1}{\ln 2} = lg\ p \qquad (5.2)$$

We can solve (5.3) iteratively for $c$, or if $c >> 1$ and $c >> lg\ c$, we can approximate (5.2) as

$$c_{opt} = \ln 2.lg\ p \qquad (5.3)$$

With a cluster size of $\ln 2.lg\ p$, the average communication delay is

$$D_{c_{opt}} = (lg\ lg\ p + \frac{\ln\ln 2}{\ln 2})(1 - \frac{1}{\ln 2.lg\ p}) + \frac{1}{\ln 2} \qquad (5.4)$$

For large systems, this can be approximated as

$$D_{c_{opt}} \approx lg\ lg\ p(1 - \frac{1}{\ln 2.lg\ p}) \qquad (5.5)$$

The delay here is a logarithmic factor better than in a system with no clusters and a single global memory.

### 5.2. Mesh Network

Consider the emulation of a toroidal mesh with dimensions $\sqrt{p}$ by $\sqrt{p}$ on a two-level hierarchical system. We map a sub-mesh of size $\sqrt{c}$ by $\sqrt{c}$ onto a cluster of size $c$. Assume (without loss of generality, by symmetry) that all the processors in the mesh access their left neighbors (Fig. 5.2). The number of cluster accesses, $a_c$, is $\sqrt{c}(\sqrt{c} - 1)$ and the number of global accesses, $a_g$, by processors in the cluster is $\sqrt{c}$. Substituting in (4.9),

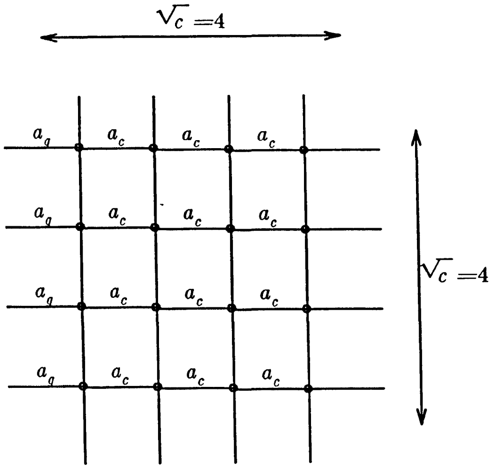

Fig. 5.2. Mapping a Sub-mesh onto a Cluster of Size, $c$ = 16.

$$D_c = \frac{\sqrt{c}(\sqrt{c} - 1)lg\ c + \sqrt{c}lg\ p}{c} \qquad (5.6)$$

Differentiating with respect to $c$, setting to zero, and solving for $lg\ p$,

$$lg\ c + \frac{2(\sqrt{c} - 1)}{\ln 2} = lg\ p \qquad (5.7)$$

We can solve (5.9) iteratively for c or if $\sqrt{c} >> 1$ and $\sqrt{c} >> lg\ c$, (5.7) simplifies to

$$c_{opt} \approx (\frac{\ln 2}{2})^2 lg^2 p \qquad (5.8)$$

For large systems, the average delay ignoring small constant terms is

$$D_{c_{opt}} = lg\ lg\ p(1 - \frac{2}{\ln 2.lg\ p}) \qquad (5.9)$$

In order to obtain a logarithmic improvement in communication delay, the cluster size has to be quite large compared to the results for a ring.

### 5.3. Hypercube Network

Consider emulating a $lg\ p$-dimensional hypercube with $p$ processors on a hierarchical system. The interconnection scheme in a hypercube is best described with a binary numbering of the processor nodes. Processors whose binary numbers differ in exactly one digit are connected by direct links. Under our model, the average communication delay of a multiprocessor interconnection strategy is the $\log_2$ of the number of links per processor. Since each processor node is connected to $lg\ p$ processors by direct links, the hypercube has an average communication delay of $lg\ lg\ p$.

We map the processors in a hypercube onto a two-level system in the following manner. A $lg\, p$-dimensional hypercube can be split into two smaller hypercubes of dimension $lg\, p - 1$, by removing the links connecting processors differing in a particular digit (for instance, all links connecting processors whose numberings differ in the leftmost digit). Since $c$ is usually a power of 2, the hypercube can be divided into $p/c$ smaller hypercubes of dimension $lg\, c$ and each of these can be assigned to a cluster of size $c$. In order to analyze the average communication delay, we assume that a hypercube is equally likely to use any of its links. Of the $lg\, p$ links available to each processor, $lg\, c$ are mapped within the cluster. Hence, the average communication delay from (4.9) is

$$D_c = \frac{lg\, c . lg\, c + (lg\, p - lg\, c) lg\, p}{lg\, p} \qquad (5.10)$$

By analysis as above, the best choice of cluster size is

$$c_{opt} = p^{1/2} \qquad (5.11)$$

The delay for this cluster size is

$$D_{c_{opt}} = \frac{3}{4} lg\, p \qquad (5.12)$$

This delay is not substantially superior to the $lg\, p$ delay for a global memory multiprocessor with no clusters and it is factor of $\frac{3 lg\, p}{4 lg\, lg\, p}$ worse than the hypercube itself.

## 6. CONCLUSION

We have developed simple models for the components of a hierarchical multiprocessor system. A two-level hierarchical system can be specified by the total number of processors, the speed of individual processors, and the size of the cluster. Based on these models, we developed expressions for the optimum number of processors and their speed. Optimum cluster size is application dependent. If the communication probability distribution curve for an application is available, we can find the cluster size which will minimize interprocessor communication delay. For a broad range of problems, we find that we can classify certain ranges of cluster sizes as unsuitable. The choice of a suitable cluster size can minimize the average communication delay when emulating certain processor networks.

While we could use more elaborate models in our analysis, we would not have relatively simple expressions as we have now. Some tradeoffs are quantified easily using the current models: the tradeoff between the cost of the processors and the cost of the communication structure, and the tradeoff between having a large cluster size that contains more references within it and having a smaller cluster size with less communication delay for each intracluster reference. We feel that even though the models are simple they do not unduly favor particular processor configurations.

Average communication delay is a useful metric in choosing a cluster size. However, if the average communication delay is $lg\, lg\, p$, it does not necessarily indicate that the execution times will be degraded by that factor. Frequently a processor can issue a read request and then perform useful computation while the request is being satisfied by the network.

University of Illinois at Urbana-Champaign
Urbana, Illinois 61801

## Abstract

The major issue in multiprocessing is not the construction of a multiprocessor system, but its efficient use in real applications. This paper describes CAMP, a program-development tool that helps a programmer in coding problems for multiprocessors. CAMP can partition programs, insert synchronization primitives, and simulate program performance. This way, a programmer may experiment with different algorithms for solving the same problem and select the one that fits his multiprocessor system the best.

## 1. Introduction

In the past several years we have seen many proposed and commercial multiprocessor architectures, all aimed at increasing machine performance by an order of magnitude. Although, faster hardware is easy to build these days, there is no agreement on how to achieve this performance increase for realistic applications.

There are basically four schools of thought as to what is the most important factor in obtaining higher performance in a particular machine. The first school of thought believes in faster circuit technology, which will allow us to retain present architectures, possibly augmented with a mechanism for synchronizing parallel processes. The second school puts priority on optimizing or vectorizing compilers, possibly interactive, that will detect parallelism and restructure sequential programs into their parallel format. The third school that believes in a dramatic increase in performance from new parallel algorithms supports development of new languages that will allow easy conversion of algorithms into programs. The fourth school supports new models of computation, such as data flow models, that will allow dramatic increases in parallelism and can be easily exploited by a multiprocessor architecture.

Although each school deals with one part of the solution, none of them shows how to optimally combine application requirements with the capabilities of VLSI technology. The first school uses the least risky approach by retaining old programming and architectural models. It takes advantage only of the speed that the new technology offers, not of its density. The second and third schools retain old architectural models, which may no longer be cost effective. Furthermore, the second school retains programming models developed for pre-VLSI architectures. The fourth school, although the most progressive, does not take into account technological limitations. For this reason, machines based on new models of computation do not exhibit impressive performance. Instead, they create new problems on their own.

The current VLSI technology allows building multiprocessors at low cost. However, This multiprocessor approach introduces three new requirements not encountered in the single processor environment [1]. First, each program must be partitioned into tasks executable on one or more processors. If a task is executed on more than one processor, it must be further partitioned into processes. Second, every task and process must be scheduled for execution on a particular processor or processors. Third, synchronization must be performed between concurrently executing tasks and processes to maintain data dependences in the program.

We support a fifth school of thought, which believes that only efficient solutions of the above problems will bring an order-of-magnitude improvement in multiprocessor performance. There are two extreme approaches in achieving this goal. In one, the application programmers (or the problem specialists) are supposed to solve the problem of partitioning, scheduling, and synchronization [2] [3]. Since parallelism is not a natural to human thinking process, this approach may be too cumbersome for all but very simple problems. On the other hand, we may use a restructuring compiler [4] [5] for partitioning, scheduling and synchronization of sequential programs. This approach assumes that such a compiler has good knowledge over wide range of application domains and that the algorithms used in the programs are optimal over different multiprocessor architectures.

We advocate an approach in the middle of the above two extremes. We assume that the programmer is an expert in his application domain. In the mean time,

[a] This work was supported in part by the **Hughes Aircraft Company** under Contract No. 1-5-37368, and the **IBM** graduate fellowship program.

[b] The author's current address: T. J. Watson Research Center, P.O. Box 218, Yorktown Heights, NY 10598.

we also realize the shortcomings of human thinking in a parallel environment. In our approach, the user extracts different segments of the program while a program-development tool helps in partitioning these program segments into a number of processes, and inserting synchronization primitives where needed. The simulator incorporated in the tool estimates the performance for different partitioning and synchronization strategies. This way, the programmer may use the tool repeatedly to explore several algorithms of solving the same problem and select one that fits his multiprocessor architecture. The essence of the computer-aided multiprocessor programming tool (CAMP) is shown in Figure 1. Note that scheduling each process to a physical processor is a runtime procedure. However, partitioning a task into a certain number of processes, each of which is associated with a virtual processor, is performed by the tool.

**Figure 1. The program-development tool**

In this paper, we select a loop example to demonstrate the program-development methodology with CAMP. We describe different partitioning and synchronization methods which have been implemented in CAMP for program loops. Most of the parallelism in scientific computations comes from loop statements. In the parallel execution of a loop, each iteration is usually treated as the smallest unit of execution and assigned to a processor in the lexicographical order of its index set. This method is very effective when all iterations are independent. However, when data dependences exist between different iterations, a proper partitioning and synchronization mechanism must be used to assure fast and correct execution.

The layout of this paper is as follows. In section 2, we will describe the basics of CAMP. Then, in the subsequent sections, we will discuss several methods which have been implemented in CAMP. We will describe the process alignment for eliminating synchronization between concurrent processes, a synchronization method, and different partitioning strategies for program loops in sections 3, 4, and 5 respectively. Finally, we will present results of a walk-through example and propose future research in section 6.

## 2. CAMP: A Program-development Tool

Figure 2 shows the flowchart of CAMP. Each step in a box is performed by CAMP and those steps without boxes are programmers' jobs. All the jobs for the programmers involve either a decision making or the extraction and rewriting of program codes, which we believe human can do better than a machine. Note that in this paper we described only the parts used for developing parallel code for program loops.

**Figure 2. The flowchart of tasks in CAMP**

Initially, a programmer extracts a loop segment from the original program. He determines whether the extracted loop has independent iterations (called a parallel loop). If so, the programmer can transform the loop into parallel format easily and send the parallel code to the simulator. If the loop is not a parallel loop, CAMP will attempt to align the loop to eliminate synchronization between iterations. If this step is successful, the programmer must rewrite the code according to the alignment results before using the simulator.

If the loop alignment is not applicable, CAMP can take two alternative approaches. First, it may partition the loop iteration space into independent execution sets. This method uses the minimum dependence distance in each dimension to divide the iteration space. The detail description of this method is given in [6]. Second, it may partition the loop with a selected synchronization method. In this approach, CAMP generates the partitioning ratio and the synchronization information, which helps the programmer in rewriting the code into parallel execution format.

A simulator has been developed for evaluating different partitioning methods. It generates the simulated execution time in helping the programmer to select the best partitioning strategy. If the original algorithm does not contain enough parallelism, the programmer may want to write a different algorithm. In the following sections, we will describe the process alignment, the bit–map synchronization scheme, and the partitioning of a loop with the bit–map method. All these mechanisms have been implemented in CAMP.

### 3. Process Alignment

The alignment of a program loop was first introduced by Padua for the purpose of increasing the number of independent partitions of a loop [7]. In this section, we will demonstrate the essence of this method by an example for minimizing the synchronization between iterations of a loop.

In the example of Figure 3 (a), there is a *constant dependence vector* [1,–1] between the second and the first statement. This constant dependence vector is due to the occurrence of A(i,j) in $S_2$ (producing a data) and A(i–1,j+1) in $S_1$ (consuming the data). We can adjust the subscripts of either occurrence of array A. Figure 3 (b) shows the adjustment of the first statement by transforming A(i–1,j+1) into A(i,j), and Figure 3 (c) shows the adjustment of the second statement by transforming A(i,j) into A(i–1,j+1). This code adjustment, called the ***process alignment***, has three significant changes:

(1) transformed subscripts in the adjusted statement;

(2) an additional IF test in each statement, and the extended loop bounds for the boundary iterations;

(3) the statement rearrangement to satisfy data dependences.

The details of an improved alignment algorithm is given in [6].

**Figure 3. A loop example and its alignment code**

After the process alignment, the dependence vector became [0,0]. Since the production and consumption of the data is now in the same iteration, the loop can be partitioned by iterations without synchronization between any partitioned set.

### 4. The Bit–map Synchronization Method

Synchronization of concurrent processes can be implemented through shared–variable or through message–passing [8]. There are different shared–variable synchronization methods such as the full/empty bit of the HEP [9], the fetch&add of the Ultracomputer [10], and the synchronization key of the Cedar [11]. In this section, we will describe a shared–variable method called the *bit–map* [12]. In the bit–map method, each synchronization data element has an attached *sync* field, and each memory operation contains a *mask* value. The data can be accessed only when the mask matches the sync. This way a proper referencing order to each data element can be maintained.

The bit–map synchronization method will be explained by using the QD–algorithm for calculating the distribution of the eigenvalues of a large positive definite tridiagonal matrix [13]. (Figure 4) This example contains several constant–dependence vectors: [1,0] for the dependences Q(i,j+1) → Q(i–1,j+1), and E(i,j) → E(i–1,j), [0,1] for Q(i,j+1) → Q(i,j), and [1,–1] for E(i,j) → E(i–1,j+1). We omit the dependence vector [0,0] since it indicates a dependence in the same iteration, which is always satisfied.

The data dependences must be preserved during a parallel execution. They can be preserved if and only if the proper order of memory operations to each memory location is maintained. The sequence of read and write operations to the same memory location, called a *referencing pattern* or RP, is denoted by $(R/W)_n$, ....., $(R/W)_i$, ....., $(R/W)_2$, $(R/W)_1$, where R/W indicates a read or a write operation and subscripts indicate the

```
     DO i = 2, N
        DO j = 0, N-1
S1:         Q(i,j+1) = Q(i-1,j+1) + E(i-1,j+1) - E(i,j)
S2:         E(i,j) = Q(i-1,j+1) × E(i-1,j) ÷ Q(i,j)
        ENDO
     ENDO
```

**Figure 4. The QD–algorithm**

sequence number. This sequence of memory operations is sorted by the indices of the multiple nested loops in which the memory location is referenced. If the memory location is referenced more than once in the same iteration, the referencing pattern will be ordered by the statement number first and inside each statement from right to left. In other word, the referencing pattern is defined by the sequential execution of the loop.

In our loop example, the RP of each read/write variable can be determined by sorting the constants in the first subscript of all the occurrences of that variable in a decreasing order. If more than one occurrence has the same constant in the first subscript, we sort them by the second subscript, and so on. If the constants in all subscripts of several occurrences are equal, then we sort the occurrences based on their sequential execution order. However, for the boundary data elements, some of the operations in a RP may not be performed.

The bit–map synchronization method preserves the RPs even if different processors in a multiprocessor system reference the same memory location out of order. Each synchronized variable has a *Sync* field and a *Data* field. The sync field contains a number of Full/Empty (F/E) bits. Each bit is used independently in the same way as the F/E bit in the HEP machine. The sync field and the data field can be implemented as two separate words in the memory to eliminate extra hardware cost. Every synchronization instruction has a *Mask* field which contains information for both *testing and modifying* bits in the sync field. We define two distinct synchronization instructions: SREAD and SWRITE, which can be expressed as:

$SREAD/SWRITE, Address, Mask.

The Address indicates the shared memory location where the accessed data and its associated sync value can be found. These instructions are implemented by the following *indivisible* sequence of microoperations, where *n* represents the length of the Mask and Sync fields and registers represent temporary storages in each processor.

For the SREAD instruction:

$$\bigwedge_{i=1}^{n} (\text{Mask}_i \text{ OR Sync}_i): \quad \text{Register} \leftarrow \text{Memory(Address)}$$
$$\text{Sync} \leftarrow \text{Mask AND Sync}$$

For the SWRITE instruction:

$$\neg\,(\bigvee_{i=1}^{n} (\text{Mask}_i \text{ AND Sync}_i)): \quad \text{Memory(Address)} \leftarrow \text{Register}$$
$$\text{Sync} \leftarrow \text{Mask OR Sync}$$

Generally speaking, the SREAD instruction tests whether certain bits of the sync field are '1' by ORing the sync field with the mask field and fetching data if the result is all '1's. After data is fetched, tested bits are cleared by ANDing the sync field with the mask. On the other hand, the SWRITE instruction tests whether one or more bits of the sync field are '0' by ANDing the sync field with the mask field and storing data only if the result is all '0's. After data is stored, tested bits are set by ORing the sync field with the mask. Only logical operations are needed in both instructions. Other types of synchronization instructions such as test without modifying the sync, can be easily implemented.

Using SREAD and SWRITE to enforce RPs allows consecutive reads to proceed in any order. In general, each read or write needs one bit in the sync field. If that bit is '1', memory location can be read but not written into, and vice versa. However, since any order of consecutive reads is allowed, the write following these reads needs a number of bits to detect if all the reads have been finished. The number of bits is equal to the number of reads ahead of the write. Whenever a read is successful, its corresponding bit is updated. Note that if there is only one write in the RP, this write can proceed when all the bits for reads become '0'.

For loops with constant dependence vectors, the number of operations in a RP of a read/write variable is equal to the number of occurrences of that variable. In general, each operation requires a bit in the sync field. Therefore, using a separate word for the sync field should be sufficient to synchronize any constant–dependence loop. Figure 5 (a) shows the parallel code of

```

(b)

**Figure 5. (a) The parallel QD–algorithm**
**(b) The RPs and syncs**

the QD–algorithm using the bit–map method. With N = 64, the RPs and syncs of Q and E arrays are shown in Figure 5 (b).

The rule of selecting the initial mask and sync values for this example is very simple. The mask value for a read operation has '0's on the corresponding position for this read as well as on the position for the following write operation. On the other hand, the mask value for a write operation is equal to all '1's. The initial sync value of each memory location can be determined by its RP. The bit position for the first (the rightmost) operation, such as $R_2$ of Q(2..64,0) is enable, i.e. '1' for a read, '0' for write. All other operations are disable. If there are consecutive reads from the first operation, then all these reads are enable. The algorithm of finding the masks and syncs for general cases was given in [12].

Thus, the bit–map synchronization transforms a sequential loop into a parallel one by removing the control dependence and preserving the data dependence. All iterations can be executed in parallel like in any other data–flow model of computation.

## 5. Program Partitioning on Multiprocessors

Using the bit–map method, the QD–algorithm can be executed in parallel. The next issue is how to run this parallel code on a limited number of processors. Two factors must be considered when partitioning a loop into processes: *amount of parallelism* and *memory access and synchronization overhead.* The best partition should exploit the maximum parallelism with the lowest overhead. However, this ideal case is usually impossible to achieve. The partitioning strategy is a tradeoff between these two contradictory goals.

In partitioning program loops, we make two restrictions. First, each iteration of the loop is an indivisible unit of execution, executed sequentially by one processor. Second, the loop can only be partitioned into regular patterns, such as by row and/or by column in a two–dimensional space. Although partitioning at arithmetic operation level and/or partitioning along a wave–front [14] may exploit more parallelism, it introduces unacceptable coding complexity and performance overhead. We propose two ways of partitioning the loop: *block* and *interleaved* partitioning.

We now define a program loop and our partitioning schemes. A *program loop* is denoted by $L = (I_1, I_2, \ldots, I_n)\ (S_1, S_2, \ldots, S_s)$, where $I_i$ is an index variable of the i–th nested level of the loop, $1 \leq i \leq n$; and $S_j$ is an assignment or a conditional statement, $1 \leq j \leq s$. Each index variable consists of three attributes $I_i(\tilde{a}_i, \tilde{b}_i, \tilde{c}_i)$, where $\tilde{a}_i$ is the initial value, $\tilde{b}_i$ is the boundary value, and $\tilde{c}_i$ is increment value of $I_i$. In a loop $L = (I_1, I_2, \ldots, I_n)\ (S_1, S_2, \ldots, S_s)$, assume that dimension $I_i$ is partitioned into p sets. The j–th set of the *block* partition is defined to have:

the initial value $\tilde{a}_{i,j} = \tilde{a}_i + \left\lfloor x_i \times (j-1)/p \right\rfloor \times \tilde{c}_i$
the boundary value $\tilde{b}_{i,j} = \tilde{a}_i + (\left\lfloor x_i \times j/p \right\rfloor - 1) \times \tilde{c}_i$
the increment value $\tilde{c}_{i,j} = \tilde{c}_i$
where: $x_i = \left\lfloor (\tilde{b}_i - \tilde{a}_i + \tilde{c}_i)/\tilde{c}_i \right\rfloor$

while the j–th set of the *interleaved* partition has:

the initial value $\tilde{a}_{i,j} = \tilde{a}_i + (j - 1) \times \tilde{c}_i$
the boundary value $\tilde{b}_{i,j} = \tilde{b}_i$
the increment value $\tilde{c}_{i,j} = p \times \tilde{c}_i$

The block and the interleaved partitioning schemes are initiated by two different considerations. The former tries to minimize memory access and synchronization overhead since synchronization is only perform at the block boundary. The latter tries to maximize the parallelism by interleaving iterations among processors so that all processors can start approximately at the same time.

### 5.1. Partitioning with Different Aspect Ratios

The best way of exploiting parallelism of the recurrence loop example is to execute the loop according to the wave–front direction. On the other hand, the easiest way of partitioning the loop is based on the lexicographical order of the index set. The former method introduces unacceptable overhead while the latter method may not utilize all the parallelism in the loop [6].

We use a general partitioning method which divides each level $i$ of a nested set of loops into different number of partitions, $n_i$. Either the block or the interleaved partitioning scheme can be used in dividing the loop. The proportion of the number of partitions on each level is called the *aspect ratio* (AR). If 4 processors are assigned to execute the QD–algorithm, then three ARs ($n_1$:$n_2$) are possible: 4:1, 2:2, and 1:4. Figure 6 (a) shows the block partition and the processor assignment of the QD–algorithm with AR = 2:2, while Figure 6 (b) shows the interleaved partition, where 1, 2, 3, and 4 indicate four different processors. Note that the AR of 1:4 with the interleaved partition is equivalent to partitioning with the lexicographical order.

There is no extra coding complexity using the aspect ratio of the block and the interleaved partitioning methods. However, the total combination of ARs for a given number of processors $p$ grows with the nested levels of the loop. In a doubly–nested loop, the number of ARs is equal to $(\log_2 p + 1)$, while in a triply–nested loop, the number of ARs is equal to $((\log_2 p + 1)^2 / 2 + (\log_2 p + 1) / 2)$, where we assume the number of processors and the number of partitions are all powers of 2, and $n_i \leq p$.

**Figure 6. (a) The block and (b) The interleaved partitioning with AR = 2:2**

### 5.2. Data Storage Scheme

Parallelism imposed by the data dependence is crucial to the program partitioning. In order to select the best AR, we need to consider another factor: memory access and synchronization overhead. Three types of memory accesses: *local access, local synchronized access,* and *network synchronized access* can be specified for testing the QD–algorithm in a distributed–shared memory multiprocessor system (Figure 7). The local access provides the fastest access time. Data with the exception of read–only data can be localized only if it is not accessed by any other processor. The local memory coherence problem is thus avoided. Data, read and written by more than one processor, can only be accessed through the synchronization instructions described in section 4.

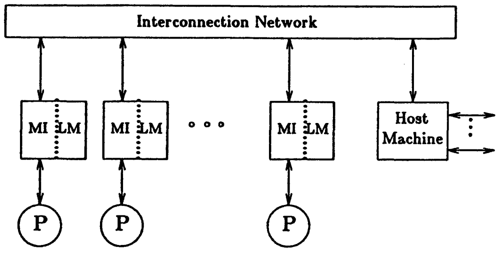

**Figure 7. The model of a multiprocessor system**

Because of the delay in the interconnection network, the synchronized access to any other memory module takes much longer than the synchronized access to the local memory. The data storage scheme is very important in reducing the number of network accesses. For instance, if 4 processors execute the QD–algorithm, with AR = 1:4, and the interleaved partition is used, then $P_2$ will execute iterations (*, 1) and (*, 5), where * stands for all iterations of the corresponding level of the loop. In each iteration, $P_2$ reads the Q array three times (Q(i–1,j+1), Q(i–1,j+1), and Q(i,j)), and writes once (Q(i,j+1)). If we allocate Q(*,1) and Q(*,5) to the local memory of $P_2$, then, only one access to the Q array will be to the local memory. On the other hand, if we allocate Q(*,2) and Q(*,6) to the local memory of $P_2$, then three out of four accesses to the Q array will access to the local memory. Thus, data should be allocated to the shared memory modules according to the allocation of iterations (i.e. the AR) and the subscript expressions of the accessed variable.

In the block partitioning, the type of memory access for each variable may vary from one iteration to another. If the iteration is not located on the block boundary, all the memory accesses in that iteration are local. Otherwise, the memory access can be either a local synchronized or a network synchronized access. The data storage scheme for the interleaved partition is applicable to the block partition.

### 5.3. Aspect Ratio Selection

Because the number of ARs in a three dimensional loop is proportional to $(\log_2 p)^2$, it is very time–consuming to simulate all the ARs for any given number of processors. A heuristic can be used for selecting the best ARs.

The sequential execution time of each iteration of a loop can be computed directly. For example, the starting and ending time for each memory access and arithmetic operation of the QD–algorithm are shown in Figure 8. In it we assume every memory access takes the same amount of time (M), and every arithmetic operation takes time (A). The *time–distance* for each dependence is computed as $t_g - t_n$, where $t_g$ is the data generation time, and $t_n$ is the time that the data is needed. In this example, the time–distance for Q(i,j+1) → Q(i–1,j+1) is 4M+2A; Q(i,j+1) → Q(i–1,j+1) is 0; E(i,j) → E(i–1,j) is 3M+2A; Q(i,j+1) → Q(i,j) is -(2M+A); and E(i,j) → E(i–1,j+1) is 7M+4A. The maximum value of the time–distance is selected for each dependence vector. Those are 4M+2A for [1,0], -(2M+A) for [0,1], and 7M+4A for [1,–1]. If the time distance is less than or equal to 0, it indicates there is no delay caused by the dependence. Therefore, the dependence vector can be omitted. Generally speaking, the time–distance indicates

| Operations | Starting Time | Ending Time |
|---|---|---|
| Fetch Q(i-1,j+1) | 0 | M |
| Fetch E(i-1,j+1) | M | 2M |
| Add | 2M | 2M+A |
| Fetch E(i,j) | 2M+A | 3M+A |
| Subtract | 3M+A | 3M+2A |
| Store Q(i,j+1) | 3M+2A | 4M+2A |
| Fetch Q(i-1,j+1) | 4M+2A | 5M+2A |
| Fetch E(i-1,j) | 5M+2A | 6M+2A |
| Multiply | 6M+2A | 6M+3A |
| Fetch Q(i,j) | 6M+3A | 7M+4A |
| Divide | 7M+3A | 7M+4A |
| Store E(i,j) | 7M+4A | 8M+4A |

M = Memory access time  A = Arithmetic operation time

**Figure 8. The sequential execution of an iteration of the QD–algorithm**

the 'delay' between two iterations with the data dependence between them. We discussed several rules in [6] for reducing this time–distance.

We now describe the algorithm which uses the time–distance for estimating the execution time of a particular AR. The algorithm is demand–driven. First, the execution time of the last iteration of the loop is demanded. This triggers evaluation of the execution time of two groups of iterations. The first group contains those iterations which produce data for the last iteration. The second group contains the iteration which must be executed right before the last iteration because of the sequential execution imposed in the same processor. The first group of iterations can be calculated from the data dependence vectors while the iteration of the second group is determined by the AR and the partitioning scheme. These triggered iterations, in turn, require the execution time of other iterations and so on. This process continues until the iteration space is exhausted or the iteration space boundary is reached [6].

In this heuristic, every memory operation has a constant access time. This assumption is valid for the interleaved partitioning method, since each occurrence of a variable has the same type of memory access for every iteration and can be determined according to the data storage scheme. However, the type of memory access varies for each variable in the block partition. The evaluation algorithm assumes all the memory accesses are local for the block partition. The results from this evaluation indicate the parallelism exploited by different ARs. Next, the number of different types of memory accesses for every AR can be computed. These numbers determine the memory latency. Two ARs are selected for the block partition. One exploits the best parallelism and the other has the lowest memory latency. Both selected ARs along with the best AR of the interleaved partition will run through the simulator to determine the best partitioning strategy.

## 6. Conclusion

We exercised the QD–algorithm with loop bound N = 64 through CAMP. Our simulator has two options for estimating the delay for the synchronization accesses [6]. In option 1, local synchronized access takes 2 units of time and network synchronized access takes 6 units of time. In option 2, local and network synchronized accesses take 3 and 9 units of time respectively.

The QD–algorithm has only one independent execution set and the alignment method is not applicable. Therefore, the partitioning with the bit–map method was selected. The ARs for different number of processors were determined by the evaluation heuristic described in section 5. The simulation results along with the selected ARs are shown in Table 1 and illustrated in Figure 9 in which INT represents the interleaved partition, BKM represents the block partition with minimum memory latency, and BKP represents the block partition with maximum parallelism. We can see that when the number of processors is small, the block partition which maximizes parallelism provides the fastest execution time. However, when the number of processors is greater than 16, the interleaved partition gives the best performance. The block partition which minimizes memory

The sequential execution time = 45056

and synchronization overhead has the worst performance.

CAMP is written in Pascal and runs on a VAX-11/780 under 4.2 BSD UNIX[a] operating system. Presently, the program-development tool uses only a limited number of partitioning algorithms and synchronization primitives. The future plans include additional partitioning schemes especially for the partitioning of the program segments without loops, shown as the dashed boxes in Figure 2. Other useful synchronization primitives such as test&set, full/empty bit etc. could be added to CAMP. Other future work should also include the partitioning and synchronization of programs for message-passage multiprocessors [3].

**Abstract-- To meet increasing demands for computing power, systems must exploit parallelism at all levels. A balance between the processing speeds of a machine's subsystems is critical for overall system performance. In this paper, we describe a queue-based vector supercomputer (QVC) which reduces the fraction of work that the scalar mode must process.**

**The proposed queue-based vector supercomputer has the following characteristics: (1) two level control is used to support out-of-order instruction initiation, (2) multiple classes of registers is provided, (3) one valid bit per vector element is included to exploit flexible chaining, (4) a very short vector startup time (one clock period) is achieved, (5) branch instructions are used only for implementing high level language control structures, (6) elements of a queue may be read repeatedly, and (7) vectorization has been generalized.**

**Several hard-to-vectorize loops from the Livermore Loops are used as the benchmark programs. The preliminary study suggests that the proposed queue-based vector architecture is a cost-effective way to implement a supercomputer for array-oriented programs.**

## 1. Introduction

Queues have been included in many architectures [3,5,20,23,24], intended primarily for high performance numerical applications in scalar mode. Most commercial supercomputers [18,21,7] have some kind of vector buffers (registers) (the Cyber 205 [15] is one exception: vector operations are carried out in memory-memory mode). In this paper, we describe a queue-based architecture for which the notion of a vector register is simply a special case.

This paper is organized as follows. Section 2 motivates the vector processors. Section 3 describes the desired features for a vector processor and presents the proposed queue-based vector supercomputer. Section 4 compares the proposed architecture with the Cray X-MP [7] using some hard-to-vectorized Livermore Loops [17,21] as the benchmark programs. Section 5 has the conclusions.

## 2. Motivations of Vector Supercomputers

It has been repeatedly observed [2,4,11,22,24,28] that for a system with two processing speed modes, the effective execution speed is limited by the slower mode, unless the fraction of workload that has to be done in this mode is nominal. Put differently, a good balance between different processing speeds is critical to the overall system performance. In the numerical supercomputer environment, the *high-speed mode* corresponds to vector operations, the *low-speed mode* to scalar instructions. We must push the limits on both ends to meet ever-increasing computing requirements. An ideal high performance system must not only have a fast scalar mode, but also a vector mode that reduces the fraction of work that must be processed in the scalar mode. The latter can be achieved by architectural innovations which facilitate the vectorization of most array operations.

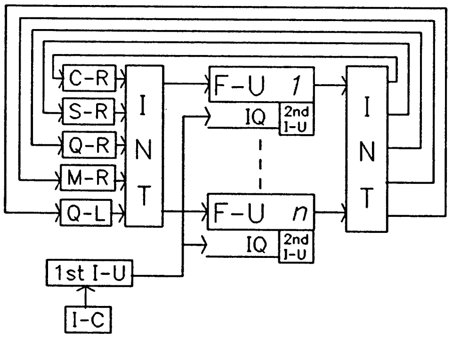
Recently, several queue-based processors [3,5,11,20,24] have been proposed to achieve fast scalar mode. The advantages of a queue-based scalar system have been publicized elsewhere [24,11, 29]. Many array-oriented programs cannot be vectorized, partly because the underlying vector computers do not provide the adequate primitive instructions to generate vector code for many commonly seen vector operations, such as vector inner product. The major goal of the proposed two level control, queue-based vector supercomputer (QVC) is to ease the task of the vectorization of array-oriented programs. Thus, QVC reduces the fraction of work that must be processed in the scalar mode.

The major considerations behind the vector instructions are the following:

1. Flynn bottleneck [9]. The performance of a computer system is sometimes limited by the instruction initiation rate. An issue unit is capable of initiating at most a fixed number (normally, one) of instructions every clock period. If each instruction does too simple an operation, this Flynn limit may become a bottleneck. A decoupled architecture [5,11,20,24] does increase the bandwidth of the instruction issue capability by including multiple (two in all the cases listed above) issue units. Another way of increasing the effective issue bandwidth is to include powerful instructions. Each powerful instruction is able to do many operations. Hence, issuing one powerful instruction can achieve the same effect as issuing multiple relatively simple ones. The issue condition of a powerful instruction, however, does not have to be complex. In the QVC, each powerful instruction (vector instruction) is just a repetition of a simple scalar operation. These vector instructions still enjoy the simple issue condition property of its scalar counterpart.
2. Out-of-order execution. The floating point unit of the IBM 360/91 [26] and the scoreboard of the CDC 6600 [25] are examples of hardware methods to achieve out-of-order execution. Out-of-order execution is an essential part of vector instructions with different vector length and the simultaneous execution of vector and scalar instructions. The vector supercomputer proposed in this study, however, provides out-of-order initiation of scalar instructions (almost) free, in the sense that a scalar instruction is just a special case of vector instruction, *i.e.*, a scalar is just a vector of length one.

## 3. Proposed Architecture

In this paper, we will emphasize the design of the vector mode operation of the QVC. Many functional units are included in the QVC. Each of them is implemented by a linear (fully segmented) pipeline [13] which eliminates the necessity of doing pipeline reorganization and avoids most structural hazards (collisions). Each function unit may either perform a single task (*e.g.*, floating point addition) or be capable of executing several operations (*e.g.*, logical operations). There is an issue unit associated with each functional unit, which checks for the issue conditions. Except for the Load/ Store instructions, all operations are carried out in a register-register fashion. The availability of the operands determines the issue conditions of the register-register instructions. For performance measurement purposes, we compare the QVC with a single CPU of a Cray X-MP having an identical set of function units (see section 4).



The terms used in the figure are explained below:
C-R: Constant Registers
S-R: Scalar Registers
Q-R: Queue Registers
M-R: Mask Registers
Q-L: Queue Length Registers
I-C: Instruction Cache
INT: Interconnection Network
1st I-U: First Level Issue Unit
2nd I-U: Second Level Issue Unit
IQ: Instruction Queue
F-U *i*: the *i*-th Functional Unit

**Figure 1: The Organization of a Processor with *n* Functional Units.**

[1] The work described here was done while this author was at the University of Wisconsin-Madison.

The desired vector properties include flexible memory-referencing instructions, arithmetic/logic operations, vector editing instructions and the easily-vectorizable properties. By easily-vectorizable properties, we mean that vector operations are applicable to the programs which are not vectorizable on the current supercomputers. Regular arrays should be treated effectively, while sparse arrays must be handled with reasonable efficiency. We suggest that all the registers be shared by all functional units. We also want to be able to intermix vector instructions with scalar ones. For example, vector A is loaded into a queue-register by a vector load instruction, but entries of A are consumed by different scalar instructions. Figure 1 illustrates the QVC with *n* functional units.

### 3.1. Vector Instruction Format

A vector instruction has the following format:

```
repeat $m$ $n$
    inst$_1$;
    ...
    inst$_m$;
```

The semantic of the above repeat statement is to execute the instruction group, inst$_1$ to inst$_m$, *n* times, where each *inst* represents a simple scalar instruction and all instructions within an instruction group use the same functional unit. The size of an instruction group (*i.e.*, *m*) is a compile time constant, while the length of a vector (*i.e.*, number of iterations) is specified by one of the queue length (QL) registers and the "repeat" instruction selects the appropriate queue length register. If the length of the vector is known to be 1, at compile time, the repeat statement is not needed. This is how we use the scalar mode of this architecture.

### 3.2. Operand Register (Queue) Sets

In addition to the status registers (*e.g.*, the queue length register just mentioned), four sets of operand registers are included:

1. Constant scalar registers. Rationale for these registers is provided elsewhere [29]
2. Scalar registers. They are just like general purpose registers in most computer architectures.
3. Queue registers. Queue registers are a set of registers, each of which is a queue. They are rationalized in the following section.
4. Mask register. Mask registers are similar to the queue registers in that they are also implemented as queues. The major difference is that each element of a mask register has only one bit.

Any one of the scalar registers or the queue registers can be used as a destination/source register of memory accessing instructions. The memory interface is treated as one functional unit.

The mechanism to handle different data dependency hazards (RAW, WAR, WAW) for queue/mask registers is detailed elsewhere [29].

### 3.3. Queue Registers

. Queue registers are a set of registers, each of which is a queue. Only limited elements (*i.e.*, the head and tail of the queue) are accessible from outside. A queue register is the hardware implementation of a "stream". Thus operands in a queue register must be accessed in a predefined order. Each queue register is implemented as an array of registers. There is a *valid bit* associated with each element of the queue register to indicate the data availability of the designated element. Two pointers are associated with each queue register. They point to the head and the tail of that particular queue. A queue may have three possible states--Full, Empty, and Normal--which can be checked by examining the appropriate valid bits. When a queue is full, an attempt to put an operand onto that queue will be blocked.

Similarly, reading from an empty queue is also blocked. One of the advantages in having one valid bit per element is that a queue register can temporarily hold a vector which is longer than the queue size, as long as there are other instructions that take operands out of the same queue register. This valid bit per element scheme also makes chaining more flexible, because the speed of the consumer and the producer does not have to be identical, *i.e.*, chaining can be performed in an asynchronous fashion. A similar scheme is used by the Hitachi S-810 [19] to allow flexible chaining. The QVC has the flavor of dataflow machines [8] except that the issue unit checks for data availability, rather than the data availability "firing" the operation. Thus, function units can operate in parallel as much as possible. We call this organization a *control-driven dataflow* computer architecture. This control-driven dataflow scheme is more flexible than that of most traditional supercomputers in the sense that data availability is checked on an element by element basis, even for vector operands. Hence, the operation of chaining is more flexibility than in the case where data availability is checked at the vector level. On the other hand, the overhead of the dataflow approach [10] is avoided.

One of the characteristics of queues is that an element of a queue is discarded after it has been read. There are cases in which we want to use an operand (a scalar or a vector) more than once. Therefore, we include three access modes in reading from a queue: (a) *destructive* mode; (b) *non-destructive* mode; and (c) *circular* mode. In destructive mode, a read operation removes the first element from the queue register. In non-destructive mode, the first element of a queue remains after a read operation, *i.e.*, a queue can be (non-destructively) read many times while its contents are not changed. In circular mode, the entire queue remains unchanged after each element has been accessed. Sometimes, the access mode is determined at run time based on the (partial) result of an instruction (*e.g.*, compare two queue registers). Since a queue register is implemented as an array of elements with two pointers, a different access mode simply suggests a slightly different interpretation in updating the pointers.

### 3.4. Two-Level Control

A two-level instruction initiating scheme is adapted in this design. The global first level issue unit decides branch outcomes and sends non-branch instructions to the proper instruction queues which are associated with the second level issue unit. For each function unit, there is an instruction queue and a second level issue unit. Each second level instruction issue unit initiates instructions in the order they were sent to the instruction queue (*i.e.*, the original machine code textual order). Instructions in different second level instruction queues, however, may be initiated in a different order than that in which they passed the first level issue unit. The second level issue unit checks for data availability and issues instructions accordingly. The implication of this two-level initiating scheme is that it takes two clock periods to issue a non-branch instruction, *i.e.*, the work of instruction initiating is divided into two stages of the pipeline. However, this scheme does not introduce extensive delay. The delay of the additional clock period in the decoding logic slows down a section of straight line code by at most one clock period. Since the branch decision is made by the first level issue unit, there is no execution time penalty even across basic blocks, as long as the expressions that participate in the branch decision are evaluated earlier, which can normally be done by properly scheduling the code (see, for example, [29]). Thus, in the best case, the penalty introduced by this two-level control scheme is one clock period per program. The worst case penalty, however, is one clock period per basic block. On the other hand, the first level issue unit sends a partially decoded instruction to the instruction queue associated with the appropriate function unit. In other words, the decoding is done in two stages (the first level issue unit and the second level issue unit). If the instruction decoding time of the original design determines the clock period, the two level decoding scheme may imply a faster clock rate, because the instruction decoding is done in two pipeline stages. The startup time of a vector instruction is just the time for the first level issue unit to send a "repeat" statement to the appropriate second level issue unit, which normally takes one clock period.

The first level issue unit is blocked only because of either (a) a branch instruction, which can be alleviated by the prepare-to-branch [11] scheme, or (b) a full instruction queue of the corresponding functional unit. The functionality of this proposed two level instruction initiation scheme is similar to Tomasulo's algorithm [26] except that instructions that use the same functional unit are executed in program order. In [29] a comparison was made to compare the performance of the two-level scheme with that of Tomasulo's algorithm using the example given by Weiss and Smith [27] in studying various instruction initiation schemes. In this example, the two-level scheme and the Tomasulo's algorithm perform equally well. The former, however, avoids the potentially expensive associative search used in the Tomasulo's algorithm.

### 3.5. Vector Load/Store

Studies [4,16] have shown that the relative ratio of vector load/store with unit stride, non-unit stride, and random access is about 70% : 20% : 10%. Thus, the vector load/store instruction has to support accessing random elements of an array. A repeated load/store with autoincrement can be used to access elements separated by a constant stride. A random access is normally represented by an additional level of indirection, *i.e.*, the addresses of the needed elements are put in another array. This random access is supported by the following two vector instructions: (a) put addresses of needed elements onto a queue register (call it %Q*q*); and (b) do a vector load using addresses in %Q*q*.

Simultaneous vector load/store operations may cause undesirable memory overlap hazard conditions (that is, read before write or write before read). One solution for eliminating such hazards is to have a smart memory system detect the conflicts. Another way is to have the software determine the cases where the hazards may occur and assure sequential execution whenever necessary.

### 3.6. Comparison Instructions

The contents of a mask register can be loaded by doing an element-by-element vector comparison. Given two vectors **A** and **B** of length *n*, the result of the vector comparison is stored in **M**. The semantics are that $M_i$ gets the comparison result of $A_i$ and $B_i$. The result of a comparison, then, is treated as an ordinary operand. We term such comparison a *logical* one in the sense the result of the comparison, rather than one of the operands, is returned. This scheme is used by some supercomputers (*e.g.*, Cray-1) to set up a mask register.

The scalar logical comparison is useful in evaluating Boolean expressions without using branches. *i.e.*, logical instructions such as AND, rather than branches, are used to evaluate complex Boolean expressions. Branches are needed only to construct high level program structures.

There are cases where one of the operands involved in the comparison, rather than the logical comparison result, is needed. We propose another set of comparisons called *contents* comparisons. This corresponds to the if-expression in some programming languages. The (vector) contents comparison is generally useful in coping with sorting-related problems.

### 3.7. Vector Editing Instructions

Different vector editing instructions can be realized by the repeat statements (vector instructions) with slightly different accessing modes described earlier. It is also possible to include scalars within a vector editing instruction. Merge (combining two vectors into one) and split (the opposite of merge) can also be carried out by two repeat-statements with proper adjustments to the mask register.

The different vector editing functions available in the commercial supercomputers are nicely surveyed by Hwang and Briggs [12]. We make no attempt to specify all vector editing instructions completely in this paper.

### 3.8. Intrinsic Functions

Some vector operations, such as vector sum (the summation of all elements in a vector), are inherently difficult to vectorize. One possible way to cope with these hard-to-vectorize operations is for the compiler to generate scalar instructions [6] which implies relatively low performance. Another possible approach is to include a large set of vector macro instructions and hope that most hard-to-vectorize operations are covered by the vector macros [15]. In the QVC, most vector macros can be composed by several of its vector instructions. The realization of the following vector macros can be found in [29]: (a) vector sum; (b) inner product; (c) linear recurrence; (d) maximum/minimum; (e) search; and (f) sorting.

We believe that most, if not all, programs can take advantage of this queue-based vector supercomputer. However, advanced compiler techniques are required to fully utilize the potential parallelism provided by this proposed architecture.

## 4. Performance Evaluation

In this section, we compare the performance of a single CPU of a Cray X-MP [7] with a similar architecture with the proposed extension. In particular, there are the same number of vector registers in the Cray X-MP as the queue registers in the QVC. The identical set of function units are included in both the Cray X-MP and the QVC. For QVC, we assume two sets of execution times for the functional units. One is that the execution time (in terms of clock period) of each functional unit in the QVC is identical to that of the Cray X-MP. The other is to include an additional delay of one clock period when the data is sent through the interconnection of the QVC (*i.e.*, two additional clock periods are added to a register-register operation). One last point is that we ignore the delays because of memory bank conflict, *i.e.*, we assume the data are nicely distributed in the memory banks and all memory access requests are serviced in a predetermined amount of time (*i.e.*, 14 clock periods to do a scalar load).

Riganati and Schneck [21] summarize the supercomputer performance reported on Livermore Loops. The execution speed of loops 4, 5, 6, 11, 13, and 14 are slower than other loops. In fact, the performance of these 6 loops is below 50 mega *flops* (floating point operations per second). In other words, if the Livermore Loops are used as the workload, the execution time of the aforementioned loops dominates the total execution time. Loop 5 and loop 6 are essentially the same provided the compiler does the induction variable analysis [1]. Therefore, we use loops 4, 5, 11, 13, and 14 as the benchmark programs.

| Loop | Cray | Cray(SP) | QVC | QVC+ |
|---|---|---|---|---|
| 4 | 2778 | 1569 | 1028 | 1380 |
| 5 | 18129 | 15148 | 12963 | 16948 |
| 11 | 20261 | 12275 | 6009 | 8008 |
| 13 | 13090 | 12066 | 1386 | 1410 |
| 14 | 22736 | 20636 | 3645 | 3753 |

Table 1. The Execution Times for Different Configurations.

In Table 1, the execution times (in clock periods) of the 5 loops on 4 different configurations are shown. There are two columns associated with the Cray X-MP. The "Cray" column has the execution times of the loops while the scalar scheduling is done within the loop boundary -- we do not employ "loop carry-over" optimizations, such as loop unrolling, other than the ones specified in the source Fortran code. The "Cray(SP)" column has the execution times where the software pipelining[2] (using the algorithm described in [29]) technique is applied. The "QVC" column has the execution time of this queue-based vector computer. The "QVC+" column has the execution time of the QVC, while an additional clock period is needed for an operand to "penetrate" through the QVC's interconnection network. We apply some known optimization techniques, by hand, to the Cray code. In particular, we try to partially vectorize the loops whenever appropriate. For example, the floating point multiplication of loop 4 (X(LV)*Y(J)) is carried out using vector instructions. Also, vectors **Y** & **Z** of loop 5, vector **Y** of loop 11, vectors **P(1,IP)** & **P(2,IP)** of loop 13, and vectors **GRD**, **VX**, & **XX** of loop 14 are *block-preloaded* into the appropriate vector registers using the vector load instructions. That is, we use the vector registers as data buffers between the processor and the memory system whenever appropriate.

For loop 4, the QVC outperforms the Cray X-MP primarily because of the following:

- Mixed mode operation. In th Cray X-MP, scalar instructions must be used to get an element from a vector register. Three instructions (a vector to scalar move, an increment to the index register, and a branch instruction) are needed for each result stored in a vector register. In other words, the overhead to get an element out of a vector register is in the order of 10 clock periods. (The execution time of the vector register to scalar register data move instruction [076*ijk*] is 4 clock periods.)
- Branches. Because we cannot express a linear recurrence in a vector form on the Cray X-MP, branch instructions are used to carry out the loop. The overhead may be as many as 5 clock periods per iteration (for an in-buffer condition).
- Chaining. The first element of the vector operation results, stored in a vector register, cannot be taken from a vector register until the vector operation has completed. The chaining on the mixed mode operation is not flexible enough.

For loops 5 and 11, the difference in the execution time comes from the following:

- Mixed mode operation. Though loop 5 is hard to vectorize due to the first order linear recurrence, arrays **Y** and **Z** should be able to be "block-preloaded" into some vector registers. Because the vector mode and the scalar mode on the Cray X-MP are not readily compatible (*i.e.*, additional move instructions are needed to move each element from a vector register to a scalar register), the mixed mode operation can not be carried out efficiently.
- Branches.
- Store. In the Cray X-MP, a store instruction cannot be issued until the result is available. In the two level control scheme, however, the first level issue unit can issue a store instruction as long as the instruction queue associated with the store functional unit is not full. Therefore, instructions following the store instruction can be issued, by the first level issue unit, even before the operand for the store instruction has been computed. Thus less instruction blockage will occur in the two level control scheme than in the one level control scheme.
- Loop unrolling. The source code of loop 5 is unrolled three times. Because of the limited number of S registers in the Cray X-MP (8 of them), some instruction issuing blockages come from the static register assignment. As stated in [29] that queues provide the dynamic register assignment property. Thus, unnecessary data dependencies, owing to static register assignment, can be avoided.

Software pipelining, however, overlaps the time of the mixed mode operation (load from a vector register), the branches, and the store instruction blockages. Thus, for loops 4, 5 and 11, the performance improvement due to software pipelining is significant.

| Loops | QVC : Cray | QVC : Cray(SP) | QVC+ : Cray(SP) | QVC : QVC+ |
|---|---|---|---|---|
| 4 | 2.70 | 1.53 | 1.14 | 1.34 |
| 5 | 1.40 | 1.17 | 0.89 | 1.31 |
| 11 | 3.37 | 2.04 | 1.53 | 1.33 |
| 13 | 9.44 | 8.71 | 8.55 | 1.02 |
| 14 | 6.24 | 5.66 | 5.50 | 1.03 |

Table 2. The Relative Performance for Different Configurations.

[2] One simple kind of software pipelining is the pre-loading and post-storing of operands.

The discrepancy in the execution times of loops 13 and 14 comes from the following:

- Memory indirection load. Memory indirection load is not well supported in Cray X-MP.
- Scalar variable expansion [14]. A scalar variable can easily be expanded to a vector in the QVC by allocating such a scalar in a queue-register. By so doing, the variable from different iterations occupies different locations in a queue-register.

Two major constraints that also limit the performance of loops 13 and 14 on the QVC are:

- Number of functional units. The performance is bounded by the number of load and floating point addition pipes. This can be remedied expensively by adding functional units to the processor. The additional functional units, however, may slow the clock cycle down.
- Data conversion. It takes several instructions to do data format conversion between integer and floating point number. This, however, is not an essential limit of the architecture. If data conversion happens frequently, we can add a special data conversion pipe to the architecture.

In Table 2, we compare the relative performance for different configurations. Looking at the QVC+ : Cray(SP) column, we find that the Cray X-MP outperforms the QVC+ only for loop 5. The data dependency graph of loop 5 is very deep, *i.e.*, every instruction depends on the result from the previous instruction. In other words, the data dependency, rather than the issue unit, limits the execution speed. Thus, the QVC with additional delay runs slower than the Cray X-MP. In most cases, however, the advantage of the two level control and the queue-based vector register still outweighs the delay going through the interconnection. Looking at the QVC : QVC+ column, we find that for loops 4, 5, and 11, where the execution time is limited by the data dependencies, the performance penalty introduced by the one clock period delay going through the interconnection is about one third. (Recall that the execution times of a floating point addition and a floating point multiplication are 6 clock periods and 7 clock periods, respectively. The time to go through two interconnections [one on the input side, the other on the output side] is 2 clock periods, which is about one third of the execution times of the floating point operations mentioned above.) On the other hand, for loops 13 and 14, where the execution time is limited by the availability of the functional units, the performance penalty caused by the delay in the interconnection is between 2% and 3%.

For highly vectorizable loops (*e.g.*, loop 7), the performance is limited by the availability of the functional unit. In this case, the extra clock period delay going through the interconnection will slow down the entire system by only a small fraction.

## 5. Conclusions

This queue-based vector supercomputer supports out-of-order instruction initiation and flexible vector chaining. Its simple vector instruction format implies very short vector startup time (one clock period). This simple format, however, is very powerful to use with the queue registers and different access modes. As demonstrated earlier in this paper, many array-oriented programs are vectorizable under this proposed architecture. The destination non-blocking interconnection network avoids the unnecessary result bus conflicts in the case where a shared result bus is used for all functional units (in Cray X-MP, all results going to S registers share the same bus). Branch instructions are needed only to carry out the high level language control structures by introducing the logical/contents comparison. Access modes are provided so that it is possible to read the elements of a queue repeatedly in a variety of ways.

The preliminary study suggests that this proposed architecture is a cost-effective way to implement a processor for array-oriented programs. The major remaining problem is the design of compiler techniques to fully utilize the suggested features automatically.

## ABSTRACT

To satisfy the growing need for computing power, a high degree of parallelism will be necessary in future supercomputers. Up to the late 70s, supercomputers were either multiprocessors (SIMD-MIMD) or pipelined monoprocessors. Future industrial realizations should combine these two levels of parallelism. In a multiprocessor, classical pipeline controls become inefficient because the interdependent behavior of the processing elements cannot be foreseen either at compile time or at decode time.

In this paper, we introduce a new model of pipeline architecture : the Data Synchronized Pipeline Architecture (DSPA). Based on an independent sequencing of the functional units, this model allows a high degree of parallelism in the pipeline, even in the case of unforeseeable behaviors of some ressource.

## I Introduction

Need for computing power seems unlimited in various scientific applications. During the last ten years, tremendous progress has been made in the domain of component integration. But todays' supercomputer clocks are of the same order of magnitude as those of supercomputers ten years ago. E.g. the clock of the Cray2 (1985) is only three times faster than the one of the Crayl (1976).

Requirements for performance have lead manufacturers to the design of parallel structures. The first industrial parallel supercomputers were pipeline processors (Crayl, CDC Cyber 205, .. ). Today, these pipeline computers can be considered as the state of the art in monoprocessor architecture. Since the late 1970's, a lot of multiprocessor projects have been initiated [5][6][14][7]. In future industrial realizations of these ambitious projects, the elementary processors will be pipeline processors. Great attention must be taken in the design of these pipeline processors.

In a pipeline computer, the execution of an instruction stream generates concurrent activities in several functional units ( FUs ). These FUs may be pipelined. Even when the FUs are not pipelined, the successive FUs crossed by the data form a macropipeline. Performance of the computer depends heavily on the overlapping of successive instructions and are bounded by the throughput of the instruction decoder. In the case of vector instructions, simple pipeline control is possible because of the regularity of the data and instruction streams. Optimization of the code can be done at compile time. For example, performance of the Crayl can be considered as near optimum on classical vector instructions. That is the reason why pipeline computers are generally refered as vector processors. Unfortunately, performance of existent pipeline computers on scalar instructions are not as good as one can expect. The overlapping of successive instructions cannot always be decided at compile time because memory access conflicts or hazards may arise at execution time. Because in a multiprocessor architecture some hardware is shared, the behavior of processing elements are interdependent. Moreover if decode time for vector instructions is small regardless of the occupation of the FUs, very fast algorithms have to be used for pipeline control in scalar mode, because the decoding delays become critical.

In section II, we recall the problems which exist on some classical pipeline computers. Then, in the following sections, we present a new model of pipeline architecture : the Data Synchronized Pipeline Architecture (DSPA). This model has been developed in order to improve the performance of pipeline computers on scalar code. We also point out that using this model, a distributed decode of instructions allows very fast sequencing and efficient overlap for both vector and scalar instructions even in the cases where memory conflicts or hazards may occur.

## II Existent pipeline models

### 1 Outlines

Today, a pipeline processor can be used as a monoprocessor ( Crayl, FPS164, Cray XMP-1, Fujitsu VP 200,.. ) or as an elementary processor in a multiprocessor system (Cray XMP-4, Cray2, BSP,..). The BSP [10] is a SIMD computer; its elementary processors (PEs) are pipelined. A set of vector instructions has been defined by the designers. These instructions are memory to memory instructions ( operands are read from memory and the result is stored in memory ). When the machine has been defined, the behavior of these instructions was studied and optimized - by introduction of delays between two functional units for example; reservation tables [1][9][8] are stored in the machine. The SIMD structure of BSP allowed global pipeline control for all PEs. In general, the distinct FUs do not have the same number of stages and many cases of memory conflicts may occur; even with a restricted number of vector instructions, the number of cases to be studied would increase exponentially with the number of operands involved by the instruction. In the BSP the number of cases to be studied remains quite limited; all the FUs have the same number of stages (the reservation table does not depend on the FUs but only on the number and the distribution of distinct FUs concerned with an instruction), and memory conflicts are almost avoided by a constant increment definition of a vector and the choice of a prime of memory banks [11][12]. On the BSP, a good overlapping of distinct iterations of the same vector instruction is performed; but there is no overlapping of the end of a vector instruction by the beginning of an other instruction : the pipeline must be filled at the beginning of an instruction, and emptied at the end. Memory to memory instruction may be quite efficient on vector operands, but scalar instructions overlapping has to be done with other techniques while the restricted choice of vector definition increases the ratio of scalar code (e.g. loop 3 proposed later must be executed in scalar mode).

In todays' multiprocessors, the behavior of a shared memory cannot be foreseen either at compile time, or at execution or decode time : it depends on the different processes being executed by the different elementary processors. Even when vector accesses are synchronized, memory conflicts may occur at anytime; memory behavior depends on the relations in the distribution of the vector elements, on the relations between two successive vector accesses and on the treatment of RAW (Read After Write) hazards [13] : memory to memory architecture are no adapted to high speed scalar execution and asynchronous PE controls.

We present the problems that remain on two existent pipelined monoprocessors.

## 2 Vector register machines

In register machines, the operands of an instruction are loaded in the functional units from registers and the results are stored in registers. In some pipeline computers, such as Cray1 [3], there are vector registers; a vector register may contain up to N words -in Cray1, N=64. A single instruction with vector register operands may generate up to N times the same operation on distinct data, results are then stored in a vector register. This approach seems very efficient on pure vector instructions.

Loop 1 :

```
        DO 1 I=1,N
      1 A(I)=B(I)+C(I)*D(I)
```

Only seven instructions are necessary to code the body of this loop for the Cray1.

```
Vector load C --> R1
Vector load D --> R2
R3 <-- R1*R2
Vector load B --> R4
R5 <-- R3 + R4
Vector store R5 --> A
Conditionnal jump
```

Time to decode such a loop is not critical : up to 256 accesses to memory are generated by these seven instructions and the Cray1 can decode one instruction by cycle.

Unfortunately accesses to memory on the Cray1 are performed in the order of the decode sequence; moreover no advance is taken on the decode sequence : the next instruction is decoded only when the present instruction is initiated. An instruction is initiated only when the presence of all its operands is guaranteed; as there is no hardware mean to verify if the $i^{th}$ element of a vector is present or not, to initiate a vector instruction, the following condition must be guaranteed :

*For every i, i cycles later the $i^{th}$ element will be present.*

These restrictions explain why 353 cycles are necessary to execute an iteration of loop 1 while the memory is only busy during 256 cycles. They also induce the same definition of a vector as in the BSP. The loop 2 is then treated in scalar mode :

Loop 2 :

```
        DO 2 I=1,N
      2 A(I)= B(H(I))+ C(I)
```

Cray1 is about ten times slower than the Fujitsu VP200 [15] for the execution of this loop; because vector registers of addresses can be computed, the Fujitsu VP200 executes this loop as a vector loop. But loop 3 is executed in scalar mode on both machines :

Loop 3 :

```
        DO 3 I=1,N
      3 A(I)= A(H(I))+ B(I)*C(I)
```

Possible hazards may occur on this loop; as H(2) may be equal to 1, A(1) has to be written before A(H(2)) is read ( at least the hardware should avoid reading A(H(2)) before writing A(1) if H(2)=1). The loop must be coded in scalar mode.

In scientific programs, some part of the code always remains scalar. If performance in scalar mode are slow compared to vector performance, the execution time of the residual sequential code may become predominant. On Cray1, for example, when loop 1 is executed in scalar mode, about 25 cycles are necessary to decode the loop body : the theoretical throughput of the memory is then more than six times higher than the real throughput!

Even in the case of a register machine where advance can be taken at the decode [16][17], it is very difficult to busy all the FUs in scalar mode : parallel decode is quite impossible for register machines. The decoder will always remain a bottleneck for performance in scalar mode for these machines : that is the reason why they are considered as vector machines.

## 3 Microcoded fully connected pipelined machines

In microcoded machines, an instruction word contains a subinstruction parcel for each of its FUs. When all operands are loaded from registers, the register throughput becomes tremendous and unrealistic. Operands for a FU may be directly taken on output buses of the FUs. On a fully connected machine, each output of a FU is connected to each input of the FUs; some connections are not so useful as others : e.g. the path between the output of the floating point adder and the input of the address unit is very rarely used; such paths may be suppressed (fig. 1).

The FPS 164 of Floating Point Systems [2] may be considered as a "nearly" fully connected pipeline processor. Each of its FUs can initiate an instruction on every cycle. As the decoder can decode an instruction word on every cycle, the FPS 164 can run at full speed on scalar code.

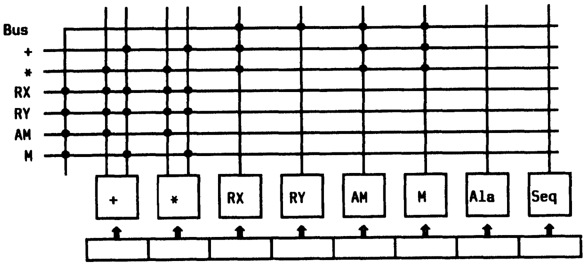
In an instruction word, the subinstruction parcel for each FU is always located at the same place. For example, the subinstruction for the adder can always be decomposed in three subparcels :

- Origin of the left operand, (i.e. the bus on which it is present)
- Origin of the right operand
- Codeoperation

The width of an instruction word for the FPS 164 is only 64 bits; it contains an order for each FU (see [2]). Controls of the crossbar network are given by the origins of the operands for the different FUs; synchronization of the FUs is explicit : the orders decoded in a cycle are initiated at the next cycle. A datum must be present on the output bus of a FU at the foreseen cycle. Delays to cross most of the FUs are constant and the date of their exit from a FU can be foreseen. Unfortunately, unforeseen memory bank conflicts may arise on an interleaved or shared memory; in this case, one solution consists of stopping the clock for the other FUs.

It is very difficult to produce efficient code for the FPS 164 because of the explicit synchronization by the microcode between the FUs. All the instructions are scalar i.e. an instruction initiates at most one order by FU. This is not critical because an instruction word can busy all the FUs; but automatic production of dense code is very difficult. Moreover efficient code cannot be produced without unrolling loops. E.g., on FPS 164, the loop body of the inner dot product may be coded on a single instruction loop preceeded by about ten instructions to fill the pipeline and about ten instructions to empty the pipeline. Unfortunately, no general compiling techniques can be used to unroll loops. To allow high performance on the FPS 164, Floating Point Systems proposes a library of frequently used functions and procedures which have been hand coded (BLAS). Performance are increased by a factor of two when coding LINPACK using BLAS instead of coding it in classical FORTRAN [4]. When possible hazards may occur (e.g. loop 3), loops cannot be unrolled : reads and writes cannot be exchanged by software.

We have pointed out the major limitations of some existent pipeline machines. Performance of existent vector register machines such as Crayl drop dramatically as soon as "good" conditions disappear, (scalar code, memory bank conflicts, scatter-gather, possible hazards ..). In scalar mode, performance are limited by the decoder : at each cycle, only one instruction can be decoded and then only one FU can be activated. Moreover the decoder cannot make any advances and no overtaking of writes by reads is allowed on memory. Fully connected microcoded pipeline processors can run at full speed in scalar mode, but they present insurmountable difficulties for efficient code production. For both models of machines, parallelism between the FUs is generated by software : possible hazards (e.g. loop 3) induce scalar execution, overlapping of the end of a loop by the beginning of the next loop is rarely performed and is always poor.



**A data interconnection scheme in the FPS 64**
**fig. 1**

In section III, we present a new model of pipeline machine. As in FPS 164, an instruction may contain a subinstruction parcel for each FU and, as the execution of these subinstructions are totally independent, a distributed decode can be done; another parallel decoder is also proposed. Vector and scalar instructions are available for this model of machine; a good overlapping of distinct instructions is possible whether they belong to same iteration of a loop or not and even when they do not belong to the same loop.

## III The Data Synchronized Pipelined Architecture ( DSPA )

### 1 goals

The basic problems which have lead us to define a new model of pipeline machines have been developed in the previous section.

As we have already pointed out, todays' pipeline processors must be designed to be included as elementary processors in a multiprocessor computer : MIMD and SIMD computers. Using fully connected microcoded pipeline processors as elementary processors in such architectures would be unrealistic : when a datum cannot be delivered by the shared memory, the clock would be stopped for the other FUs of the elementary processor; this is unacceptable and has lead us to express a first condition that we want to be satisfied by the design of a pipeline processor :

**Condition 1 :** *The sequencings of the different FUs of a pipeline processor have to be independent*

When this condition is satisfied, a delay in the delivery of a datum for a FU will not necessarily block the other FUs. Also, an instruction is not necessarily initiated at the cycle where its operands are produced and the production of the operands of an operation do not have to be synchronized.

In section I, we have seen that the decoder becomes a bottleneck for performance in scalar mode for vector register pipelined machines, so we propose a second condition :

**Condition 2 :** *Parallel decode is necessary on pipeline processors.*

We have also noticed that performance on the FPS 164 depends heavily on hand coded libraries. We wish to design machines able to reach correct performance on a very large set of scientific programs. This has led us to a third condition :

**Condition 3 :** *Natural code generation (by a compiler ) must produce efficient code.*

Two hardware tools seem to favor this goal : possible advance on decode and a RAW detection mechanism to enable reads to overtake writes on memory.

## 2 The DSPA model

We have rejected register pipeline machines because of the tremendous throughput demand on the registers and on the decoder to achieve performance in scalar mode. A Data Synchronized Pipeline processor is a "nearly" fully connected pipeline processor in which a FIFO (First In, First Out) queue is associated with each crosspoint on the interconnection scheme between the producers -outputs of the FUs- and the consumers - entries of the FUs. Except for the sequencer, each FU also has a FIFO queue of instructions (fig. 2). When a datum flows out from a producer P, it is stored in a FIFO queue associated with a pair (P,C) where C is a consumer i.e an input of a FU F : the datum is stored in this FIFO queue until F is ready to treat it (fig.3 ). An instruction for a FU may be decomposed in three parcels :

-Origins of the operands -i.e. names of producers; the FIFO queue associated to the path between the producer and the input of the FU is refered.

-Destination of the result -i.e. the name of a consumer.

-Codeoperation

The sequencing of the FUs is very simple.

We detail here the sequencing of the adder (fig. 4)

*1.If the FIFO queue of instructions is empty then GOTO 1.*

*2.Load the instruction in the adder's sequencer and decode it.*

*3.If one of the origin FIFO queues is empty then GOTO 3.*

*4.Load the operands; initiate the operation.*

*5.Store the result in the referenced FIFO queue **and** GOTO 1.*

These five steps may be pipelined :

-Step 5 is always overlapped by the other steps;

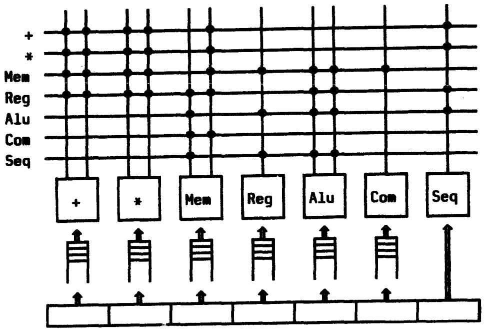
-The next instruction -when existing in the FIFO queue- may be decoded during step 3 and 4;

-Operands may always be loaded and the operation initiated : this operation can be aborted if the operands are not valid.

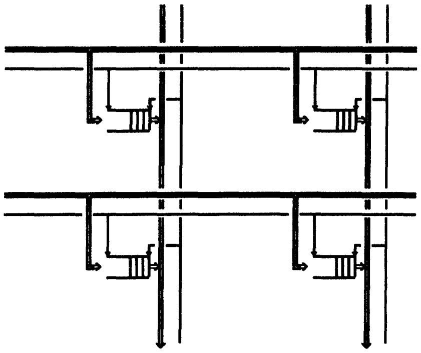
## 3 Deterministic execution

In classical machines, instructions are executed in the same order they are decoded : this guarantees the unique interpretation of a sequence of instructions. This constraint is respected on the FPS 164 : instructions are immediatly executed.

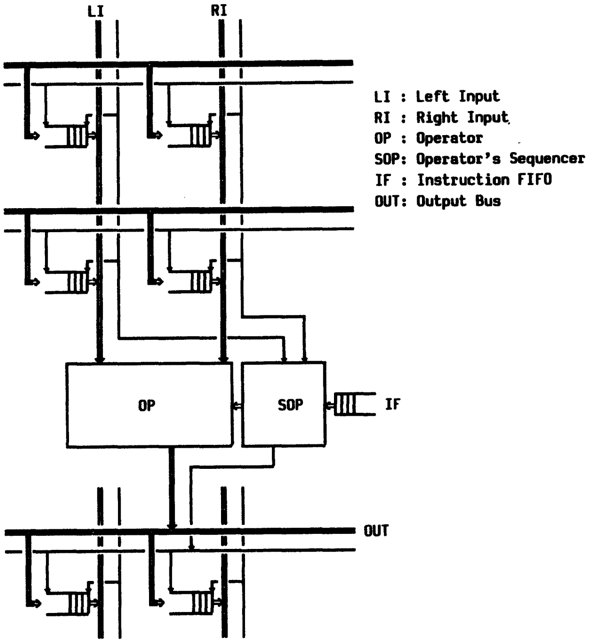
In our model, the FUs are synchronized by the data; an instruction may wait for its operands during a few cycles : there is no reason to decode the memory load of an operand for an addition before decoding the addition; if the adder is not busy, it can wait for the datum. The only significant order in this model of pipeline machines is the order of the data which enter the same FIFO queue.



An example of DSPA integration scheme
fig. 2



Crosspoint FIFOs
fig. 3



A typical DSPA functionnal unit
fig. 4

A FIFO queue is associated with only one producing functional unit. The instruction FIFO queue of a FU guarantees that this FU initiates its operations in the same order it receives its instructions : it is reasonable to impose the constraint that the results flow out from the FU in the same order that their production is initiated : in most cases, the delay to cross a FU is constant.

This constraint guarantees the unicity of the signification of a code sequence.

## 4 DSPA interleaved memory

In the DSPA model, the memory FU can be considered as a producing unit ( reads ) and also as a consuming unit ( writes ). The DSPA model imposes the constraint that the results of the reads flow out from the memory in the same order that the reads have been decoded. On an interleaved memory, this may dramatically decrease the throughput of the memory if the reads are really done in the same order they are decoded; let us suppose a four memory bank interleaved memory whose banks are busy during four cycles of a read and let us consider the following distribution of read requests :

read 1 and 2 on bank 0
read 3 and 4 on bank 1
read 5 and 6 on bank 2
read 7 and 8 on bank 3

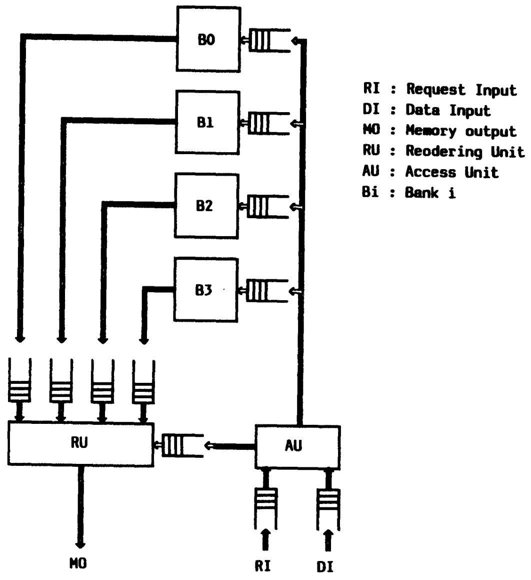
The results flow out from the banks in good order if the reads are initiated in the following order :

read 1 is initiated on cycle 1
read 2 is initiated on cycle 5
(bank 0 is busy on cycles 2, 3, 4)
read 3 is initiated on cycle 6
read 4 is initiated on cycle 10
read 5 is initiated on cycle 11
read 6 is initiated on cycle 15
read 7 is initiated on cycle 16
read 8 is initiated on cycle 20

In this extreme case, the real throughput of the memory is only two fifths of the theoretical throughput.

We propose a design of an interleaved memory which increases the real throughput of the memory and which respects the DSPA philosophy (fig.5). Addresses (and data for the write instructions) flow out from the access unit (AU) in good order and enter the FIFO queue of requests for the desired banks. Bank i loads its requests from the FIFO queue, then read data are stored in a FIFO queue associated with bank i. Then the reordering unit (RU) reads the data on the desired FIFO queues. The data flows out from the memory unit on the memory output bus (MO) in the desired order.

One can easily verify that when the sequence of reads of the previous example is repeated, the asymptotic throughput of the memory reaches the theoretical throughput. We will see later that a RAW detection hardware mechanism is necessary in the memory of a pipeline mechanism; this mechanism can be implemented in the AU (global detection) as well as in each bank (local detection).



A DSPA-compatible interleaved memory
fig. 5

## 5 Instruction decode

### 5.1 A distributed decode

We have already pointed out that the relative order of two instructions for two distinct FUs does not matter. Many solutions may be imagined for the global decoder. For example, as in the FPS 164, an instruction may contain a subinstruction parcel for the distinct FUs : these subinstructions may always be located at the same places in the instruction word and then can be directly routed to the distinct instruction FIFO queues of the FUs :

*The global decoder is only a bus.*

When, in an arbitrary sequence of instructions the most frequently used FU receives N instructions, the whole sequence can be coded on only N instruction words; the relative order of the subinstructions for the same FU is the only significant relation.

Very dense code is obtained without unrolling the loops as for the FPS 164 for example. Moreover, in the FPS 164 case, a lot of instruction words are necessary to fill and to empty the pipeline : in our model, these instructions are not necesssary; all the iterations of a loop have the same code. Let us suppose a DSPA processor which FUs have the same characteristics as in the FPS 164. Natural code generation will produce only one instruction by FU for the loop body of the inner dot product : without unrolling loops, a compiler will generate a single instruction word loop for this machine.

Nevertheless, we do not think that this solution of the decode is the only possible : 64 bits are necessary to code an instruction word for the FPS 164, more information must be given in subinstructions in our model, the width of an instruction word may result in an instruction memory or cache that is too expensive.

### 5.2 Decoder throughput

We discuss here why the throughput of the decoder may be more limited.

#### 5.2.1 Flexibility of the model

In the design of the FPS 164 and other machine as Crayl, all the FUs are assumed to have the same basic cycle : this allows initiation of a new instruction on each FU at each cycle. This simplifies the microcoding of the FPS 164 and the sequencing of the Crayl.

But this cannot be considered as a good balance between the throughput of the FUs : most of the classical algorithms require at the minimum an average of one memory access per floating point operation. On the FPS 164, this difficulty has lead to the introduction of an auxiliary memory having the same throughput as the main memory. In the design of the successor of the Crayl, the Cray-XMP, two pipelined channels are used to simultaneously access the memory : they can be considered as distinct FUs which have to respect very strong constraints.

Our model processor can support distinct basic cycles for the distinct FUs; e.g. the basic cycles of the floating point operators may be two times longer than the basic cycle of the memory. Moreover the delay in which a FU delivers a result may vary; we have only imposed the constraint that results flow out from the FU in the order their productions have been initiated.

#### 5.2.2 Vector instructions

On the FPS 164, vector instructions cannot exist because of the explicit synchronizations by the microcode at each cycle. In the DSPA model, no difficulties exist to prevent vector instructions. Executing a vector instruction of length k consists of executing the same scalar instruction k times. As in vector register machines, the physical support of the FIFO imposes a maximum vector instruction length. In some cases as in loop 4, vector instructions increase the performance by removing strict dependences between the data in the pipeline :

Loop 4 :

```
        DO 4 I=1,N
      4 A(I)= B(I) + C(I) + D(I)
```

In the body of this loop, two instructions concern the adder; the second addition cannot be initiated before the end of the first one. If the delay to cross the adder is k cycles –seven cycles in Crayl– no addition can be initiated during k-1 cycles. A vector instruction of length k works on k independent flows of data : in loop 4, the adder should then be busied when the memory throughput is sufficient. Our model allows coding many loops as vector loops; loops 1 and 2 are coded with vector instructions; the following loop 5 is also coded as a vector loop.

Loop 5 :

```
        DO 5 I=1,N
      5 A(H(I))= B(P(I))*C(Q(I))
```

The loop 3 may be coded by mixing vector instructions and scalar instructions; accesses to H, B, C, the multiplication and also the addition may be coded as vector instructions. In order to detect possible RAW hazards, the two accesses to A must be scalar coded : an internal scalar loop has to be coded in the global loop.

Let us suppose that the maximum vector length of a vector instruction is 8, the body of loop 3 can be coded by the following sequence :(1)

```
V M: ?VpRead H ↣ Ma
  M: ?VpRead A ↣ *l
  M: ?VpRead B ↣ *r
  *: ?V*(M,M)  ↣ +l
  +: ?V+(*,M)  ↣ Md
S M: ?SiRead A (M) ↣ +r
  M: ?SpWrite A (+)
 Seq: C←C-1,if C>0 then GOTO S
 Seq: N←N-1,if N>0 then (VL←min(N,8);C←VL;GOTO V)
```

The floating point additions have been extracted from the internal scalar loop : these instructions are kept in the adder's instruction FIFO queue until the operands are received.

The flexibility of the vector instruction definition associated with the possibility to access vector operands in scalar mode and to concatenate scalar operands to form vector operands increases the ratio of vector instructions in DSPA programming.

#### 5.2.3 Towards another proposition for distributed decode

In a loop body of scientific programs, some FUs are not as heavily used as others; in the previous examples, no registers were used. When an instruction word may contain a subinstruction parcel for each FU, the ratio of empty instructions parcels in a sequence of code may be tremendous. In most of the cases, there is only one instruction for the sequencer in a loop body; on the other hand, in all classical examples the memory is the critical resource : it does not seem natural to decode an instruction for the sequencer on every cycle, but it may be critical for the memory. Our experiments have shown that for a machine with well designed FUs, nearly half of the instructions are memory accesses. We recall that we consider that the memory FU computes postincremented addresses and indirect based addresses.

(1) M is the memory, Ma is the address input of the memory, +l is the right input of the adder .. . ?V (resp. ?S) refers to vector (resp. scalar) instructions. Memory instructions are p-access (post -incremented) or i-accesses (indirect). p-access refers to a descriptor containinq a base address A and an increment R. A vector p-access generates VL addresses of the form A + iR and leaves the descriptor with a new base address A + VL R; a scalar p-access sends the address A to the memory and assigns the value A + R to A. Address for a i-access is computed by adding an internal base address to a value read on Ma.

Then we have managed to decode only a few instructions at the same cycle. These instructions must be applied to distinct FUs. It seems that decoding two instructions during a memory cycle represents a good balance between the decoder throughput and the possible performance of the machine. The global decode is very simple : names of the FUs involved by the instructions are decoded and then the two instructions are routed to the correct instruction FIFO queues.

## IV RAW hazards

The DSPA model respects the conditions 1 and 2. When producing code for a processor of DSPA family, the compiler can forget that this processor may be an elementary processor of a multiprocessor computer. The code may be generated in the same manner it would have been generated for a monoprocessor : the real behavior of the shared memory can be ignored. This has allowed us to treat loop 2 and 5 as vector loops : this cannot be done on the Cray1 because the behavior of the memory cannot be foreseen at compile time.

Independency of the FUs also allows parallel decode -two solutions have been proposed, others may be imagined. Code generation may be relatively simple : as the instruction flows for two distinct FUs are completely independent, the compaction of a linear sequence of code is very easy.

Unfortunately advance on decode is not very useful when the effective accesses to memory have to be done in the order of their decode; in most of the cases, a loop body begins by a read and ends by a write to memory. This prevents the overlapping of the end of an iteration of the loop by the beginning of the next iteration unless some mechanism is used to allow passing the writes by the reads (when the read address and the write address are distinct). Software mechanisms have been proposed in the past : two distinct flows of memory accesses may be generated and reads of a flow overtake the writes of the other flow. Many examples where these solutions are not efficient can be imagined.

```
Loop 6 :
      DO 6 I=1,N
      DO 10 J=1,I
   10 A(J)=A(J)+B(I,J)
      6 CONTINUE
```

When executing the internal loop, it is very interesting to pass the write of A(J) by the reads of A(J+1), A(J+2),.. . But when I becomes small, one cannot ensure that A(1) has been written by the previous external iteration. The only software solution to prevent hazards in the execution of this loop is to empty the pipeline after each iteration of the internal loop.

We think that a hardware detection of RAW hazards on memory has to be implemented in a pipeline processor; in loop 3, there are possible hazards on memory, no software means can be imagined to treat this case. Using one of the two models of decode we have presented, the decode of this loop programmed with vector instructions and an internal scalar loop will take no more than 20 cycles : the decode will not be a bottleneck -40 accesses to the memory are done. If a hardware detection of RAW hazards is done, one can hope that when real hazards don't occur, performance will only be limited by the memory throughput.

Another advantage of a hardware detection of hazards is to enable the reaching of correct performance on unoptimized code : performance on loop 1 when scalar coded can be equal to vector performance, even where start-up delays are longer if an interleaved memory is used. One can hope for correct performance on long loop bodies. To detect RAW hazards on a DSPA computer, the memory access instruction and the corresponding address are extracted from the FIFO queues in the decode order; but write addresses are saved in some associative memory until corresponding data is present; read addresses are checked against the associative memory.

## V Some limitations of the DSPA model

### 1 Registers

In the examples we have detailed, the registers have never been used. In the case where a datum is used two times or more in an algorithm, it must be explicitly saved in a register and each operation requiring this datum as an operand will cost two instructions : the instruction to initiate the operation and the read of the register. The most important case of two uses of the same operand is the complex multiplication : a solution may consist in implementing a complex mode on the multiplier.

### 2 A blocking machine

In a DSPA processor, an instruction waits for its operands; this instruction may have been decoded before the decode of the production of its operands and if these productions are never done ( a bad generation of code may lead to this extremity ), the FU will never be activated as in example 7 :

```
 7 +:  (M,M) ↦ +1
   Seq:  GOTO 7
```

On the other hand, data may be produced and never consumed :

Example 8 :

```
 8 M:  pRead X ↦ +1
   Seq:  GOTO 8
```

Correct codes must be written : when a datum is produced by a FU, it must be consumed by an other; when a data has to be consumed, its production has to be guaranteed.

We define a correct unbreakable sequence of code (CUS) as :

*No external jump inside the sequence is possible unless to its first instruction.*

*No jump out of the sequence is possible unless from the last instruction.*

*Each datum produced in the sequence is consumed in the sequence.*

*Each datum consumed in the sequence is produced in the sequence.*

The loop body of example 3 is a CUS, but the internal scalar loop is not a CUS : data which are consumed are not produced in the loop.

The following loop body of an inner dot product is not a CUS :

```
S  M:  pRead A ↣ *l
   M:  pRead B ↣ *r
   *:  *(M,M) ↣ +r
   +:  +(+,*) ↣ +l
  Seq:  C← C-1, if C>0 then GOTO S
```

When executing this loop, the first left operand for the adder must have been previously produced in order to initiate the pipeline; this corresponds to the initialization of the sum – note that p subsums may be computed by p initializations.

The following condition must be respected to guarantee the execution of all the decoded instruction :

*Each sequence of code must be included in a CUS.*

There are no problems for a compiler to produce correct code (e.g. a solution may consist in treating DO loops as CUS, addresses of jumps delimiting distinct CUSs), but hand optimizations of the code may be dangerous : if the previous condition is not respected, the machine will be blocked. But this is not a real problem : machines on which badly coded programs produce the desired results don't really exist.

## VI Conclusion

We have presented an original model of architecture for pipeline processors. In this model, the decoder does not remain a bottleneck for performance in scalar mode as in existent pipeline processors : independency of the FUs and distributed decode of their instructions allow very fast sequencing. Synchronization of the FUs is done by the data. Such a processor can be integrated in synchronous multiprocessor architectures as well as in classical MIMD structures.

Generating code for machines based on our model will be very easy; natural sequential code can first be generated –instruction by instruction–, then independent codes for the distinct FUs can be extracted. For classical pipeline computers, complex reordering algorithms are applied to code at compile time to ensure performance at execution time; these algorithms may also be applied to the distinct codes for the FUs but this is less necessary than for classical architectures. When possible hazards may occur on memory or registers, there is no mean to optimize code for classical pipeline computers; on a DSPA architecture only real hazards may degrade performance.

At present, we are studying a real implementation of a pipeline processor of this family. Many solutions can be adopted : buses can be shared by several FUs, this sharing may be static or dynamic ... Great attention has to be taken in the design of the FUs; for example, in this paper we have already exposed some characteristics of the memory FU (computation of the addresses by the FUs, need of a RAW hazard detection mechanism). Another important point to be optimized in the design of the machine is the interconnection scheme : connections can be quite expensive in this mode because a FIFO queue is associated to each crosspoint on this interconnection scheme; infrequently used paths between the FUs can be suppressed; several FIFO queues may be implemented on the same support.

In the theoretical model, arbitrarily large FIFO queues are used. In a real machine, the sizes of the FIFO queues are limited by the physical support which limits the length of vector instructions. All these questions will be discussed in future papers.

# Multipipeline Networking for Fast Evaluation of Vector Compound Functions*

Kai Hwang and Zhiwei Xu

Computer Research Institute
University of Southern California
Los Angeles, CA 90089-0781

## Abstract

Multipipeline networking is a generalized technique to expolit maximum parallelism in vector computations. A *pipeline net* can be viewed as a two-level pipelined systolic array, which is dynamically reconfigurable for evaluating various vector compound functions. In other words, the pipeline net can best match the various data dependency relationships in program graphs which can be vectorized. Multiple vector streams flow through the net to achieve significantly higher throughput than using conventional pipeline chaining. The reconfigurability provides the flexibility in various vector processing applications. This paper discusses design issues of the pipeline net and presents techniques for converting program graphs into pipeline nets.

## 1. Introduction

This paper addresses the design of scientific supercomputers which involve heavy vector computations. In such an environment, a computational job can often be decomposed into a number of communicating tasks. Each task may comprise several vector compound function evaluations [8, 13, 21]. Henceforth, we define a *vector compound function* (VCF) as a collection of linked scalar operations, which will be repeatedly processed many times in a looping structure. So far, these VCFs have been realized in array processors (Illiac-IV, MPP), pipelined uniprocessors (Cray-1, Cyber-205, and FPS-164/max) and multiprocessors (Cray X-MP, Cyberplus, FPS Tesseract, Remps, and Cedar) [4, 6, 9, 10, 12, 14, 20]. Most commercially available supercomputers are equipped with multiple pipelines in each central processor. Pipelining has been proven effective in implementing linked vector computations. However, only linear chaining has been implemented in commercial machines. This paper generalizes the conventional linear pipelining to a multipipeline networking approach. The goal is to further speed up the evaluation of VCFs for future pipelined multiprocessors.

As illustrated in Fig.1, the pipeline networking concept originates from the internal forwarding technique used in IBM 360/91 and the dynamic linking of functional units in CDC 7600 [12]. The concept of two-level pipelining has been practised in Cray-1 and Cray X-MP in the form of pipeline chaining [6]. However, only linearly connected patterns appear in these linked vector operations. In the Cyberplus [4], fifteen FPs in each processor can be linked by a crossbar network. In FPS-164/max or the recent FPS Tesseract, dot-product operations are executed by a multiplier pipeline cascaded with an adder pipeline [10, 20]. The networking concept generalizes the chaining practice to a two-level, reconfigurable systolic approach.

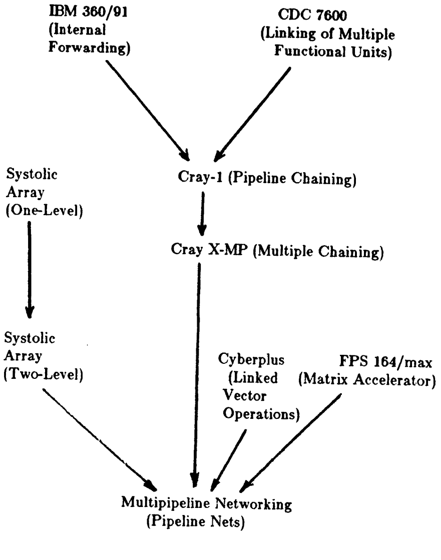

**Figure 1**. Historical evolution of the concept of pipeline networking

*This research was supported in part by an NSF grant DMC-84-21022 and in part by an AFOSR grant 86-0008

A *pipeline net* consists of multiple functional pipelines (FPs) interconnected by a buffered switching network, which is itself pipelined. Whenever a new VCF is to be evaluated, the pipeline net is reconfigured into a topology that best matches with the dataflow pattern in the program graph of the VCF. The evaluation is then performed with multiple operand strams flowing through the pipeline net in a synchronous fashion. Thus we can view a pipeline net as a two-level pipelined, dynamically reconfigurable systolic array. Using a single physical pipeline net, we can provide many *virtual* systolic arrays to support a large collection of application algorithms.

In this paper, we first characterize the functional structure of pipeline nets and describe their operational principles. We define *program graphs* and discusses their basic properties. We model VCFs with program graphs and provide a unified theory for converting program graphs into pipeline nets. Two *pipeline networking* techniques are presented, one using the concept of cut sets and the other using a retiming technique modified from Leiserson, Rose, and Saxe [18, 19].

## 2. The Concept of Pipeline Net

A *pipeline net* is made of three types of hardware resources, namely multiple *functional pipelines* (FPs), a *buffered crossbar network*, and a set of *data registers*, as illustrated in Fig.2. All FPs used in a net are identical and multifunctional. Different operations can be performed by the same FP at different times. They may, however, use different pipeline stages thus require different amount of pipeline delays. The registers are used as interface latches for holding operand and result data. The buffered crossbar network is used to provide dynamic interconnection paths among the FPs and the registers.

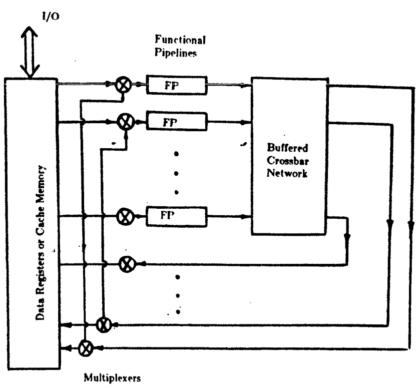

**Figure 2**. The schematic of a pipeline net

A crucial component of the pipeline net is the buffered crossbar network. We choose the crossbar over multistage packet switching networks [5] due to the demand of full connections in pipeline nets. In general purpose computations, pipeline nets with many different topologies may be needed. Thus the crossbar network should support arbitrary 1-to-1 and 1-to-many mappings. (Many-to-1 mappings are not allowed in pipeline networking operations). Apart from the full connectivity, crossbar switching has the advantages of ease to set up, which is very important since the network setup time is a major source of the startup overhead of the pipeline net. The main critique for crossbar network is the hardware complexity, which is $O(m^2)$ for an $m$ by $m$ network. However, if the number of FPs is relatively small (say 64), a crossbar switch is feasible with today's VLSI and packaging technology. In fact, several crossbar designs have been reported to have up to hundreds of inputs and outputs [2, 3, 7]. The recent progress in optical interconnection [22] promises the hope for even larger optical crossbar networks.

The pipeline net supports arbitrary connections among multiple pipelines. Thus local connections as necessary in a systolic array, are no longer a structural constraint in a pipeline net. However, the systolic flow of data through pipelines is still preserved. For example, when two operand streams arrive at a certain pipeline, they may have traversed through some data paths with different delays. These path delays must be equalized in order to have the correct operand pairs arriving at the right place at the right time. In the pipeline net, delay matching is handled by the crossbar network. Some programmable bufferes (latches) are provided on each output port of the crossbar network, so that proper noncompute delays can be inserted on each data path. An example design is the LINC chip [11], which is an 8-by-8 crossbar with up to 32 units of programmable delays on each data path.

The pipeline net performs computations based on the *pipeline networking* concept, which is a natural generalization of pipeline chaining in Cray-1 and Cray X-MP. The idea is that after the operand data are loaded into the register file, a pipeline net consisting of vector registers, functional pipelines, and a crossbar network is dynamically set up. A block of operands (which is called as a *wavefront* in Kung [17]) may traverse multiple pipelines via the network, before it finally returns to the register file. Intermediate results flow directly from a pipeline to another without memory accesses. The pipeline net best matches the dataflow pattern of the VCF to be evaluated, thus operand fetchings, arithmetic/logic operations, intermediate result routing, and final result storing are executed concurrently in a pipelined fashion as illustrated by the following example.

**Example 1.** Consider the following Fortran loop representing a VCF. Each iteration of the loop is characterized by the program graph shown in Fig.3a.

```
       DO 10 I=1, 400
       T(I) = B(I)*C(I)
    10 E(I) = (A(I)*B(I)+T(I))/(T(I)*(C(I)+D(I)))
```

Suppose that the add, multiply, and divide pipelines require 2, 4, and 6 pipeline stages respectively. This graph can be systematically mapped into an equivalent pipeline net shown in Fig.3b. Noncompute delays are inserted into data paths connecting FP3 and FP4 to FP5 and FP6. All inter-pipeline data paths are provided by the crossbar network as shown in Fig.3c. After the pipeline net is configured, the VCF is evaluated by passing 400 operand blocks (wavefronts) from the vector registers A, B, C, D through the net. And the final result data will be stored in register E. Note that no temporary storage is needed for the intermediate result T.

## 3. Properties of Program Graphs

A *program graph* $G=(V,E,f_1,f_2)$ is a weighted directed graph, where

1. $V$ is a set of nodes representing arithmetic/logic operations;
2. $E$ is a set of edges representing data dependency;
3. $f_1$ is a function from $E$ to $\{0,1,2,...\}$ denoting the edge delays;
4. $f_2$ is a function from $V$ to $\{0,1,2,...\}$ denoting the nodal delays; and
5. There are two specific nodes $v_{in}, v_{out} \in V$ for handling I/O operations. Note that $v_{in}$ has no inbound edges and $v_{out}$ has no outbound edges.

A *synchronous* program graph is one in which every cycle has at least one nonzero node or edge delay. Since asynchronous graph involves nondeterministic behavior, we only consider synchronous graphs in this paper. In the following, the term graph refers to synchronous graphs only. A $(k_1,k_2)$-graph, is a program graph in which $k_1 \leq f_2(v) \leq k_2$ for all $v \in V$. A $(k_1,k_2)$-graph is abbreviated as a $k$-graph when $k_1=k_2=k$. Note that 0-graphs and 1-graphs are special cases of $k$-graphs. A systolic graph is a 0-graph with positive edge delays (i.e., $f_1(e)>0$ for all $e \in E$). We shall denote such a systolic graph as $G_0^+$.

When a graph is implemented by a hardware circuit, the delay of an edge represents the number of delay registers on that edge. A computing node with delay $k$ corresponds to a $k$-stage linear pipeline which has $k$ latches. At any time, the graph has a *state* which is defined to be the contents of all edge registers and pipeline latches. All input data are issued from the input node $v_{in}$ and all results are sent to the output node $v_{out}$. A set of input data which is issued at the same time is called a wavefront (operand block). A computational task is performed by a program graph $G$ synchronously: Suppose at time $t_0$ the *initial state* of $G$ is $s_0$. A sequence of wavefronts, $I$, is input from the the input node at time $t_0+i\alpha$ for $i=1,2,\cdots,n$, which produces an ouput sequence $O$ at the output node at time $t_0+d+i\alpha$ for $i=1,2,\cdots,n$. Note that $n$ is the number of wavefronts feeding into $G$ from the input node, and $\alpha$, called the *spacing*, is defined as the number of clock periods elapsed between two successive wavefronts.

Two program graphs $G$ and $G'$ are *equivalent*, denoted as $G \equiv G'$, if the same input sequence produces the same output sequence on both graphs. In other words, equivalent graphs have the same input/output behavior. However, the nodal and edge delays and the spacings between wavefronts on each graph may be different.

The following lemmas provide basic tools for transforming a program graph into an equivalent pipeline net, as illustrated in Fig.4. Detailed proofs of these lemmas can be found in [15]. A *cut-set* in a graph $G$ is a minimal set of edges the removal of which partitions the graph into two isolated subgraphs, called the *left subgraph* (which contains $v_{in}$) and the *right subgraph* (which contains $v_{out}$). All edges from the left subgraph to the right subgraph are called ***rightbound*** edges, and those in the reverse direction are called *leftbound* edges.

**Lemma 1**. Adding $k$ delays to any node in a program garph and then subtracting $k$ delays from all inbound-edges (or all outbound-edges) of that node will produce an equivalent graph. An equivalent graph can also be obtained, if "adding" and "subtracting" are exchanged in the above operation. (Fig.4b)

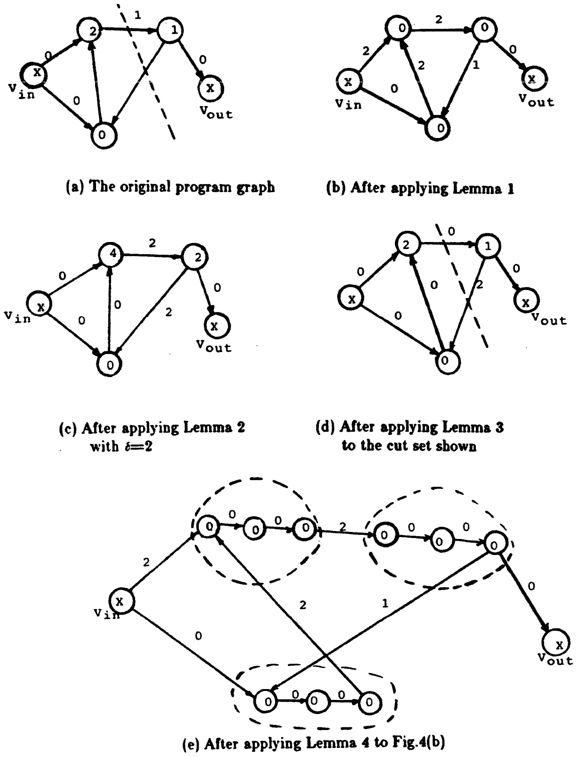
**Lemma 2**. An equivalent graph is generated, if all nodal and edge delays and the spacing are multiplied by a positive integer. (Fig.4c)

**Lemma 3**. For any cut-set of a program graph, adding $k$ delays to all leftbound (or rightbound) edges and at the same time subtracting $k$ delays from all rightbound (or leftbound) edges will result in an equivalent graph. (Fig.4d)

**Lemma 4**. For any 0-graph, an equivalent graph is obtained by splitting any node into a linear cascade of $k$ nodes with zero nodal and edge delays in the cascade. (Fig.4e)

## 4. Mapping Program Graphs to Pipeline Nets

A user task is specified with a program graph $G_0$. Usually $G_0=(V,E,f_1,f_2)$ is given as a 1-graph if we assume each arithmetic/logic operation takes one time unit to complete; or it is specified as a 0-graph if it is given as a *signal flow graph* [17]. we hope to transform it into an equivalent program graph $G_k=(V,E,f_1',f_2')$, which corresponds to the required pipeline net. Note that the transformed graph $G_k$ has the same topology as $G_0$, but the delays and the spacing may be modified.



(a) The original program graph

(b) After applying Lemma 1

(c) After applying Lemma 2 with $\delta$=2

(d) After applying Lemma 3 to the cut set shown

(e) After applying Lemma 4 to Fig.4(b)

**Figure 4. Illustrating Lemma 1-4 with an example graph**

The new nodal delay function $f_2'$ is determined as follows: for any node $v_i$ other than $v_{in}$ and $v_{out}$, if $v_i$ is implemented by a pipeline of $k_i$-stages in the required pipeline net, then $f_2'(v_i)=k_i$.

Leiserson et al [18, 19] studied the problem of minimizing the clock period of a synchronous system by a technique called "retiming". They provided algorithms to tramsform a synchronous system into a systolic array. Similar work is also reported in [17], where a systolization procedure is used to transform a signal-flow graph into a systolic array. In this paper we choose a different approach for a different purpose. All the previous researchers tramsform a program graph $G$ into a single-level systolic array, $G_0{}^+$; while our purpose is to convert the graph $G$ into a $k$-graph $G_k$, which can be implemented by a two-level pipeline net.

Two systematic methods are presented below to perform the network conversion. We first present cut-set method based on Lemmas 1, 2, and 3. This method is closer to what has been reported in [16], where a cut-set rule is used to transform feedback-free program graphs into two-level pipelined systolic arrays. We investigate more general cases which allow feedbacks in the program graphs. We then extend Leiserson's retiming method to generate two-level pipelined systolic arrays. These network conversion methods are compared with previous approaches in Fig.5. The following theorem is a direct concequence of the two network conversion algorithms to be presented shortly.

**Theorem.** Any synchronous graph $G_0$ can be transformed into a pipeline net characterized by a $k$-graph $G_k$ such that $G_0 \equiv G_k$.

In what follows, the delay of a cycle $c_j$ in a program graph $G$ is denoted as $d(c_j)$. The sum of all the nodal delays of the same cycle $(\bar{c}_j)$ in $G_k$ is denoted as $\bar{d}(\bar{c}_j)$. A *chain* is a garph whose nodes can be arranged in a linear cascade as examplified in Fig.6a. The rightbound (leftbound) edges connecting distant nodes are called *forward* (*backward*) edges as shown in Fig.6a. A *multichain* consists of several chains linked by forward or backward edges as shown in Fig.6c.

Given a graph $G$, we define a *maximal acyclic subgraph* (MAS) of $G$, as a cycle-free subgraph of $G$ which contains all the nodes of $G$ and by reattaching one more edge, we will have a cyclic graph. For example, an MAS of the cyclic graph shown in Fig.7a is depicted in Fig.7b. Before describe the main algorithm, we recall that any acyclic graph can be converted into a chain by *topologic sorting* [1]. In the following procedure, we first transform a given graph $G$ into a multichain. Then we use cut sets, which seperate successive adjacent nodes in the multichain, to convert $G$ into $G_k$.

**Cutset Conversion Algorithm:** This algorithm transforms a program graph $G$ into a $k$-graph $G_k$ such that $G \equiv G_k$.

1. Find an MAS of $G$. Note that if $G$ is a cyclic graph, then some edges are removed.

2. Perform topologic sorting to obtain a multichain $v_{in}, v_1, v_2, \cdots, v_m, v_{out}$.

3. Reattach all edges removed in Step 1.

4. Apply Lemma 1 to obtain a 0-graph $G_0$ by removing all nodal delays to the corresponding inbound edges.

5. For $i$=1,2, $\cdots$ ,$m$+1, apply Lemma 3 to the cut set $S_i$ consisting of all edges between $v_{i-1}$ and $v_i$. Note that $v_0$ and $v_{m+1}$ represent $v_{in}$ and $v_{out}$ respectively.

   a. Let $e_1, e_2, \cdots, e_r$ be all the rightbound edges in cutset $S_i$, $w$=min{delay of $e_j$ for $1 \leq j \leq r$}. If $w=k_i$, then do nothing.

   b. If $w>k_i$, then add $w-k_i$ to the delay of all leftbound edges in $S_i$ and subtract $w-k_i$ from the delay of all rightbound edges in $S_i$.

   c. If $w<k_i$, then we must consider two cases. If the cut set contains leftbound edges and there is a forward edge $e$ in the cut set with delay $w$, examine whether $e$ belongs to any previous used cut set without leftbound edges. If so, apply Lemma 3 to raise the delay of $e$ to $k_i$ and goto Step 5c. Otherwise add $k_i-w$ to the delay of all rightbound edges and subtract $k_i-w$ from the delay of all leftbound edges.

   At the end of Step 5, a new edge delay function is obtained. Denote it as $f_1'$.

6. If all inbound edges of $v_i$ have delay $\geq k_i$ for $i$=1,2, $\cdots$ ,$m$, go to step 7. Otherwise

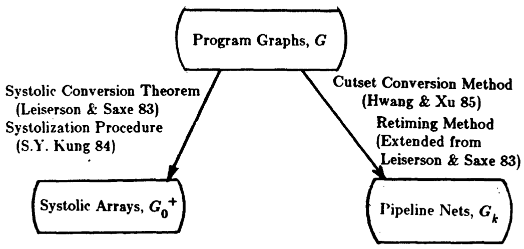


**Figure 5.** Various methods for converting program graphs to systolic arrays or to pipeline nets

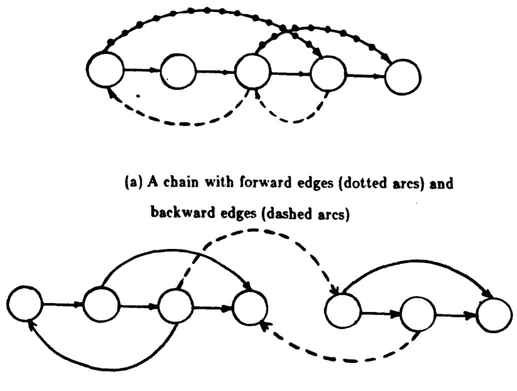

(a) A chain with forward edges (dotted arcs) and backward edges (dashed arcs)

(b) A multichain consisting of two chains linked by distant edges (dashed arcs)

**Figure 6.** Chain and multichain of functional pipelines

a. Compute the scale-up factor

$$\delta = \operatorname*{Max}_{\substack{e_i \in c_j \\ c_j \in C}} \left\{ \frac{\bar{\bar{d}}(c_j) - f_1'(e_i)}{d(c_j)} \right\}$$

where the $e_i$ is a leftbound edge in cycle $c_j$ and $C$ is the set of all cycles.

b. Apply Lemma 2 to scale up the 0-graph $G_0$ obtained in Step 4 $\delta$ times. Goto Step 5.

7. Transfer $k_i$ delays to $v_i$ from its inbound edges for all $v_i \in V$, we obtain the required pipeline net corresponding to $G_k$.

**Example 2**. Consider the program graph in Fig7a. We want to convert it into a 4-graph with $k_1$=2,$k_2$=$k_3$=3, and $k_4$=4. By removing edges ($v_4$,$v_1$), and ($v_2$,$v_1$), we obtain an MAS in Fig.7b. Applying topological sorting, reattaching the removed edges, and transfering nodal delays to corresponding inbound edges, we obtain the graph in Fig.8a. applying Lemma 3 to cut sets $S_1$, $S_2$,$S_3$, $S_4$, and $S_5$ in Fig.8a, the edge delays are modified as shown in Fig.8b. Now the two leftbound edges in Fig.8b, having delay less than $k_1$=2, creat 4 cycles in the multichain. The scale-up factor $\delta$={ 5/3, 14/8, 11/6, 11/6}=2. Scaling up the graph in Fig.8a two times, we obtain the graph in Fig.8c. We then repeat Step 5 once more to obtain the graph in Fig.8d. Now all edges have delay greater than or equal to the required value. By moving $k_i$ delays from the inbound edges of $v_i$ into $v_i$, we obtain the required 4-graph in Fig.8e, which is explicitly redrawn as a pipeline net in Fig.8f.

## 5. Designing Pipeline Nets by Retiming

Leiserson and Saxe [19] studied the problem of mapping synchronous graphs into systolic graphs. Their results are modified below for generating pipeline nets. Before describing our algorithm, we restate their retiming technique using our terminology.

**Retiming Lemma.** Let $G$ be a synchronous 0-graph and *lag* be a function that maps the I/O nodes to zero and any other node to an integer. Suppose that for every edge $e=(u,v)$, the value $f_2(e)+lag(v)-lag(u)$ is nonnegative. Let $G'$ be the 0-graph obtained by replacing the delay $f_2(e)$ of every edge $e=(u,v)$ by $f_2(e)+lag(v)-lag(u)$. Then $G \equiv G'$.

**Systolic Conversion Theorem** (Leiserson and Saxe). Let $G$ be a synchronous 0-graph, and $\overline{G}$ is the graph obtained by subtracting all edge delays $G$ by 1. Suppose that $\overline{G}$ has no cycles of negative delay, then there exists a systolic graph $G_0{}^+$ which is equivalent to $G$.

A constructive proof of the above theorem can be found in [19]. Given any 0-graph $G$, they first derive $\overline{G}$. Then they specify the *lag* function as follows: for any node $v$, there exists in $\overline{G}$ a path of minimal delay from $v$ to the output node. $lag(v)$ is then determined as the delay of any such ***shortest path***. They proved that by applying the Retiming Lemma to $G$ with the defined *lag* function, $G$ can be mapped into a equivalent systolic graph if $\overline{G}$ has no cycle of negative delay. The following algorithm applies the above results to map a program graph $G_0$ into a pipeline net.

**Retiming Conversion Algorithm:** This algorithm convert a program graph $G$ into a pipeline net $G_k$.

1. Transfer all nodal delays to inbound edges to obtain a 0-graph $G_0$.

2. Compute $\delta = \max_j \{\overline{d}(c_j)/d(c_j)\}$ for all cycles $\{c_j\}$ in $G_0$. Scale up the graph $G_0$ $\delta$ times using Lemma 2.

3. For every node $v_i$, if it corresponds to a $k_i$-stage pipeline in the required pipeline net $G_k$, then apply Lemma 4 to split it into a linear cascade of $k_i$ nodes with zero nodal and edge delays. Denote the obtained graph as $G'$.

4. Apply the Systolic Conversion Theorem to $G'$ to obtain a systolic graph $G_0{}^+$. Apply Lemma 3 to eliminate negative or zero delays on all outbound edges of $v_{in}$, if there is any.

5. Merge the splitted nodes in each cascade into a single node by assigning $k_i-1$ delays to $v_i$ for all $v_i \in V$.

6. Transfer one delay from all inbound edges $v_i$ for all $v_i \in V$, we obtain the required pipeline net corresponding to $G_k$.

**Example 3.** Consider the conversion of the program graph Fig.7a to an equivalent 4-graph. After Steps 1 and 2, we obtain the 0-graph shown in Fig.9a. Note that the multiplying factor $\delta$ is found to be 2. The 0-graph is then expanded into a 14-node graph $G'$ as shown in Fig.9b. The Systolic Conversion Theorem is then applied to obtain an equivalent systolic graph $G_0{}^+$ as shown in Fig.9c. Note that Lemma 3 has been applied to the outbound edges of the input node to eliminate negative delays. Grouping every cascade of nodes into a single node, we obtain the graph $G_3$ shown in Fig.9d. The final pipeline net is shown in Fig.9e corresponding to the graph $G_4$.

## 6. Conclusions

This paper generalizes the conventional linear pipelining principle. Pipeline networking offers a new design methodology for vector multiprocessor supercomputers. Basic techniques are provided for mapping program graphs into pipeline nets. These techniques are useful for designing two-level pipelined systolic arrays. By matching the multiprocessor configuration with the dataflow patterns of user programs, and by combining pipelining with parallelization, the pipeline net architecture provides higher flexibility and higher throughput, especially for compound vector/matrix operations.

# A Parallel Vector Reduction Architecture

H.X. Lin and H.J. Sips
Delft University of Technology
The Netherlands

## Abstract

The ability to perform fast vector reduction evaluations, such as inner product and vector summation, is very important in many scientific and engineering computer applications. Most vector reductions are performed by using a single arithmetic unit in a repetitive way. In this paper the architecture and performance of a pipelined, parallel vector reduction processor is discussed.

The performance of the parallel reduction processor is given as a function of the size of the vector to be reduced and the number of pipeline segments of the reduction processors involved. In addition to that, the number of required reduction processors can be determined as a function of the length of the vector to be reduced and a prespecified space-time criterion based on a doubling improvement ratio.

## I. Introduction

Vector reduction techniques for arithmetic pipelines have been proposed by Kuck [1], Kogge [2], and Ni and Hwang [3]. In essence, the vector reduction operation is the application of the dyadic operator on the elements of a vector, such that the order of evaluation is immaterial, i.e. the operations are associative and commutative. Let "$o$" be the dyadic operator, $X[i]$, $i=1,\dots,n$ the vector, and $Z$ the scalar output, the vector reduction operation can then be formulated as

$$Z = X[1]oX[2]o\dots oX[n] \qquad (1)$$

The vector reduction operation can be performed by a pipelined reduction processor (Fig. 1), where $q$ is the number of sections in the pipeline. To establish the performance of a vector reduction method M, it is convenient to partition the process into three phases:

$$T_M^{re} = T_M^f + T_M^m + T_M^d \qquad (2)$$

where $T_M^f$ is the number of cycles needed to enter all elements of the vector $X$ into the reduction processor (feed phase), $T_M^m$ is the number of cycles needed to merge the partial results in the pipeline to a single result (merge phase), and $T_M^d$ is the number of cycles to drain the pipeline (drain phase).

It can easily be observed that $T_M^f + T_M^d = n + q - 1$ for all methods $M$, leading to

$$T_M^{re} = n + q - 1 + T_M^m \qquad (3)$$

Therefore, the main difference between the methods in [1-3] is the merging time $T_M^m$. The smallest values of $T_M^m$ are obtained by applying the methods of Ni and Hwang [3], which are further improvements of Kuck's and Kogge's method [1,2]. They developed two different methods: a *symmetric* and an *asymmetric* method.

In Fig. 1 the hardware configuration for both methods is shown. The first $min\{n,q\}$ cycles the elements of $X$ are merged with a constant $C$ into the reduction processor ($C=0$ for vector summation and inner product). If $n \leq q$, then the merging phase is started. If $n>q$ the next elements of $X$ are paired with the results leaving the pipeline. This procedure continues until no element of $X$ is left.

In the symmetric method (SM-method) two consecutive productive segments are merged, when leaving the pipeline. A segment is said to be productive, if it contains data which is part of the overall reduction operation. The register is used to hold a partial result until the next partial result leaves the pipeline. These two partial results are then entered again into the reduction processor. If the number of productive segments is odd, the last partial result is merged with a dummy result, keeping the distance between the productive segments always $2^i$ after the $i$-th iteration. The merging time $T_M^m$ then equals [3]

$$T_{SM}^m = \begin{cases} q\lceil log q\rceil + 2^{\lceil log q\rceil} - q & if \quad n>q \\ q\lceil log n\rceil + 2^{\lceil log n\rceil} - n & if \quad n\leq q \end{cases} \qquad (4)$$

The asymmetric method (AM-method) differs from the symmetric method in the treatment of the last partial result in the case of an odd number of productive segments. In this situation the last partial result is not merged with a dummy partial result, but is left in the register waiting for the next partial result leaving the pipeline. The merging time of the asymmetric method equals [3]

$$T_{AM}^m = \begin{cases} q\lceil log q\rceil - 2^{\lceil log q\rceil} + q & if \quad n>q \\ q\lceil log n\rceil - 2^{\lceil log n\rceil} + n & if \quad n\leq q \end{cases} \qquad (5)$$

Clearly, the asymmetric method is faster than the symmetric method, with the exception of $q=2^r$, $n \geq q$, when both methods have equal performance. However, the control sequence of the asymmetric method is more difficult to implement, because it cannot be expressed in a simple formula [3].

In this paper a parallel processing architecture for performing the vector reduction operation, consisting of a linear array of pipelined

0190-3918/86/0000/0503 $01.00 © 1986 IEEE

processors, is presented. The performance of the proposed architecture is determined. A formula is derived, by which the number of required reduction processors can be determined as a function of the size of the vector to be reduced and a prespecified space-time criterion.

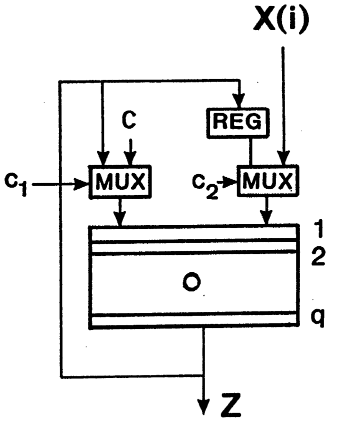

*Fig. 1. Pipelined reduction processor*

## II. Architecture of the parallel reduction processor

The parallel reduction processing structure considered in this paper is the linear array. The linear array consists of $N$ reduction pipelines (Fig. 2); every reduction pipeline having its own local memory. In order to be able to produce a scalar output value, the $N$ pipelines are connected by means of an interconnection network. A single reduction pipeline consists of $q$ segments. Some values of $q$ in actual systems are $q=7$ (o=*) and $q=6$ (o=+) for the CRAY-1 [5], and $p=7$ (o=*), $q=8$ (o=+) for the Cyber 205 [6].

In the following, we will consider the reduction of a vector of dimension $n$, by using $r$ of the $N$ reduction pipelines.

The $n$ vector is divided into $r$ subvectors, each with $\lceil n/r \rceil$ elements. Each of the $r$ subvectors is fed to one of the processors $P_1, P_2, \dots, P_r$. The merging phase can be done in two different ways:

method-1: All subvectors are merged into a single result in each of the $r$ processors. These partial results are then transferred, one by one, from $P_2$ until $P_r$ to $P_1$. In fact this can be viewed as the reduction of an $r$ element vector into a single result. The process is depicted in Fig. 3a. The total number of processing cycles is equal to

$$T_M^{re} = \left\lceil \frac{n}{r} \right\rceil + r + 2(q-1) + T_M^m\left(min\left(\left\lceil \frac{n}{r} \right\rceil, q\right)\right) + T_M^m(min(r,q)) \qquad (6)$$

method-2: After the individual feed-phase of the $i$-th subvector on the $P_i$-th processor, the $min\{\lceil n/r \rceil, q\}$ results in each pipeline are pairwise merged; $P_1$ and $P_2$ in $P_1$, $P_3$ and $P_4$ in $P_3$, etc. Then $P_1$ and $P_3$ are merged in $P_1$, $P_5$ and $P_7$ in $P_5$, etc. This process continues until all results are transferred to $P_1$, where they are finally merged to a single result (Fig. 3b). The transfer and merge process from $P_1, \dots, P_r$ to $P_1$ takes $q \lceil log r \rceil$ cycles. The total number of processing cycles equals

$$T_M^{re} = \left\lceil \frac{n}{r} \right\rceil + q.\lceil log r \rceil + q - 1 + T_M^m\left(min\left\{\left\lceil \frac{n}{r} \right\rceil, q\right\}\right) \qquad (7)$$

An alternative way of achieving the same result as in (7) is shown in Fig. 3c. The $min\{\lceil n/r \rceil, q\}$ results are first merged to a single result. Then the results are pairwise merged, taking $q.\lceil log r \rceil$ cycles. Therefore, with the inclusion of the feed phase and the final drain phase, the same number of processing cycles, as denoted in Eq. (7), is derived. However, this version of method-2 has the important advantage that only $\lceil log r \rceil$ instead of $(min\{\lceil n/r \rceil, q\})$. $\lceil log r \rceil$ results have to be transferred between the reduction processors.

The difference between method-1 and method-2 equals

$$\begin{aligned} DIFF(M) &= T_M^{re}(method1) - T_M^{re}(method2) \\ &= r + T_M^m(min(r,q)) + q - 1 - q.\lceil log r \rceil \qquad (8) \end{aligned}$$

For $r \leqslant q$, we substitute the AM-method, yielding $DIFF(AM) = 2r - 2^{\lceil log r \rceil} + q - 1$. The worst case is obtained for $r = 2^k + 1$, resulting in $DIFF(AM) = q + 1$. Therefore, if $r \leqslant q$, method-2 is always faster than method-1. For $r > q$, we get from eq. (8) $DIFF(AM) = r + q.\lceil log q \rceil - 2^{\lceil log q \rceil} + 2q - 1 - q.\lceil log r \rceil$. Substitution of $r = k.q$, $k > 1$ leads in the worst case to $k.q + q\lceil log q \rceil - 2^{\lceil log q \rceil} + 2q - 1 - q.\lceil log(k.q) \rceil \geqslant k.q - 2^{\lceil log q \rceil} + 2q - 1 - q.\lceil log k \rceil$. Since $k > \lceil log k \rceil$ and $-2^{\lceil log q \rceil} + q \geqslant -q + 2$, it follows that $k.q - 2^{\lceil log q \rceil} + 2q - 1 - q.\lceil log k \rceil > 0$. Therefore, it is concluded that method-2 is faster than method-1.

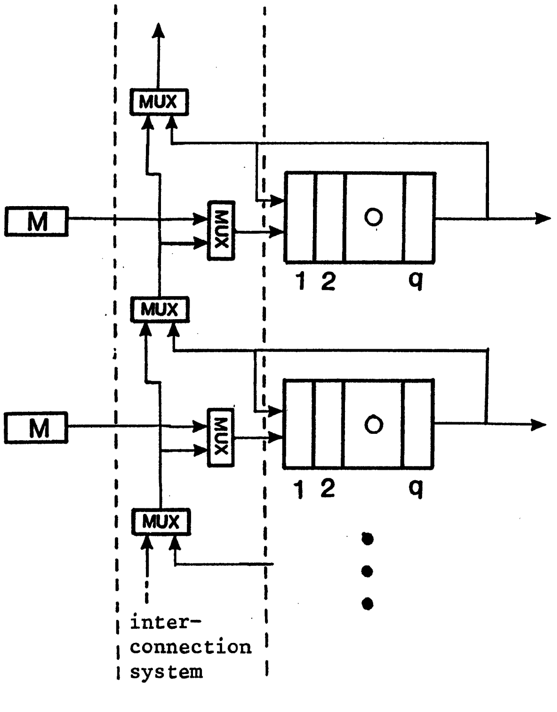

*Fig. 2. The partitioned linear array of reduction processors*

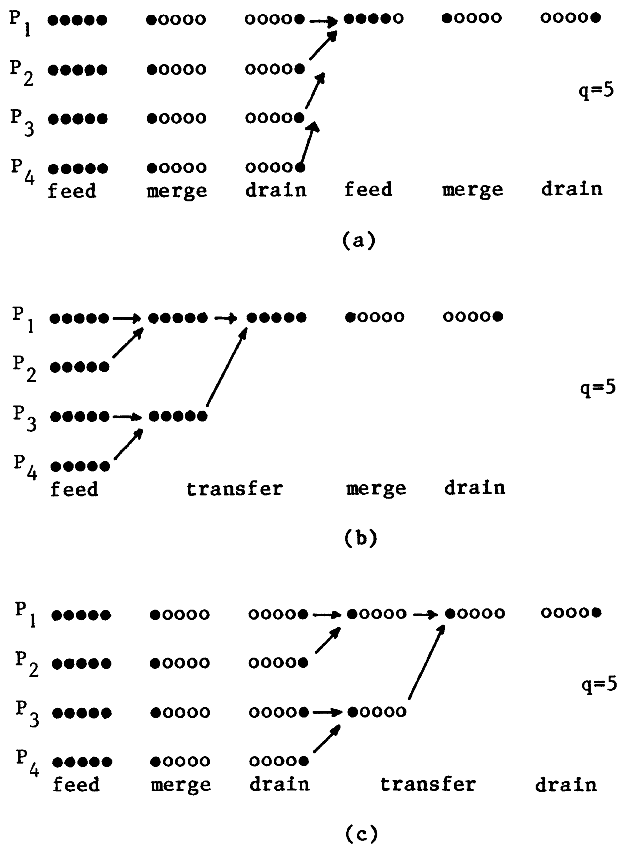

*Fig. 3. a) Processing according to method 1,*
*b) Processing according to method 2,*
*c) alternative for method 2.*

A possible realization of the interconnection system between the $r$ pipelines is shown in Fig. 2. By means of a linear chain of multiplexors the interconnection system can easily be partitioned in $1, 2, \ldots, \lceil r/2 \rceil$ separate buses. Since the inter-pipeline transfers do not overlap in time, this simple system is adequate. The interconnection network in Fig. 2 has an advantage over non-partitionable linear array approaches, since the latter needs $O(N)$ cycles to merge the $N$ partial results from the individual reduction pipelines, whereas by using the approach of Fig. 2, this requires only $O(logN)$ cycles.

### Performance of the binary tree

In the following, we consider the performance of a pipelined binary tree processor for vector reduction. The structure of such a processor is illustrated in Fig. 4.

Suppose a subtree with r pipelined units of the (maximal) $N$ pipelined units is used to reduce an $n$-element vector, $r=1,2,4, \ldots, N$. To evaluate Eq. (1), $n$ elements of the vector are divided into $\lceil n/r \rceil$ groups, $G(j)$, for $j=1,2, \ldots, \lceil n/r \rceil$ . When $n$ is not an integral multiple of $r$, $\lceil n/r \rceil . r-n$ zero-elements are added to the end of the vector, such that each group consists of $r$ elements. Group $G(j)$ is fed into the uppermost $r/2$ pipelined units at the $j$-th clock cycle, for $j=1,2, \ldots, \lceil n/r \rceil$ . After $\lceil n/r \rceil +q. \lceil logr \rceil$ cycles, $min\{q, \lceil n/r \rceil \}$ partial results are obtained in the segments of the cumulative pipeline unit. Next, these $min\{q, \lceil n/r \rceil \}$ partial results in the cumulative unit must be merged into the final result, the reduction time of this group-merging phase is given in Eq. (4) and Eq. (5). Finally, $q-1$ cycles are required to drain the last pipeline. Thus the total reduction time is

$$Trt^{re}_{M}(n,r)=\left\lceil\frac{n}{r}\right\rceil+q.\lceil logr\rceil+ T^{m}_{M}\left(\left\lceil\frac{n}{r}\right\rceil\right)+q-1 \qquad (9)$$

($rt$=reduction-tree)

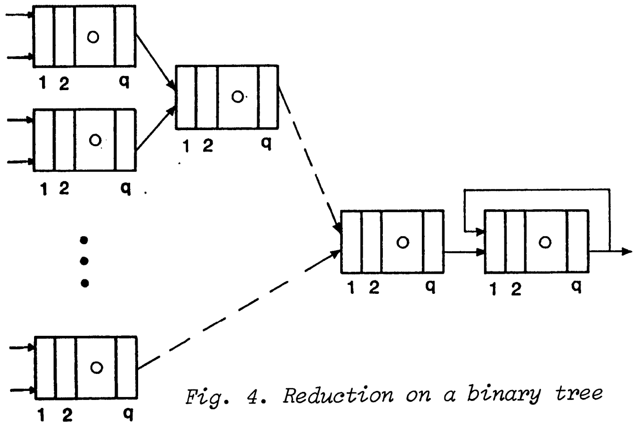

*Fig. 4. Reduction on a binary tree*

From Eq.(7) and Eq.(9), we can see that the reduction time is the same for the partitioned linear array and the binary reduction-tree. However, the proposed approach is much simpler to implement. It is also very regular, so this approach is suited to VLSI-implementation. For large chains, the multiplexors will give some extra delay. However, if the method of Fig. 3c (method-2) is followed, only one result per bus topology connection has to be transferred. Another solution is to construct a system with a large number of processors in a modular and hierarchical way. For example, every $p=2^{8}$ processors form a cluster. Within the cluster the interconnection is as described above; between every $p$ clusters a similar type of (multiplexor) interconnection network is established, etc. In vector reduction, the data only has to be transferred between the "bottom" pipelines of each cluster ($P_1$ in Fig. 3). Consequently, the the maximal interconnection distance is $2+log(p)$ multiplexors. The partitioned linear array is also fault tolerant. If one of the processor faults, it can easily be isolated. When the global controller of the system has detected a faulty processor, it just "shunts" the corresponding multiplexor to allow the incoming data to be passed on to the next processor. Of course, the performance will degrade, since the data for the faulty processor must be fed to the correctly operating processors within the cluster. However, the decrease in performance is gracefully. In this way, any malfunctioning processors can be localized. Compared with a fault-tolerant approach for a binary tree structure [9], the partitioned linear array is much simpler and more superior; there is no need of extra processors and connections.

## III. Minimal computation time

For the determination of the minimal computation time, we will only consider method-2. Suppose we have a maximum of $N$ pipelines in a reduction system. Then the minimal evaluation time of an $n$ term vector can be expressed as follows:

$$T_{min} = min\left\{T_M^{re}(n,r)\,\middle|\,r=1,2,\ldots,N\right\} \tag{10}$$

We are interested in the value of $r$ for which Eq. (10) is reached. This is not so simple, since the function in Eq. (7) has many discontinuities and is difficult to handle analytically. Instead of that we will try to approach Eq. (10) by the following method. First Eq. (10) is replaced by a continuous function by means of canceling the ceiling signs. Substitution of the SM-method or AM-method then gives

$$Tc_M^{re} = \frac{n}{r}+q\,log\,r+q-1+\begin{cases} q\,log\,q, & \frac{n}{r}\geqslant q \\ q\,log(\frac{n}{r}), & \frac{n}{r}<q \end{cases} \tag{11}$$

Differentiating (11) with respect to $r$ leads to

$$\frac{d(Tc_M^{re})}{dr} = \begin{cases} \frac{-n}{r^2} + \frac{q}{r.ln2} & if\ \frac{n}{r}\geqslant q \\ \frac{-n}{r^2}, & if\ \frac{n}{r}<q \end{cases} \tag{12}$$

The minimum of (11) is reached at either $r_1 = min\{(n.ln2)/q,N\}$ or $r_2=min\{n,N\}$ (remember that $N$ is the maximum number of available pipelines). Whether $r_1$ or $r_2$ is chosen depends on the minimum of $T(n,r_1)$ and $T(n,r_2)$. The approximation of $r$ is denoted as

$$r_{appr}(n)=opt(r_1,r_2)=opt\left(min\left\{\frac{n.ln2}{q},N\right\},min\{n,N\}\right) \tag{13}$$

where $opt(r_1,r_2)=\{r\,|\,T(r)=min(T(r_1),T(r_2))\}$. It is shown in Fig. 5a and 5b that equation (13) is a reasonable approximation. In these curves the optimal and approximated values of $r$ are shown as a function of $n$, with as parameter values $N=16$ and $q=7$. Fig. 5a also shows a peculiar behavior of the reduction system. The optimal and approximated optimal value of $r$ behave quite discontinuously. The curve jumps up and down and gives large differences in $r$ for some nearby values of $n$. In Fig. 5b it is shown that despite the wild behavior of the curve in Fig. 5a, the number of processing cycles is a monotone increasing function of $n$. If we fix the choice of $r_{appr}$ to $r_{appr}=r_1$, the curves of Fig. 6a and 6b result. The latter choice $r_{appr}$ is a monotone function of $n$, but the deviation from the minimal computation time is slightly larger. Simulations with other values of the parameters $N$ and $q$ globally give the same results [7].

## IV. Computation time and efficiency, the DI-ratio

We will now face the question whether the choices of $r$ as derived in the previous section are efficient choices of $r$. The only thing that the formula (13) guarantees is that the choice of $r$ is such that the computation time is within a certain bound of the minimal computation time. This is not necessary an efficient choice of $r$. Fig. 7 shows the behavior of the computation time of a vector with length $n=320$ on $r$ pipelines, with $q$ segments each. It shows that the computation time decreases fastly with an increase of $r$ in the first part of the curve, but soon the curve flattens and the improvement becomes insignificant. This implies that in order to obtain a minimal computation time, many more pipelines are required beyond the point where the computation time decreases significantly as a result of an increase in the number of pipelines. For example, if $q=8$ and $n=320$, the optimal choice of $r$ is $r=32$ (with $N=32$), however, above the values of $r$ in the region $(4,8)$, no significant improvements of the computation time are obtained. At $r=8$, the computation time is $T(320,8)=95$, and at $r=32$, the computation time is $T(320,32)=81$, yielding a $10\%$ improvement in speed at the cost of $4$ times the number of pipelines. Therefore, the minimum computation time criterion leads to a very low processor-efficiency.

For practical purposes a different criterion on the choice of $r$ is needed. We will try to establish a criterion for determining $r=r_0$, such that beyond the point $r_0$ no acceptable improvement in speed can be made.

Normally, we could use an efficiency measure, such as $\eta(r)=T(1)/(r.T(r))$. However, $\eta(r)$ is strongly nonlinear and the above definition leads to cumbersome formulas. Moreover, an excessive number of processors may be needed to meet an efficiency criterion (see also the discussion at the end of point 2 of this section). Instead of that, we will introduce the Doubling Improvement ratio (DI-ratio). We are interested in the relative speed improvement (DI-percentage) when the number of pipelines is doubled. The DI-improvement can be expressed as follows:

$$k_{DI} = \frac{T(n,r)-T(n,2r)}{T(n,r)} \tag{14}$$

Thus, $k_{DI}.100\%$ improvement in speed is obtained by doubling the number of pipelines. In general, $k_{DI}$ will be in the range $(0,\ 0.5)$.

The use of the DI-ratio as an efficiency measure has the advantage that it is a better match to the behavior of the computation time curve of a vector reduction, it smoothens discontinuities, and leads to formulas, which can be analyzed.

In the following the behavior of $k_{DI}$ for a system using the SM-method of reduction will be analyzed first. Three cases are considered:
1. $1\leqslant\lceil n/r\rceil\leqslant q$, 2. $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$, and 3. $\lceil n/2r\rceil\geqslant q$.

1. $1\leqslant\lceil n/r\rceil\leqslant q$. For $\lceil n/r\rceil=1$, substitution of Eq. (4) and Eq. (7) into (14) leads to a negative improvement, so we are only interested in the range of $2\leqslant\lceil n/r\rceil\leqslant q$. It can be proved that $\lceil log\,r\rceil - \lceil log\,2r\rceil=-1$ and for $\lceil n/r\rceil>1$ , $\lceil log\lceil n/r\rceil\rceil - \lceil log\lceil n/2r\rceil\rceil=1$ [7]. By using these properties, substitution of Eq. (4) and (7) into Eq. (14) leads to

$$k_{DI} = \frac{\frac{1}{2}.2^{\lceil log\lceil n/r\rceil\rceil}}{2^{\lceil log\lceil n/r\rceil\rceil}+q.\left\lceil log\left\lceil\frac{n}{r}\right\rceil\right\rceil+q.\lceil log\,r\rceil+q-1} \tag{15}$$

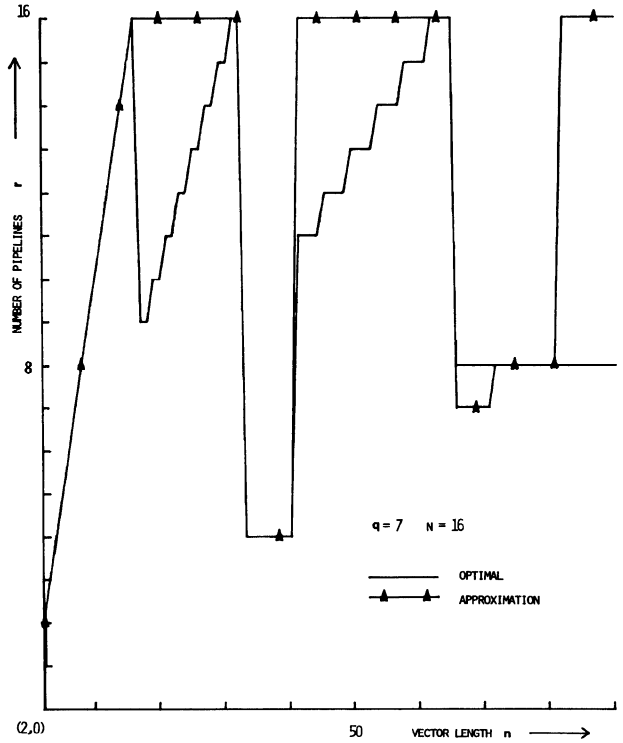

*Fig. 5a. The number of reduction processors as a function of the vector length.*

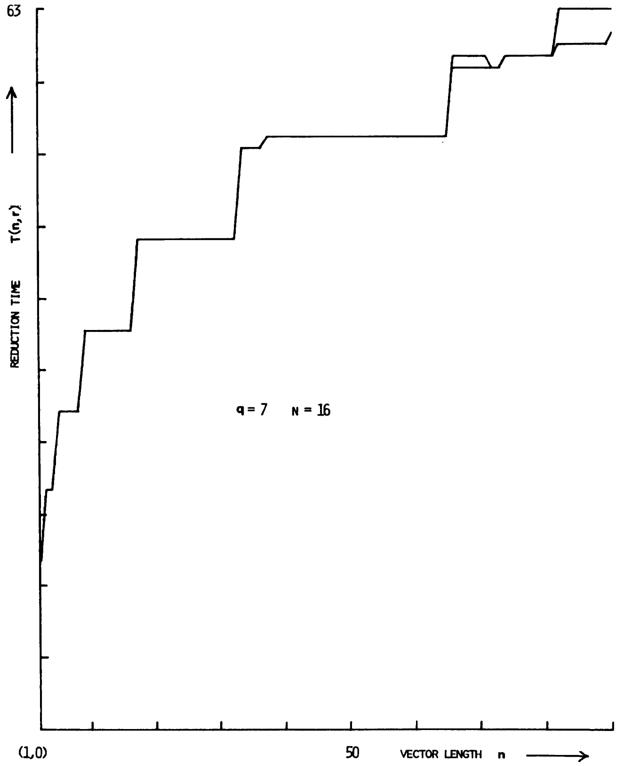

*Fig. 5b. The reduction time as a function of the vector length.*

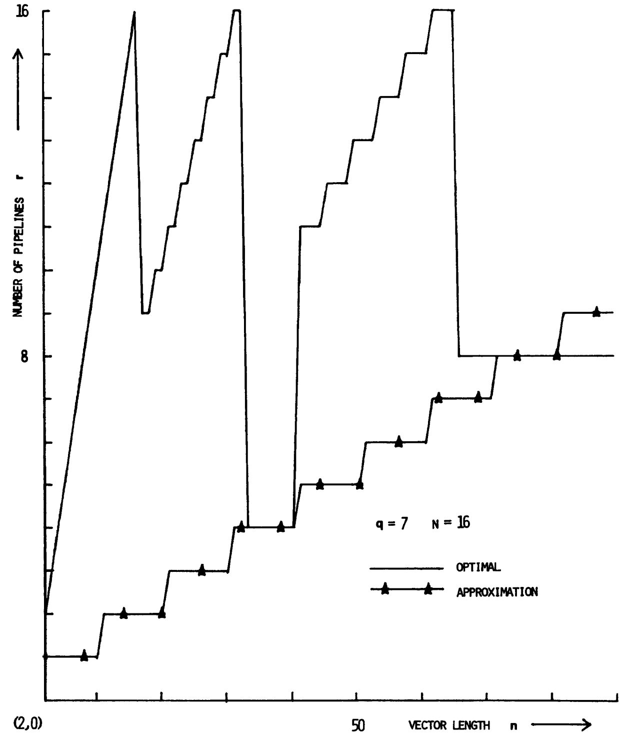

*Fig. 6a. The number of reduction processors as a function of the vector length, if $r_{appr}=r_1$.*

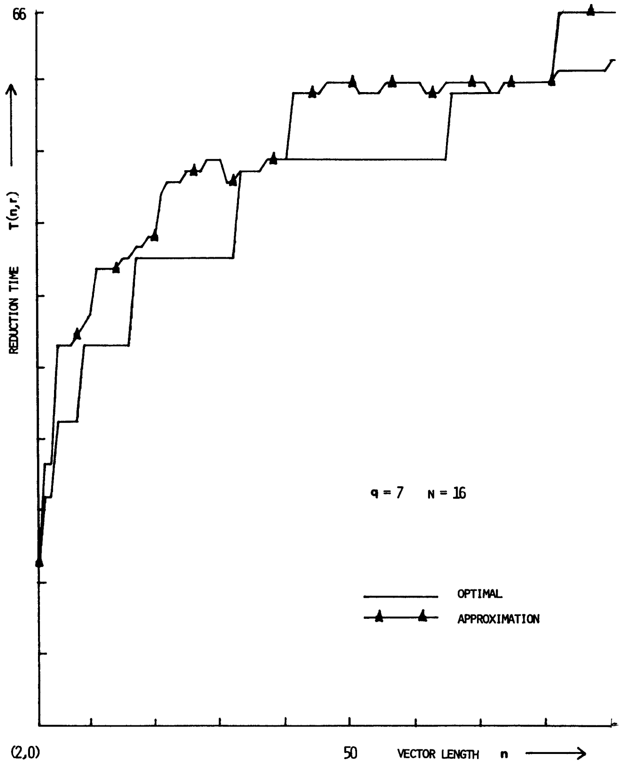

*Fig. 6b. The reduction time as a function of the vector length, if $r_{appr}=r_1$.*

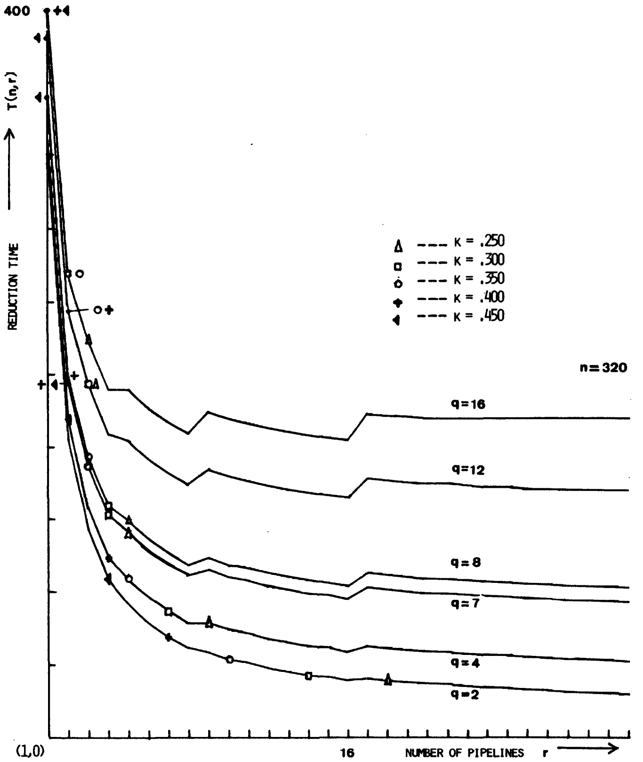

*Fig. 7. The reduction time as a function of the number of reduction processors for several values of q.*

Let $i=\lceil \log\lceil n/r\rceil\rceil$, and then differentiating $k_{DI}$ in Eq. (15) with respect to $i$ yields $\partial k_{DI}/\partial i>0$ for $i\geqslant 0$. Thus, $k_{DI}$ is maximal at $\lceil n/r\rceil=q$ for $1\leqslant\lceil n/r\rceil\leqslant q$, i.e.,

$$k_{DI}\leqslant\frac{\frac{1}{2}\cdot 2^{\lceil \log q\rceil}}{2^{\lceil \log q\rceil}+q.\lceil \log q\rceil+q.\lceil \log r\rceil+q-1} \qquad (16)$$

It also holds that $2^{\lceil \log q\rceil}\leqslant 2q-2$ [7], therefore, from Eq. (16) it follows

$$k_{DI}\leqslant\frac{q-1}{3q-3+q.\lceil \mathit{loq}r\rceil+q.\lceil \log q\rceil} \qquad (17)$$

For $r=1$ and $q\geqslant 2$, $k_{DI}\leqslant 0.2$, and for $q\geqslant 4$, $k_{DI}\leqslant 0.18$. For $r\geqslant 2$, this figure is $k_{DI}\leqslant 0.14$ for both $q\geqslant 2$ and $q\geqslant 4$. Therefore, no impressive improvements can be achieved.

Furthermore, since the inequality (17) gives only an upper bound, the actual values of $k_{DI}$ may be much smaller. Thus, we may summarize the above consideration as follows: for $1\leqslant\lceil n/r\rceil\leqslant q$, doubling the number $r$ to $2r$ leads to a speed up of less than $20\%$.

<u>2. $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$</u>. For $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$, after some substitution, equation (14) can be transformed into

$$k_{DI}=\frac{\left\lceil\frac{n}{r}\right\rceil-2q+q(\lceil \log q\rceil-\left\lceil \log\left\lceil\frac{n}{2r}\right\rceil\right\rceil)+2^{\lceil \log q\rceil}-2^{\lceil \log\lceil n/2r\rceil\rceil}}{\left\lceil\frac{n}{r}\right\rceil+q\lceil \log r\rceil+2^{\lceil \log q\rceil}+q\lceil \log q\rceil-1} \qquad (18)$$

From $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$, it follows $q/2\leqslant\lceil n/2r\rceil\leqslant q$, this means that either a. $\lceil \log\lceil n/2r\rceil\rceil=\lceil \log q\rceil-1$ or b. $\lceil \log\lceil n/2r\rceil\rceil=\lceil \log q\rceil$.

a. Substitution of $\lceil \log\lceil n/2r\rceil\rceil=\lceil \log q\rceil-1$ in Eq. (18) leads to

$$k_{DI}=\frac{\left\lceil\frac{n}{r}\right\rceil-q+\frac{1}{2}\cdot 2^{\lceil \log q\rceil}}{\left\lceil\frac{n}{r}\right\rceil+q.\lceil \log r\rceil+2^{\lceil \log q\rceil}+q.\lceil \log q\rceil-1} \qquad (19)$$

Since $r\geqslant 1$, $\lceil n/r\rceil\leqslant 2.\lceil n/2r\rceil\leqslant 2.2^{\lceil \log\lceil n/2r\rceil\rceil}=$ $=2^{\lceil \log q\rceil}$, and (19) is an increasing function of $\lceil n/r\rceil$, it follows that

$$k_{DI}\leqslant\frac{2^{\lceil \log q\rceil}-q+\frac{1}{2}\cdot 2^{\lceil \log q\rceil}}{2^{\lceil \log q\rceil}+2^{\lceil \log q\rceil}+q.\lceil \log q\rceil-1} \qquad (20)$$

For $q\geqslant 2$, $q$ can be written as $q=2^s+t$ with $s\geqslant 0$ and $1\leqslant t\leqslant 2^s$; substitution of $q=2^s+t$ in (20), leads to

$$k_{DI}\leqslant\frac{2^{s+1}-t}{2.2^{s+1}+(2^s+t)(s+1)-1}\leqslant\frac{2^{s+1}-1}{2^{s+2}+(2^s+1)(s+1)-1} \qquad (21)$$

After some calculation, it follows that for $s\geqslant 0$ the maximum of $(2^{s+1}-1)/\{2^{s+2}+(2^s+1)(s+1)-1\}$ is $0.233$ at $s=2$. Therefore, it holds $k_{DI}\leqslant 0.233$.

b. Substitution of $\lceil \log\lceil n/2r\rceil\rceil=\lceil \log q\rceil$ in (18) leads to

$$k_{DI}=\frac{\left\lceil\frac{n}{r}\right\rceil-2q}{\left\lceil\frac{n}{r}\right\rceil+q\lceil \log q\rceil+2^{\lceil \log q\rceil}+q\lceil \log q\rceil-1} \qquad (22)$$

from $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$ and $\lceil n/r\rceil\leqslant 2.\lceil n/2r\rceil$, it follows that $k_{DI}\leqslant 0$.

From a and b, it has been shown that $k_{DI}\leqslant 0.233$ for $q\geqslant 2$ and $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$. Therefore, we may now conclude that for $1\leqslant\lceil n/r\rceil\leqslant q$ and $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$, the DI-percentage is less than $23.3\%$ for $r\geqslant 1$ and $q\geqslant 2$. For $r\geqslant 2$ and $q\geqslant 2$, this DI-percentage is even smaller, having a value of less than $20\%$.

From the above consideration, we conclude that in the cases of $1\leqslant\lceil n/r\rceil\leqslant q$ and $\lceil n/2r\rceil\leqslant q\leqslant\lceil n/r\rceil$, the DI-percentages for the SM-method are below $23.3\%$ for $r\geqslant 1$ and $q\geqslant 2$, and below $20\%$ for $r\geqslant 2$ and $q\geqslant 2$. For the AM-method, a similar analysis can be made. It can be shown that in this case the DI-percentage is below $20\%$ for all $q\geqslant 2$ [7].

In order to get an interpretation about the consequences of such a low DI-percentage, we want to discuss shortly the relationship between the DI-improvement and the processor-efficiency. It is a well-known fact that the processor-efficiency in a multi-processor system is lower than a single processor system as a result of the intercommunication overhead (which is the price paid for greater speed). In the following, we will use the reduction time $T(r=1)$ as the reference to define the processor-efficiency as

$$\eta(r)=\frac{T_M(1)}{r.T_M(r)}\cdot 100\% \qquad (23)$$

where $M$ denotes the reduction-method, and $T_M(r)$ is the reduction time under method $M$ when $r$ pipelines are involved in the computation. The relationship of the DI-percentage and processor-efficiency can be expressed as

$$\eta(2r) = \frac{\eta(r)}{2.(1-k)} \tag{24}$$

Further, it is shown in [7] that $\eta(r) \leqslant 65.2\%$ for $r=2$, $1 \leqslant \lceil n/r \rceil \leqslant 2q$ and $q \geqslant 2$ for both SM- and AM-method. Therefore, from the fact that $k \leqslant 23.3\%$, it follows $\eta(2r) < 0.652/(2^* 0.767) = 42.5\%$ for $r \geqslant 2$. Thus, the processor-efficiency is less than $42.5\%$ for $1 \leqslant \lceil n/r \rceil \leqslant q$ and $\lceil n/2r \rceil \leqslant q \leqslant \lceil n/r \rceil$ with $q \geqslant 2$ and $r > 2$. To reduce a vector of length $n$, the number of (dyadic) operations is equal to $(n-1)$. If we use the definition $\eta(r) = (n-1)/r.T_M(r)$, then we will have $\eta(r) < 50\%$ for $1 \leqslant \lceil n/r \rceil \leqslant 2q$ and $q \geqslant 2$ for both SM- and AM-method, leading to $\eta(2r) < 30.6\%$ for $r \geqslant 1$. This processor-efficiency is far too low, so it should be avoided. Thus, for a given problem with a vector length $n$, we should choose $r$ such that $\lceil n/2r \rceil \geqslant q$, in order to obtain a reasonable processor-efficiency (in the case of $n \leqslant 2q$, $r=1$ is an obvious choice).

3. $\lceil n/2r \rceil \geqslant q$. Substitution of Eq. (7) with the SM-method into Eq. (14), it yields

$$k_{DI} = \frac{\lceil n/r \rceil - \lceil n/2r \rceil - q}{\lceil n/r \rceil + q.\lceil log r \rceil + q.\lceil log q \rceil + 2^{\lceil log q \rceil} - 1} \tag{25}$$

The asymptotic value of $k_{DI}$ is $50\%$ as $n/r \rightarrow \infty$. However, the requirement of $k_{DI}=50\%$ is not realistic, even undesirable for the sake of computing speed. If we require that $k_{DI} \geqslant 0.45$, then the usage of more than one reduction pipeline is only possible when $n$ is very large. So, our aim is to determine a reasonable compromise between speed and processor-efficiency.

We want to determine a choice $r=r_0$ as a function of $n$ under a given condition $k_{DI}=k$ $(k \in [0.25, 0.5))$. It is not trivial to solve Eq. (25) and to express the DI-choice $r_0$ as an explicit function of $k_{DI}$. Furthermore, it is desirable to have a simple formula for the determination of $r_0$.

By canceling all the ceiling functions in Eq. (25), and substituting $r=r_0$ and $k_{DI}=k$, the following approximation is obtained:

$$r_0 \simeq \frac{(0.5 - k).n}{q(1+k+k log r_0 + k log q)} \tag{26}$$

Eq. (26) is an implicit function of $r_0$. We want to find a simple formula from which an approximation to $r_0$ can be easily calculated.

Substitution of $r_0=\alpha.n$ into Eq. (26), gives

$$\alpha \simeq \frac{0.5 - k}{q(1+k+k.log\alpha + k.log n + k.log q)} \tag{27}$$

where $\alpha$ is an unknown parameter which is a function of $k$, $q$ and $n$.

For a given vector of length $n$, $\alpha$ in Eq. (27) can be computed by means of one of the known numerical root finding methods (e.g., Newton-method). However, it is impractical to iterate $\alpha$ before every vector reduction operation (it may even take more time than the reduction itself!). From Eq. (27), we have learned that $log\alpha$ varies very smoothly as $n$ increases; it is approximately a function of $log(log n)$. One solution is to approximate $log\alpha$ by $a+b.log(log(n))$, where the parameters $a$ and $b$ can be determined by means of the least square error method [7].

Thus, by using the approximation function of $log\alpha$, Eq. (26) is transformed to

$$r_0 = \frac{c_1.n}{c_2+c_3 log(log(n)) + c_4 log(n)} \tag{28}$$

where $c_1=(0.5-k)$, $c_2=q^*(1+k+k.a+k log q)$, $c_3=q.k.b$ and $c_4=q.k$ with $k=k_{DI}$. All $c_i$'s are constants when a choice of $k$ is made. Simulations show that the approximation formula (28), together with the calculated values of $a$ and $b$, gives satisfactory results (error between Eq. (28) and Eq. (26) is less than 5%). Furthermore, Eq. (28) is valid for both the SM-method and the AM-method.

The computation of $log(n)$ and $log(log(n))$ can be done in a simple way by means of the following approximation scheme: determine the position $P_{MSB}$ of the most significant bit (MSB) of $n$; then $P_{MSB}$ is an approximation of $log(n)$ with an error of less than $1$. Another approximation with an error of less than $0.585$ can be obtained by looking at the bit next to the MSB, if this bit is $1$ then $P_{MSB}+1$ is used as the approximation for $log(n)$, otherwise, $P_{MSB}$ is used. Applying now the same process to the obtained result of $log(n)$, an approximation value of $log(log(n))$ is determined.

Fig. 7 shows a plot of the reduction time $(T(n,r))$ as a function of the number of pipelines $(r)$ involved in the processing of a given vector of length $n$. The points related to several different $k_{DI}$ values are shown by means of the markers. The numerical results in Fig. 7 also show, that a choice of $k_{DI} < 25\%$ will only greatly increase the use of the number of pipelines and result in very low processor-efficiency as has already been pointed out earlier.

## V. Performance

Generally, in vector processing a parallel pipelined system performs better than a parallel non-pipelined system. Suppose a non-pipelined processor has a cycle time of $t_{nonp}=s$ $ns$, then with the same technology a pipeline cycle time of $t_{pipe}=(s/q + c)$ $ns$ can be realized, where $q$ is the number of segments of the pipelined processor, and $c$ represents the delay of a latch which is introduced to hold the partial result between each segment. For example, consider a 6 segment adder (like the one in the Cray X-MP) having a cycle time of $t_{pipe}=9.5$ $ns$, then in the ideal case a non-pipelined adder has a cycle time of $t_{nonp}=45$ $ns$ (i.e. assuming that the delay of a latch is about $2.0$ $ns$ for the pipelined case). However, in reality, the ratio $R_\infty$ of the maximum vector processing rate and the maximum scalar processing rate is usually in the order of $10$ (e.g., $R_\infty=13$ for Cray-1 [8]), where $R_\infty$ is defined as $R_\infty = r_{\infty v}/r_{\infty s}$ [8], and $r_{\infty v}$ and $r_{\infty s}$ are the maximal vector and scalar processing rates respectively. Thus, in reality the cycle time of a non-pipelined (general purposed) processor will have a cycle time much greater than the ideal cycle time of *45 ns* in our example. This is due to the fact that instructions must be fetched and decoded for each operation before performing the operation itself, whereas this is not the case for a pipelined processor. The performances of the non-pipelined approach and the pipelined approach are shown in Table I for a system of *8* processors. The computation speeds are listed for different values of $k$. In Table I, the performance of both the ideal parallel non-pipelined system and the practical non-pipelined system with $R_\infty=10$ are shown. $S_{pipe}$ is the speed of the pipelined approach, $S_{nonp}$ and $S_R$ are the speed of the ideal nonpipelined approach and the practical nonpipelined approach respectively. From the table, it is clear that the pipelined system outperforms the ideal non-pipelined system, except for very small vector lengths, and the parallel pipelined system outperforms the practical non-pipelined system in all the cases shown in the table.

## VI. Conclusion

In this paper, we have studied vector-reduction techniques in a parallel arithmetic pipeline processing environment. It has been shown that with a simple partitionable linear array structure, reduction algorithms can be implemented efficiently. The proposed approach performs the same as a binary-tree network in the reduction of an $n$-element vector.

Regularity and fault tolerance of a system are important criteria to VLSI implementations, the partitioned linear array approach satisfies these two criteria.

The minimal reduction time in a system consisting of $N$ pipelines and an approximation method to achieve the minimal reduction time also have been analyzed. It is known that parallelism and processor-efficiency are tradeoffs. In a multi-pipeline system, the issue of processor-efficiency is a more important problem than in the non pipelined cases, since the time overhead in merging the partial results of each pipeline ($=q\cdot\lceil log r\rceil$, see Fig. 3) is larger. The DI-ratio has been introduced as a means to be able to make a trade-off between computing speed (parallelism) and processor-efficiency.

The DI-ratio can be used to calculate a proper choice of the number of pipelined processors, given the typical maximal vector length of the operations the system will be dealing with, and a required processor efficiency.

# SHARED PIPELINES: EFFECTIVE PIPELINING IN MULTIPROCESSOR SYSTEMS

Amos R. Omondi
J. Dean Brock

Department of Computer Science
University of North Carolina at Chapel Hill

## Abstract

This paper discusses pipelining in the context of multiprocessor systems. It is proposed that for such an architecture, it is possible to design near-optimal pipeline machines by coupling pipelines, using buffers to balance instruction/data flows, concurrently processing several instruction streams, and allowing out-of-order execution of instructions within a stream. We have investigated the issues involved in the design of such a machine by using a uniprocessor pipeline machine as a basis for the type of architecture proposed.

## Introduction

Pipelining has long been a method of obtaining high throughput in uniprocessor systems by overlapping the execution of several instructions; an example of such an arrangement being that shown in the block diagram of Figure 1 in which each stage of the pipeline performs one of the phases in the sequence involved in processing an instruction. Ideally the throughput of such a system is one result per pipeline beat. In practice, however, it is rarely the case that this ideal throughput is achieved. Instructions requiring the transfer of control usually cause severe disruption in the flow of instructions; similar effects occur, although to a lesser extent, in the operand-fetch stage, as a result of the methods employed to resolve conflicts, and a multitude of other (relatively minor) reasons.

In addition to pipelining, performance may be gained through the use of multiple processors; examples of machines which combine extensive pipelining and multiple processors being the S-1 [14] and the HEP[ 11]. This paper deals with the subject of pipelining in the context of multiprocessor systems. In such a case, we believe that it is possible to overcome many of the problems inherent in pipelining by "sharing" pipelines between different instruction streams and using buffers to balance flows through the pipelines. Such an architecture is shown, at a fairly high level, in the diagram in Figure 2. The main idea here is to take several pipelines of the type shown in Figure 1 and to couple them through inter-stage buffers (capable of holding several instructions) in such a manner that during peak processing rates, the flow into the buffer exceeds the flow from the buffer. Thus when processing instructions that would normally cause a disruption in the rate of inter-stage flow, the overall effect would be that while the flow out of some stage would fall to below maximum, the succeeding stage would continue to accept instructions at the maximum rate (by processing instructions buffered during peak flow); strictly, therefore, buffers are not necessary at the output of every stage as implied by Figure 2. The ability to process several instruction/data streams also has many benefits which are discussed below. The same techniques can be applied to data streams in order to ensure that pipelined vector processing units do not experience any performance degradations as a result of disruptions in the delivery of data.

The type of architecture most closely related, in as far as the use of buffers goes, to what we propose is the HEP although essentially the same reasoning also lies behind the use of queues in PIPE [2] and a related scheme, in which several independent processors (cyclically) share a buffer, has also been described by Goto and Shimizu [3]. We have attempted to identify the issues that are involved in the design of a more practical machine than that depicted by the block diagram of Figure 2 and have been concerned with the complexity of such a task relative to that of designing a multiprocessor system consisting of independent pipelines. For this purpose we chose a practical pipelined uniprocessor, the MU5 [8], as a starting point and attempted to develop a shared-pipeline multiprocessor from this.

### The MU5 Processor

In this section we briefly describe the uniprocessor that has formed the basis of our studies [9]. A high-level organization of the MU5 processor is shown in Figure 3. It consists of two major pipelines, the Primary Operand Pipeline (PROP) which is largely concerned with the accessing of primary (named) operands and the Secondary Operand Pipeline (SEOP) which is largely concerned with the accessing of secondary operands such as data structure elements. Instructions fetches are initiated by the Instruction Buffer Unit (IBU) to which the store returns upto eight instructions at a time; IBU then supplies the Primary Operand Unit at the rate of about one instruction per beat (peak). IBU also contains a branch prediction mechanism, the Jump Trace. The B-Unit executes fixed point arithmetic instructions, such those required for computing array indices, and some organisational instructions. The A-Unit executes floating point and fixed point arithmetic instructions.

PROP is a five-stage pipeline: *Initial Decode* in which sufficient decoding is done to isolate the name and select a base register (Stack Pointer, Name Base, etc.), *Add Name to Base Register* in which a name is added to the contents of a base register; *Associate Address* which is the first stage of accessing the Name Store (a "cache" for named operands); *Read Value*, the second part of Name Store access; and *Assemble Operand* in which the operand is assembled and the Program Counter is incremented.

SEOP consists of three main stages: *Descriptor Addressing Unit* (Dr) generates secondary addresses using named descriptors from PROP and the output of the B-Unit as modifier, *Operand Buffer Store* (OBS) makes store requests and buffers operands returned, and *Descriptor Operand Accessing Unit* (Dop) performs masking and shifting to select the required element.

## A Shared Pipeline Multiprocessor

In this section we present a shared-pipeline multiprocessor. The philosophy underlying the architecture is very similar to that of the HEP computer [11]; it centers around the idea of processing several instruction/data streams in a single pipeline and can be viewed as one that develops the multiprocessing-pipelines concept to its ultimate conclusion in that several instructions from the same stream may be processed concurrently and possibly out of sequence.

As previously stated, the main driving problem here is

0190-3918/86/0000/0511 $01.00 © 1986 IEEE

that of pipeline flow disruptions. Conventional pipelined machines have dealt with the problem of flow disruptions by designing hardware to limit the effects of these within individual instruction streams; an example in point being branch prediction strategies [7,10]. The success of these has, however, been limited by the inherent nature of pipelining and of the instructions being processed. Considering conditional control transfers, for example, it can be observed that when both the instruction setting condition codes and the control transfer order fall within the so-called Gulf of Ignorance [5], i.e. the separation between the pipeline entry and the execution units, the latter instruction is unresolvable and such mechanisms as double-fetching (employed in the IBM 360/91 [1]) or the prediction Jump Trace of MU5 must necessarily be of limited success. Pipeline sharing is based on the observation that disruptions within an individual stream are acceptable as long as some other stream can be processed to fill the gap created. The main design issue is, therefore, that of being able to switch streams rapidly; in fact, ideally, the delay incurred should be nil. This is precisely what the interleaving of instructions from different streams is intended to achieve. There are also gains to be made if the instructions in a particular stream can be executed out of their initiation order if the data dependencies so permit; this, for example, reduces the number of active processes (streams) that are needed in order to sustain maximum throughput.

From the above description and Figure 3, it will be observed that in an MU5-like pipeline, the points at which the averaged input rate into a stage may exceed the averaged output rate out of the stage are:

- At the output of IBU as a result of processing branch instructions and other organisational instructions. This is the case even with branch prediction and prefetching.
- At the Name Store, since some instructions will give non-equivalence on association.
- As with the Name Store, an instruction may fail to find its operand in the Operand Buffer Store hence the rate of flow into the A-Unit may be disrupted on certain occasions.
- At the Control-Point/Assemble-Operand stage. Since some instructions are executed at this stage, the flow into the stage will, on the average, exceed the outward flow into the arithmetic units.

Thus recalling the diagrams of Figures 1 and 2, buffers can be inserted at these points to balance the flow into and out of the various stages. This would be the obvious organization and represents the architecture that was considered initially. A much better organization turned out to be that shown in Figure 4. In this all the buffers, that one would expect, in the primary stages of the pipelines still exist although in a different form and they, in effect, been moved into the IBUs. This excludes buffering at the end of the primary pipelines; which we have not, for various reasons, investigated at the present. To keep the diagram simple, not all the relevant features of the architecture are shown as will be apparent from the following discussions. Such omissions include connections from the Instruction Issue to the IBUs (via the IBU-PSB network). Although only two inter-stage buffers per stage are shown, a practical system would include as many buffers as necessary to balance the average flows without any undue performance requirements on the hardware. It is also to be expected that the number of Scalar Execution Units will be much smaller than the number of Vector Execution Units; reasonable numbers being, say, 4 and 32 respectively. In general, the number of units in the primary pipelines can be altered independently of the number of units in the secondary pipelines. No claim is made that Figure 4 of itself depicts a practical machine; at this point, we have emphasized concepts over practical matters whenever conflicts existed.

There are fundamental differences between the organization shown and one that would be obtained from a straightforward extension of an MU5-like machine to multiprocessor system. By far, the most apparent is the decision to separate the single primary store into a *Program Store* and a *Data Store*; in fact the latter is further split into a *Scalar Store* and a *Vector Store*. The main reason for this is to reduce the bandwidth requirements of the various interconnections. With a single (interleaved) store an interconnection system with enough bandwidth to support the accessing rates of all the IBUs, the Scalar Units, and the Vector Units may be an impractical proposition. The separation of a (possibly) single data store into two separate stores arose from the decision to have highly pipelined vector processing units; the use of a separate Vector Store, apart form reducing bandwidth requirements, also allows vector processing orders to be implemented in a more natural way.

## Multiple Instruction Buffer Units

Essentially, the system runs several processes concurrently with instructions from each stream being initiated in a different IBU. A Decode module cycles through the IBUs connected to it and interleaves instructions from several streams into the next stage, after the necessary decoding. Whenever an instruction that would normally cause a disruption, e.g. a branch instruction, is decoded, the corresponding IBU is (temporarily) abandoned until it is known that valid instructions may be taken from the IBU, say when a transfer of control actually takes place.

The important point about the use of several IBUs per Decode is that since instructions from different streams are continually being interleaved, the end effect is that streams (as seen by the pipeline stages) as also being changed at the same rate which is also the maximum rate possible. Thus when a disruption occurs within some stream, the necessary change of stream is obtained, in effect, "for free".

No attempt is made to predict control transfers or to explicitly trap loop instructions. Regarding the former, the implications of trying to do otherwise are quite clear: identifying the instructions belonging to some stream for which an incorrect prediction was made and flushing these out is likely to be very messy at best. Hence all instructions entering the pipelines must be guaranteed to complete. Loop-trapping on the other hand would be quite easy to include since in the case of loops an IBU tends to contain the same set of instructions most of the time.

## Name-Associate Units and Name Caches

At the Name-Associate Stage those instructions causing a non-equivalence are held-up until it can be guaranteed that their operands are available; other instructions may also be held-up at this stage in order to resolve conflicts. We have extensively modified [9] the original MU5 Name Store (Cache) to allow a very large number of instructions to execute out of sequence. In additions to modifications to the Name Store itself, an associatively addressed buffer has been added to each cache unit to store instructions that are held-up in order to resolve conflicts and a queue has also been added to hold instructions with pending store requests. The end result, admittedly, is a rather complex organisation that in its present form needs to be simplified.

Instructions for which the association is successful proceed to the next stage, tagged with a specification of a Name Cache unit holding the operand, and have their operands read out. At the Control Points, branch instructions and some organisational instructions are executed and other instructions are issued to a Scalar Execution Unit or a Vector Associate Unit (VAU) and to a Vector Execution Unit, as appropriate.

### Vector Processing Modules

For vector instructions, the VAU units compute addresses and performs the necessary associate operations, operands are obtained from the Vector Cache, (possibly after a store fetch) and the instruction and operands are forwarded to a Vector Execution Unit for processing. The results of a VEU operation are stored in one of the two data caches, depending on its type, while those of a scalar operation are stored in the Name Cache. The modules involved with the processing of vector orders are also another area where we have had to make significant changes to the original organisation. Modifications in the former have been made to allow out-of -sequence execution, and are similar to the changes made to the Name Store, and to allow data-driven communications such as are to be found in the MU6-V prototype [6].

### Miscellaneous

The Instruction Issue Units (IIUs), which are also the location of Control Points, have also turned out to be more complex than their counterpart in the MU5 PROP; a major addition has been to include a unit resembling the CDC 6600 Scoreboard [13]. Some of the added complexity arose from the attempt to maintain compatibility with the MU5 instruction set, primitive architecture, and general philosophy. An example of this is that while compiler-generated code assumes (for simplicity), for example, that only one Scalar Execution Unit exists, IIU on the other hand assigns schedules instructions according to the availability of execution units. This creates many difficulties, particularly when code assumes that the stack will be used to hold temporary values. The same applies to many orders that explicitly use the base registers; since these registers are located in the early stages of the primary pipelines while part of the execution takes place in the IIUs or the Scalar Execution Units, there is some difficulty in providing the necessary communication. Our solution at the moment is to connect the IIU-SEU/VAU network and the PSB-IBU network and to communicate through these, but this is clearly a solution that leaves much to be desired. It, therefore, appears that any solution short of changing the instruction set and/or changing the primitive architecture is likely to end up being rather complex.

Other significant architectural changes that have been necessitated by the sharing of pipelines are: Certain machine registers, such as the Processor Status Register, Program Counter, and Base Registers have to be replicated so that there is one register of each type for each IBU. As a consequence of this, and of the need to provide communication (which takes place via the PSB-IBU network) between Control Points and IBUs, it is necessary for instructions to be tagged both with a process identifier and the identifier of the IBU in which they are initiated.

## CONCLUSIONS

The original inspiration for the architecture described came from [4] although it may now be hard to discern many similarities with what is described therein. The abstract architecture is one that that combines pipelining and multiprocessing and whose main features are: *shared-buffered pipelines with almost no overhead in stream switching* and *no disruptions in the inter-stage flow of instruction/data* and, hence, no performance degradation on all types of orders, *ability to execute instructions out-of-sequence across a wide window in the stream*, and *high-performance vector processing* It is based on a practical uniprocessor machine and the relative complexity/major issues of realizing such an abstract machine have been partially evaluated (detailed in [9]). The main lessons that have been learned from the exercise so far are that: (1) such a machine probably needs to have a both "tailor-made" instruction set and primitive architecture as its basis and (2) there are inherent difficulties in some of the underlying ideas and these needs to be re-examined carefully; the splitting of the data store, for example, has resulted in far more difficulties than were anticipated. These represent the major avenues for any further work. have

## ACKNOWLEDGEMENTS

We have been influenced by the past and present work of Roland Ibbett and Nigel Topham. This includes, in particular, our vector instruction set, which was wholly designed by the latter, and also the same individual's own work on dealing with pipeline flow disruptions [12]. Topham also read early drafts of [9] and trying to answer some of his harder questions has resulted in many improvements. The first author acknowledges the encouragement given to his research by David Plaisted

# PIPELINED REGISTER-STORAGE ARCHITECTURES [1]

Steven R. Kunkel and James E. Smith

Department of Electrical and Computer Engineering
University of Wisconsin-Madison
Madison, Wisconsin 53706

## Abstract

Instruction sets of Register-Storage (RS) architectures allow functional operations to take one operand from memory and one from a register. In contrast, Register-Register (RR) architectures always take both operands from registers. A simple, generic instruction set is defined for an RS architecture. A basic RS pipeline structure is developed for studying design and performance characteristics. The resolution of register hazards, placement of the memory access, branch instructions, and handling of stores to memory are examined in detail. For purposes of comparison, a basic RR architecture and pipelined implementation are also developed. The RR and RS models are used to calculate the performance of several of the Lawrence Livermore Loops to gain additional insight into the effect that the architectures have on performance.

## 1. Introduction

Register-Storage (RS) architectures are based on instruction sets that allow functional operations (e.g. floating point addition) to take one operand from memory and one from a register. The result is placed in a register. In contrast, Register-Register (RR) architectures always take both function operands from registers; explicit loads and stores to or from registers must always be used to communicate with central memory. A third class of architectures, those that permit Storage-Storage (SS) operations, can also be defined, although we do not study them here.

The suitability of RR architectures for high performance computation has been clearly demonstrated. The CDC6600 [THO70], CDC7600 [BON69], and the more recent CDC CYBER 180 [CDC84] architectures are based on an RR architecture. In addition the scalar section of the CYBER 205 [CDC81] is an RR architecture, as are both the scalar and vector sections of the CRAY-1S [CRA80], CRAY X-MP [CRA82], and CRAY-2 [CRA85]. Furthermore, the suitability of RR architectures for high performance implementations has not escaped the attention of researchers studying high-speed microprocessor architectures [PAT85], [RAD82].

RS architectures are widely used in practice; the IBM 370 architecture can generally be considered an RS architecture, although it does support some SS operations. Unfortunately, the IBM 370 architecture also contains some features that make high performance implementations difficult (e.g. implicitly-set condition codes, self-modifying code, and precise interrupts) [AND67]. Consequently, based on real implementations, it is difficult to clearly visualize the fundamental structures of pipelined RS architectures and to see the relative advantages and disadvantages of RS architectures for high performance implementations.

In this paper, we propose a simple RS architecture, suitable for pipelining, in order to clearly study the advantages and disadvantages of RS architectures for high performance implementations. To permit comparison, we also describe and discuss RR pipelines. The discussion in this paper is primarily in the context of numeric (floating point) applications, although many of the results and observations apply to other applications.

## 2. Model Architectures

A fundamental RS instruction couples a memory access with a data operation. An RS instruction is of the form $Ri \leftarrow Rj \; op \; (Rk + disp)$. The content of register $Rk$ is added to the displacement to form the memory address from which one of the operands is fetched. There are several other ways that a memory address could be formed, but we use only this mode. An operation, signified by $op$, is performed between the memory operand and a second operand taken from register $Rj$. The result is placed in register $Ri$.

Also included as part of a basic RS architecture are simple register loads, register-register operations, register stores, and branches. The register-register instructions are of the form $Ri \leftarrow Rj \; op \; Rk$ and $Ri \leftarrow Rj \; op \; data$. Here the second operand comes from a register or directly from the instruction. Loads and stores are of form $Ri \leftarrow (Rk + disp)$ and $(Rk + disp) \leftarrow Ri$ respectively. For single operand instructions, the operand can come from either a register, memory, or the instruction. Conditional branches are of the form $BrCond \; Rk + disp$ where a branch condition is specified and the target address is computed by adding the contents of register $Rk$ to the displacement. In all cases the register R0 is tested and the branch decision is based on this test. Condition codes are not used.

As a model RR architecture, we use the RR subset of the above. Hence, it is like the scalar CRAY-1 architecture, except one uniform set of registers is used, not two types.

## 3. Pipeline Structures

### 3.1. The Basic RS Pipeline

Fig. 1 shows a typical implementation. An instruction fetch sequence consists of address generation, memory reference, and instruction decode. The instruction fetch step may contain an instruction cache.

The operand fetch phase consists of reading address registers, operand address calculation, and memory access. Reading registers requires checking for hazards which will be detailed later. In the memory access step, an operand cache may be used. In fact, an operand cache is an important aspect of RS designs and will be discussed further later.

Before an instruction can be issued to the execution unit, register operands must also be obtained. This can be performed either in parallel with or after the memory operand fetch. In our basic pipeline, instructions are placed in a queue, shown in Fig. 1, after completing the memory operand fetch. Note that the queue may be of length 1. The instruction at the front of the queue checks for register hazards, reads register operands, and then issues to the execution unit.

The execution unit may take many forms. It may be a single non-pipelined unit, several parallel non-pipelined units, or several parallel pipelined units. Note however that the type of execution unit used is

[1] This is material based upon work supported by the National Science Foundation under Grant ECS-8207277.

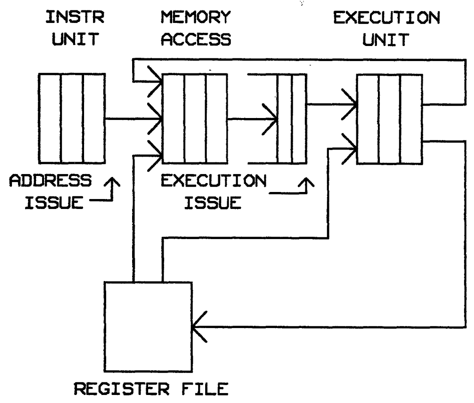

Fig. 1 A typical Register-Storage implementation model

independent of the type of architecture being implemented. The type of execution unit used is based on other issues such as performance and cost. In our study, a parallel pipelined execution unit is assumed to minimize execution time and expose other delays that are inherent in the implementation of the architecture.

Once execution has completed the result needs to be stored. Most instructions return their result to a register, so storage is a simple register file write. However, stores to memory can take place at this point also. In a later section, we consider the tradeoffs involved with performing memory stores at different points in the pipeline.

### 3.2. A Basic RR Pipeline Structure

The basic pipeline phases are much the same as in the RS model. Here, the instruction fetch step is followed by either memory operand access or execution, but not both. Storage to memory is done at the same point as operand access. Fig. 2 shows a typical RR model. As in the RS pipeline, instructions flow through the instruction fetch unit where they are decoded. Following instruction fetch, all register interlocks are cleared and then an instruction is issued to either the execution unit or the memory unit. All registers are read at the same point in the pipeline whether they are for addressing or contain operands. Each of these units returns its result to the register file.

## 4. Design Considerations

### 4.1. Register Hazards

The way register hazards are handled is an important difference between RS and RR implementations. In the RS implementation, there are two points at which registers are read. The first follows the instruction fetch phase; at this point registers for addressing are read. The second follows the memory access phase; here register operands are read. We refer to these as *issue* points. To be more specific, the point where address registers are read will be referred to as *address issue* and the point where operand registers are read will be referred to as *execution issue.*

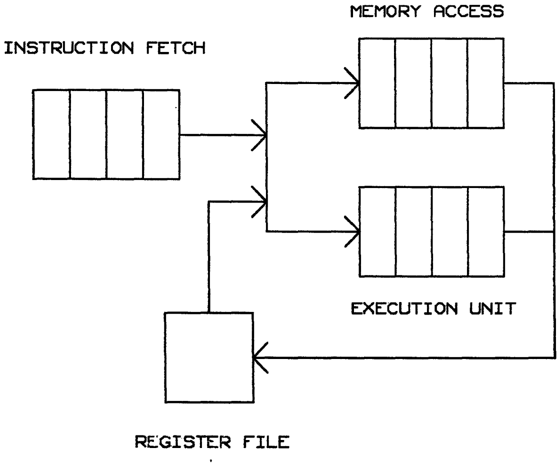

Fig. 2 A typical Register-Register implementation model

In an RR pipeline, where all registers are read at one point, one bit is typically used for each register to indicate that the register is *reserved.* When an instruction is ready to be issued, it checks the reserved bits for all the registers it uses. It is blocked from issuing until they are all free. A result register is reserved when an instruction that writes the register is issued. The reserved bit is cleared when the result register is written.

We first consider a simple-minded extension of the above method for an RS pipeline. Place a separate set of reservation bits at both issue points. The reservation bits at each issue point are handled as with the RR architecture. The first set is held at the *address issue* point, and are checked and set for all result registers as instructions pass. They are also checked for address registers as part of *address issue.* The second set is held at the *execution issue* point and are also reserved by all instructions that write a register. They are checked for both operand and result registers for functional operations before instructions issue to the execution phase. Both reservation bits are simultaneously cleared when the appropriate result register is written.

However, this method limits performance. This can be seen in the following sequence of instructions

(1) R1 <- R2 op R3
(2) R4 <- R5 op R1
(3) R1 <- R6 op R7.

Register R1 is reserved by instruction (1) at *address issue.* Instruction (2) does not read R1 until *execution issue* and is therefore not held up at *address issue.* The problem occurs with instruction (3). Because R1 is already reserved, this instruction must wait at *address issue* until the register is no longer reserved. Otherwise, if it is not held, the reserved bit for R1 will be cleared when instruction (1) finishes. When in fact, R1 should still be reserved for instruction (3). Because only one bit is used to reserve a register at *address issue,* only one instruction that writes R1 can be beyond the *address issue* point at any given time.

This problem can be corrected by using a small reservation counter for each register at *address issue* instead of a single reserved bit. The counter keeps tracks of the number of instructions that have passed *address issue.* The counter is incremented at *address issue* by an instruction that writes the register, and is decremented when the register is actually written. When an instruction needs to read an address register, it must wait until the counter becomes zero. When an instruction needs to write a register, it does not have to wait at *address issue;* it simply increments the counter and proceeds. This method enables the two issue points to make decisions independently, and performance is not restricted. In our later performance study, we use the method just proposed. The counter method for handling register reservations at the *address issue* point was proposed in [AND67]. There are of course, other methods for handling register conflicts but they will not be discussed.

To summarize, register reservation logic is more complex in an RS pipeline than in an RR pipeline. This is because registers must be read in two different places rather than one. In our RS implementation, there is a set of reservation counters, as well as a set of reservation bits; there is only a single set of reservation bits in an RR pipeline. This additional RS complexity is in terms of the amount of logic required, not in terms of the time required to make control decisions. That is, the length of time needed to make an issue decision regarding the availability of registers should be no greater with an RS pipeline.

### 4.2. Memory Access

Because memory accesses are often tied to data operations in an RS architecture, it would seem to be more difficult to schedule code to hide memory access delays. In fact, the organization of the RS pipeline with the memory access phase preceding the execution phase can actually improve performance. In the RS pipeline, instructions may go through the memory access phase and obtain memory operands while previous instructions are waiting for execution. In effect, a RS instruction is given a head start by beginning the memory access ahead of execution operations occurring earlier in the program. In a typical RR implementation this does not occur.

Because load operations sometimes get a head start, cache misses also get a head start, reducing their degradation effect on performance. Fig. 3 shows an example of code in which this occurs. In this example, assume the second load instruction has a cache miss. The first load is issued to memory at the same time in both implementations. In the RR implementation the second instruction waits for the load to complete while in the RS implementation the second instruction follows the load through memory. This causes the second load to wait in the instruction fetch unit in the RR implementation. Whereas, in the RS implementation, the second load is issued to the memory unit without any wait. This gives the cache miss a head start over the same cache miss in the RR implementation.

To counter the above advantage of an RS implementation, there is a corresponding disadvantage that sometimes occurs at the beginning of a segment of code. Fig. 4 shows an example in which this occurs. In the RR implementation, the second instruction in this example starts execution immediately following the load. But in the RS implementation, the second instruction follows the load through the memory unit before starting, causing a delay. Because the three floating point operations are all dependent, the initial delay in the RS implementation is retained, and the entire sequence is slower. As we shall see later, there is a similar effect involving conditional branches. This effect can be reduced by shortening the length of the memory access phase; this is most easily done by using an operand cache.

```
              RS architecture                     RR architecture

start:   R3   <-   (R1 + disp1)          start:   R3   <-   (R1 + disp1)
         R2   <-   R3 +f R4                       R2   <-   R3 +f R4
         R5   <-   R2 *f (R1 + disp2)             R6   <-   (R1 + disp2)
                                                  R5   <-   R2 *f R6
```

Fig. 3 Code in which RS memory access/cache miss gets a head start.

```
            RS architecture                      RR architecture

start:   R5   <-   (R1 + z(12))    start:   R5   <-   (R1 + z(12))
         R6   <-   R2 *f R3                 R6   <-   R2 *f R3
         R7   <-   R6 *f R5                 R7   <-   R6 *f R5
         R8   <-   R7 +f R5                 R8   <-   R7 +f R5
```

Fig. 4 A code segment with lower RS performance.

It should be noted that in the examples given, we have taken a small piece of code out of its original context. If R2 or R3 are dependent on an instruction occurring just before the sequence given in Fig. 4 begins, then the second instruction may be delayed by the same amount in both sequences.

It is our observation from the code we have examined, that overall performance speedups for RS architectures as typified in Fig. 3 are more common that performance losses as in Fig. 4. To summarize, placing the memory access phase ahead of the execution phase leads to performance advantages because memory accesses may be started earlier than they would with an RR pipeline. A disadvantage comes occasionally when execution must sometimes wait longer because of an unnecessary transit through the memory access phase.

### 4.3. Stores to Memory

In an RS pipeline, there are several points at which stores can be issued to memory. First, they can be issued at the same point as loads. This has the advantage of keeping all memory accesses in program order, preventing many hazards involving memory. It also eliminates conflicts for a single memory path; the path is required at only one point in the pipeline (disregarding the instruction fetch path). A major disadvantage is that a store, waiting for the data to be stored, blocks at an early point in the pipeline and holds all the following instructions until the data becomes available. A second disadvantage is that it makes implementation of precise interrupts more difficult because stores may complete before previous instructions in the instruction stream are known to be error-free.

Second, stores can be issued at the same point at which function execution begins. With this method, the store instruction can read its address registers and "reserve" its result address in the memory access phase, then wait for its data at the *execution issue* point. When the store data are available, the instruction must then "steal" a memory access cycle to perform the store. The act of "reserving" its result address amounts to saving the address in a table so that hazards involving later loads from the same address can be resolved. With this second method, the primary advantage is that instructions following the store are not blocked as early in the pipeline. The disadvantage is that control complexity is increased. Memory hazards must be resolved with additional logic, and the memory access path may be used from two different pipeline phases so conflicts may occur.

Third, stores may be sent to memory following the execution phase. Here, registers are read at the same point as in the second method. This method further increases the control complexity of resolving memory hazards by delaying the store to memory. But all instructions would complete in order making the implemenation of precise interrupt easier.

### 4.4. Branches

Up to this point we have said very little about branch instructions, which are a very important aspect of pipeline design. Both RR and RS architectures can be made to handle branches in a similar way. Because of the variety of ways of performing branches, we have chosen a specific one for illustrative purposes. Conditional branches all test register R0. In an RR pipeline, this test occurs at the single issue point, and in an RS pipeline, at the *address issue* point. This assumes that there is hardware in the instruction fetch phase to perform the test of R0 for branches. This eliminates the delay of issuing the instruction to a functional unit to perform the test.

The primary performance advantages and disadvantages are very similar to those already noted for the placement of the memory access phase. The advantage for an RS pipeline occurs when R0 is set early and an independent instruction, preceding the branch, is blocked due to data dependencies. In this case, an RR pipeline holds the branch instruction behind the blocked instruction. In the RS pipeline, the blockage of the independent instruction may occur at the *execution issue* point, so that the branch is not blocked and may be performed earlier.

A potential performance loss occurs when an instruction modifying R0 is followed closely by a conditional branch testing R0. In this case, the branch instruction may block waiting for R0 to be written. The wait can take longer in an RS architecture if the instruction modifying R0 must pass through the memory access phase before being executed as in our implementation model. This can be viewed as part of the penalty one pays in return for earlier execution of conditional branches as described above and for early accessing of memory data as was pointed out in section 4.2.

For the FORTRAN code we have examined, R0 is often set well in advance of a conditional branch that tests it. This is because the branch is typically based on a loop counter which can be incremented early in a loop. Hence, the performance penalty for these kinds of branches is low. Nevertheless, for other types of code where a test is made closely before a branch, an RS pipeline could suffer significant delays for conditional branches.

## 5. Experimental Results

Following are the results of a preliminary study we have performed to test some of the conclusions given above. Because of the limited set of benchmarks and the methods used, no general conclusions should be based solely on these results.

Using the above-defined architectures and the implementation models, the execution time for eight of the Lawrence Livermore Loops [MCM72] were calculated. These are a standard set of small FORTRAN kernels. These eight loops were chosen because a hand compilation method was used, and quite simply, these were the easiest to hand compile. Compiler output from the Cray FORTRAN Compiler was used as a guide, and our hand compilation is at the same level of optimization.

We assumed execution times similar to those in the CRAY-1. For models with no operand cache we assume an 11 clock period memory access time. For models with operand cache, we assume a 3 clock period memory access. We assume the instruction fetch unit contains an instruction cache with a 100% hit ratio. The code is scheduled separately for each architecture and each memory speed to give optimum performance for each case. Given these assumptions, we calculated the time required for one iteration of each loop. The results of the timings are given in Table 1.

These results indicate that six of the eight loops executed in the same time for both architectures regardless of the memory speed used. It would seem that there is little difference between the performance of the two architectures based on these timings. However two of the loops did have different execution times. Loop 2 is a case where the RS architecture is able to take advantage of issuing fewer instructions to perform better than the RR architecture. The RS architecture had five fewer instructions to issue in this loop. Loop 3 also had a different execution time. In this loop, the RS architecture is faster because it reads operand registers at a different place than it executes branch instructions. Since there is no store near the end of this loop, the branch at the end of the loop is not held up waiting for the final result to be stored. In the RR implementation the branch must wait for the last data operation to obtain its operand data before it can be issued. In the RS implementation the branch is able to execute sooner because the last data operation reads operand registers at *execution issue* and does not hold up the branch instruction.

| loop | RR | | RS | |
|---|---|---|---|---|
| | M= 11 | M = 3 | M= 11 | M = 3 |
| 1 | 38 | 30 | 38 | 30 |
| 2 | 45 | 39 | 45 | 37 |
| 3 | 25 | 17 | 19 | 11 |
| 5 | 57 | 49 | 57 | 49 |
| 6 | 57 | 49 | 57 | 49 |
| 7 | 69 | 61 | 69 | 61 |
| 11 | 23 | 15 | 23 | 15 |
| 12 | 23 | 15 | 23 | 15 |

Table 1 Results of Timing of Models. Execution time is in clock periods. M is the memory access time in clock periods.

## 6. Conclusions

RS architectures have three primary performance advantages.

(1) There are fewer instructions; in some code sequences, the limitation of issue rate to one per clock period is important, and in these cases, RS architectures can give better performance.

(2) Placing the execution segment of the RS pipeline after the memory access segment permits memory load instructions to proceed even though an earlier instruction may be blocked at the execution units due to a data dependency.

(3) Placing the execution segment of the RS pipeline after the conditional branch logic permits some conditional branches to proceed even though an earlier instruction may be blocked at the execution units due to a data dependency.

Occasionally, the last two advantages are offset by a performance loss when an execution operation must pass through the memory access segment part of the pipeline before it can begin. Nevertheless, it is our observation that, at least for scientific code, the performance advantages outweigh the disadvantages. Our experimental results show a relatively small difference in performance between the two architectures. Whenever there is a difference, however, the RS pipeline is faster.

The primary disadvantage of RS pipelines is the additional implementation complexity. This comes about because registers are read from at least two different points in the pipeline. This at least doubles the amount of register interlock logic that is needed. On the other hand, the control complexity at the individual stages is not significantly increased, so the clock frequency does not necessarily need to be reduced.

# EXECUTION OF PARALLEL LOOPS ON PARALLEL PROCESSOR SYSTEMS

*Constantine D. Polychronopoulos, David J. Kuck, and David A. Padua*

Center for Supercomputing Research and Development
University of Illinois at Urbana-Champaign
Urbana, Illinois 61801

**ABSTRACT** -- *Ways of coordinating large numbers of processors to execute a parallel program as fast as possible are of key importance to the design and efficient use of parallel processor systems. In this paper we discuss issues on program parallelism and scheduling for parallel processor systems. We break the scheduling process into three basic activities, and focus on processor assignment to parallel loops. Optimal processor assignment algorithms are presented for simple and complex nested parallel loops. These algorithms can be applied at compile-time, or can be implemented as hardware modules to solve the processor assignment problem optimally at run-time. Speedup measurements for EISPACK and IEEE DSP subroutines that result from the optimal assignment of processors to parallel loops are also presented. These measurements indicate that optimal assignments result in almost linear speedups on parallel processor machines with a few tens of processors, and significantly high speedups for machines with hundreds or thousands of processors.*

## 1. INTRODUCTION

It is becoming increasingly clear that modern and future supercomputers will be based on the shared memory parallel processor architecture. The flexibility, scalability and high potential performance offered by parallel processor machines are simply necessary "ingredients" for any high performance system. The performance potential for these machines is indeed greater than that of single array processor computers [7], and they can run more efficiently a larger family of programs. However we have little experience in using efficiently a large number of processors. This is especially true when maximum (single) program speedup (as opposed to high throughput) is our objective. This inexperience in turn is reflected in the small number of processors used in modern commercially available multiprocessors such as the CRAY-XMP and Alliant FX/8 systems.

Truly parallel languages, parallel algorithms, and ways of defining and exploiting program parallelism are still in their infancy. Only recently these problems have attracted the appropriate attention. Several factors should be considered when designing high performance supercomputers [7]. Parallel algorithms, carefully designed parallel architectures and powerful programming environments including sophisticated restructuring compilers, all play equally important roles on program performance. This unified approach has been adopted in the design of the Cedar multiprocessor at the Center for Supercomputing Research and Development of the University of Illinois. In addition several crucial problems such as scheduling and synchronization and communication overheads, must be adequately solved in order to take full advantage of the inherent flexibility of parallel processor systems.

Loops are the largest source of parallelism but the problem of using several processors for the fast execution of complex parallel loops had not been given enough attention until recently [10], [1]. A key problem in designing and using large parallel processor systems is finding out how to schedule independent processors to execute a parallel program as fast as possible. There is more to be said on ways of exploiting loop parallelism, both from the system and the compiler point of view. From the system's point of view we know little about coordinating large numbers of processors to execute multiply nested parallel loops; and from the the compiler's point of view no significant work has been done so far to adequately solve this problem. This paper addresses the second part of this problem namely, compile-time scheduling of arbitrarily complex parallel loops on parallel processors. We discuss the different activities of the problem traditionally referred to as scheduling of a parallel program on a parallel processor system, and present algorithms that generate optimal loop schedules at compile-time. Some experiments we conducted to illustrate the speedups resulting from such schedules are also presented.

The rest of this paper is organized as follows. In Section 2 we present some background for the following discussion, including basic definitions and the structure of the Parafrase compiler used for our experiments. In Section 3 we briefly consider the general problem of scheduling parallel programs on parallel processor systems. In Section 4 we discuss processor assignment issues for parallel loops, and propose an optimal processor assignment algorithm based on dynamic programming. In Section 5 we present some experimental results for EISPACK [13], and IEEE DSP subroutines [2], and finally Section 6 gives the conclusion of this paper.

## 2. BACKGROUND AND BASIC CONCEPTS

In this paper we consider parallel Fortran programs. By parallel, we mean programs that have been written using language extensions or programs that have been restructured by an optimizing compiler. For our purposes we use output generated by the Parafrase restructurer [6], [15]. Parafrase is

a restructuring compiler which receives as input Fortran programs and applies to them a series of machine independent and machine dependent transformations. The structure of Parafrase appears in Figure 1. The first part of the compiler consists of a set of machine independent transformations (passes). The second part consists of a series of machine dependent optimizations that can be applied on a given program. Depending on the architecture of the machine we intend to use, we choose the appropriate set of passes to perform transformations targeted to the underlying architecture. Currently Parafrase can be used to transform programs for execution on four types of machines: *Single Execution Scalar* or SES (uniprocessor), *Single Execution Array* or SEA (array/pipeline), *Multiple Execution Scalar* or MES (multiprocessor), and *Multiple Execution Array* or MEA (multiprocessor with vector processors) architectures [7].

In a restructured Fortran program we observe several types of parallelism and all of them can be potentially utilized by an MES machine. We can roughly classify the different types of parallelism into two categories: *Fine grain parallelism* and *Coarse grain parallelism.* Fine grain parallelism includes the parallel execution of different statements of the program on different processors, or even different operations of the same statement on different processors or functional units. Coarse grain parallelism arises from the parallel execution of independent disjoint modules of the program, or from parallel loops. For the purposes of this paper we ignore branching statements (IFs and GOTOs) without loss of generality. In Parafrase the branches of each such statement are assigned *branching probabilities* either by the user or by the compiler automatically. We can therefore view a program as consisting of a sequence of block of assignment statements (BAS), with each such BAS having a weight associated with it.

To expose program parallelism, Parafrase builds for each program the data dependence graph [5] which indicates data and control dependences between statements of the program [4]. A series of machine in/dependent optimizations are then applied on the program using the data dependence graph as a guide. During parallel execution of a program, data and control dependences must be observed in order to preserve the semantics of the program. One of the most vital Passes in Parafrase involves the recognition of several types of parallel loops.

In the transformed programs, loops can be of one of the following four types: *Serial, reductions* (e.g., vector sum/product), *do all* or DOALL (all iterations of the loop can execute in parallel) [9], and *do across* or DOACR (successive iterations can be partially overlapped) [9], [1]. The restructured programs are to be executed on a multiprocessor such that DOALLs and DOACRs can be distributed across many processors. Furthermore, execution of many loops of different kinds may also be overlapped. Given a Fortran program that executes on a $P$ processor multiprocessor system, we define program speedup $S_P$, as follows: $S_P = T_1 / T_P$, where $T_1$ is the serial execution time of the program and $T_P$ the execution time when it runs on $P$ processors. The efficiency of the execution of a parallel program that achieves a speedup of $S_P$ on $P$ processors, is then defined as $E_P = S_P / P$, and obviously $0 \leq E_P \leq 1$.

## 3. PROCESSOR ALLOCATION, ASSIGNMENT, AND SCHEDULING

Our approach to program scheduling is a combination of compile and run-time schemes. At compile-time we decide how to partition a given program into independent tasks. A task graph called a *Task Flow Graph* (TFG) is then constructed by the compiler. Each node of the TFG corresponds to a program segment, and arcs represent data and control dependences. A task node for instance, may correspond to a block of assignment statements, or a nested parallel do loop. Nodes of the TFG are executed in order so that data and control dependences are satisfied. Each node of the task graph may execute serially or it may be distributed across different processors. At compile-time it is decided whether the iterations of a given loop will execute in a *pre-scheduled* or a *self-scheduled* fashion as explained below.

The scheduling of a restructured program (TFG) on a parallel processor system is performed in three phases. As mentioned above the first phase decides whether a loop will run in a pre- or self-scheduled fashion. During the second phase which we call *processor allocation,* we decide how to distribute the available processors to the nodes of the graph. Each node receives a number of processors by the second scheduling phase, and it is up to the *processor assignment* (third) phase to decide how to use the allocated processors for each particular node. Recall that a single node of the task flow graph can be an arbitrarily complex nested parallel loop. Processor assignment decides how to assign the allocated processors to the parallel loops of each node (if any).

Allocation is usually done by the run-time system by taking a subset of the available processors (real or virtual), and devoting them to a running program or to a part of it. Allocation requires decision on the number of processors. The decision on the number of processors could be totally made by the run-time system. However, this is inefficient. To circumvent this problem, the user program could advise the system on the number of processors (or range of them) that it can efficiently use. Processor allocation may be performed at load-time, and remain constant until execution completes. On the other hand, processors may be allocated at different times during execution. The decision on how often allocation is to be performed depends on the amount of overhead involved in processor allocation, since frequent allocations is clearly better if overhead is ignored.

After allocation, a decision has to be made on the number of processors to assign to the different program components. For the purposes of this paper we are interested in processor assignment to do loops. The assignment is trivial if the process consists of a sequence of singly nested parallel loops and sequential code. The assignment may be more complex if multiply nested parallel loops are present. The algorithms of this paper deal precisely with this problem. If the loop bounds and the number of processors to be allocated at run-time, are not known at compile-time, then the algorithms described below will have to be executed at run-time once these values are known. A hardware device will accelerate the computation required for assignment.

Loops may be executed in a pre-scheduled or self-scheduled fashion. This decision can be made when the program is written or at compile-time. Pre-scheduled means that the order and the iterations to be executed on each assigned processor is decided at compile-time. The output from the compiler can be parametrized on the number of processors assigned to the loop by producing a blocked loop with a variable blocking factor. Loops can also be executed in a self-scheduled way. This means that each processor upon completion of an iteration will continue by executing the next iteration not yet executed or being executed. If $p$ processors are assigned, the first $p$ iterations are executed first, one by each processor. Pre-scheduling has the advantage that the local memory of a processor (including its registers) can be used to transfer information from one iteration to subsequent ones executed in the same processor, so that in certain cases interprocessor communication cost may be greatly reduced. Consider for example two disjoint adjacent loops at the same nest level. Both loops will be allocated the same number of processors and corresponding iterations will execute on the same physical processors. When data are communicated from one loop to the other they can be temporarily stored into a local memory, thus eliminating the need for interprocessor communication. On the other hand, self-scheduling is useful if the execution time of the different iterations varies widely. These factors should be taken into consideration by the compiler to decide how to compile a given loop. Also, the presence or not of hardware for self-scheduling should be taken into account. It should be noted that pre-scheduling and self-scheduling can be combined in a program, and even in a multiply nested loop. Thus, the outer loop could be scheduled in one way, and the inner loop in another.

## 4. OPTIMAL PROCESSOR ASSIGNMENTS

It has been shown that in most programs parallel loops are the source of the greatest percentage of parallelism [7]. In this section we will investigate the problem of processor assignment to parallel loops. This problem becomes especially important when we deal with nested parallel loops where inefficient assignment algorithms may result in an execution time far worse than the optimal. In programs with several nested parallel loops the efficiency may then drop down to unacceptable levels. We can informally define the limited processor assignment problem as follows: Given an arbitrary multiply nested loop which contains serial and parallel (DOACR, DOALL) loops and a number of $P$ processors, find the (optimal) way of assigning the $P$ processors to the loops so that the parallel execution time of the entire module is minimized. For loops with very few nest levels and systems with a small number of processors, exhaustive search might be affordable at compile-time. But as the number of processors increases, the number of processor-loop combinations grows exponentially. Moreover, loops with large nest levels are not very uncommon in scientific computations. As an example, 10 to 17 nested parallel loops were observed in several subroutines of the restructured (by Parafrase) IEEE Digital Signal Processing Package.

### 4.1. Simple Assignments to DOALLs

In the following sections we discuss processor assignments schemes. A metric called the *efficiency index* is defined in this section. The usefulness of this metric is twofold. First it makes it easier to formulate the processor assignment problem, and secondly it allows us to observe several interesting properties of the problem that are otherwise hidden in modular arithmetic.

A processor assignment algorithm (OPTAL) is proposed that solves the general problem optimally. The optimal processor assignment is guided by the use of a function called the *assignment function.* The assignment function can be easily defined to measure parallel execution time.

Before we discuss processor assignment issues we need to introduce some notation and definitions. To simplify the notation each loop is assumed to be normalized and denoted by the upper bound of its iteration space. Thus, $N_i$ denotes a DOALL whose loop body is executed $N_i$ times, and $L = (N_1, N_2, \ldots, N_m)$ denotes an $m$ level nested DOALL where loop $N_i$ is surrounded by $N_{i-1}$ and surrounds $N_{i+1}$, $i = 2, \ldots, m-1$ ($N_1$ and $N_m$ are the outermost and innermost loops respectively).

In what follows the number of available processors $P$ is always assumed to be "useful", that is, less or equal to the maximum number of processors that a loop $L$ can fully utilize. As mentioned in Section 3, processor allocation (phase two) allocated a number of processors to each outermost loop (task node). Theorems and lemmas given in this paper are stated without proof [11].

**Definition 4.1.** For a DOALL with $N_i$ iterations that has been assigned $p_i$ processors we define $\epsilon_i$, the *efficiency index* or *EI* of $N_i$ as follows:

$$\epsilon_i^{p_i} = \frac{N_i / p_i}{\lceil N_i / p_i \rceil} \tag{1}$$

The efficiency index is an indicator of how efficiently a loop runs on a given number of processors. The higher the EI the higher the efficiency (as defined in Section 2). Some other properties of the efficiency index that will be used directly or indirectly in the following sections are:

**P1:** For any DOALL $N_i$ and any number of processors $p$ we have: $0 < \epsilon_i^p \leq 1$.

**P2:** For any $N_i$, $\epsilon_i^1 = 1$.

**P3:** For $N_i \geq p$, $\epsilon_i^p > 1/2$.

It should also be noted that $p \neq q$ does not necessarily imply $\epsilon_i^p \neq \epsilon_i^q$.

**Definition 4.2:** For a nested DOALL $L = (N_1, N_2, \ldots, N_m)$, a number of $P = p_1 p_2 \ldots p_m$ processors and a particular assignment of $P$ to $L$ we define the *efficiency index vector* $\omega = (\epsilon_1^{p_1}, \epsilon_2^{p_2}, \ldots, \epsilon_m^{p_m})$, of $L$, where $\epsilon_i^{p_i}$ is the EI for loop $N_i$ and for $p_i$ processors.

In what follows the terms "assignment of $P$" and "decomposition of $P$" are used interchangeably. Any assignment of $P$ to $L$ defines implicitly a decomposition of $P$ into factors $P = p_1 p_2 \ldots p_m$ where each of the $m$ different loops receives $p_i$, $i = 1, 2, \ldots, m$ processors. A processor assignment profile $(p_1, p_2, \ldots, p_m)$ can also be described by its efficiency index vector as defined above.

**Definition 4.3:** For an assignment $\omega = (\epsilon_1^{p_1}, \ldots, \epsilon_m^{p_m})$, of $P = p_1 p_2 \ldots p_m$ processors to $L$, we define $\mathrm{E}_L$, the *compound efficiency index* ( *CEI* ) of $L$ as

$$\mathrm{E}_L = \prod_{i=1}^{m} \epsilon_i^{p_i} \tag{2}$$

For any $L$, $P$, we also have $0 < \mathrm{E}_L \leq 1$. Let $T_1$ be the serial execution time of a perfectly nested DOALL $L$. Next suppose that $L$ is executed on $P$ processors and let $T_P$ and $T_P'$ denote the parallel execution times for two different assignments $\omega = (\epsilon_1, \epsilon_2, \ldots, \epsilon_m)$ and $\omega' = (\epsilon_1', \epsilon_2', \ldots, \epsilon_m')$ of $P$ to $L$, where $P = p_1 \ldots p_m = p_1' \ldots p_m'$. We can express the parallel execution time $T_P$ of $L$ in terms of its CEI as follows:

$$T_P = \prod_{i=1}^{m} \lceil N_i / p_i \rceil B \rightarrow$$

$$\frac{1}{T_P} = (1/B) \frac{\prod_{i=1}^{m} N_i / p_i}{\prod_{i=1}^{m} \lceil N_i / p_i \rceil} \prod_{i=1}^{m} p_i / N_i =$$

$$(1/B) \left( \prod_{i=1}^{m} \frac{N_i / p_i}{\lceil N_i / p_i \rceil} \right) \frac{\prod_{i=1}^{m} p_i}{\prod_{i=1}^{m} N_i} = \prod_{i=1}^{m} \epsilon_i^{p_i} \frac{P}{NB} = \frac{\mathrm{E}_L P}{NB} \quad \text{or}$$

$$T_P = \frac{NB}{\mathrm{E}_L P} \tag{3}$$

where $B$ is the execution time of one iteration of the loop, and $N = \prod_{i=1}^{m} N_i$. The following is a direct application of (3).

**Lemma 4.1:** $T_P < T_P'$ iff $\mathrm{E}_L > \mathrm{E}_L'$.

In the next few sections we show how the efficiency index can be used to direct the efficient assignment of processors to perfectly nested parallel loops.

Given a nested loop $L$ and a number of processors $P$ we call a *simple* processor assignment one that assigns all $P$ processors to a single loop $N_i$ of $L$. A *complex* processor assignment on the other hand is one that assigns two or more factors of $P$ to two or more loops of $L$.

**Theorem 4.2.** The optimal simple processor assignment over all simple assignments of $P$ processors to loop $L$ is achieved by assigning $P$ to the loop with $\epsilon = \max_{i=1,m} \{\epsilon_i^P\}$.

For the next lemma and most of what follows we assume that processors are assigned in units that are equal to products of the prime factors of $P$ unless stated otherwise. Therefore each loop is assigned a divisor of $P$ including one.

**Lemma 4.3.** If $N$ is a (single) DOALL loop, $P = p_1 p_2 \ldots p_m$ is the number of available processors and $\epsilon_i$, $i = 1, 2, \ldots, m$ are the efficiency indexes for assigning $p_1, p_1 p_2, p_1 p_2 p_3, \ldots, p_1 p_2 \ldots p_m$ respectively, then

$$\epsilon_1 \geq \epsilon_2 \geq \epsilon_3 \geq \ldots \geq \epsilon_m.$$

From Lemma 4.1 we conclude that the optimal processor assignment of $P$ to $L$ is the one that maximizes $\mathrm{E}_L$. Each assignment defines indirectly a decomposition of $P$ into a number of factors less than or equal to the number of loops in $L$. As $P$ grows the number of different decompositions of $P$ into factors grows very rapidly. From number theory we know that each integer is uniquely represented as a product of prime factors. Theorem 4.4 below can be used to prune (eliminate from consideration) several decompositions of $P$, or equivalently, several assignment profiles of $P$ to $L$ that are not close to optimal. From several hand generated tests we observed that the use of Theorem 4.4 in a branch and bound algorithm for determining the optimal assignment of processors eliminated more than ninenty percent of all possible assignments. In some instances all but the optimal assignments were pruned by the test of Theorem 4.4.

Again let $L = (N_1, \ldots, N_m)$ be a perfectly nested DOALL that executes on $P$ processors and $P = p_1 p_2 \cdots p_k$ be any decomposition of $P$ where $k \leq m$. Now let $\epsilon = \max_{1 \leq i \leq m} \{\epsilon_i^P\}$ be the maximum efficiency index over all simple assignments of $P$ to $L$, and $\epsilon_i = \max_{1 \leq j \leq m} \{\epsilon_j^{p_i}\}$, $i = 1,2,\ldots,k$ be the maximum efficiency indexes (over all loops of $L$) for the factors $p_1, p_2, \ldots, p_k$ of $P$ respectively (where $\epsilon_j^{p_i} = (N_j/p_i) / (\lceil N_j / p_i \rceil))$. Note that here we do not perform any actual assignment of processors to loops but simply compute the maximum efficiency index for each factor $p_i$ of $P$ over all loops of $L$ excluding the loop that corresponds to $\epsilon$. If $T_s$ and $T_c$ are the parallel execution times for $L$ corresponding to the optimal simple assignment of $P$ and the optimal complex assignment of the specific factors of $P$ respectively, and $S_s$ and $S_c$ their respective speedups, we have the following theorem.

**Theorem 4.4.** If there exists $i \in \{1,2,\ldots,k\}$ for which $\epsilon \geq \epsilon_i$ then $T_s \leq T_c$ and thus $S_s \geq S_c$. In other words if one of the factors of $P$ has a maximum efficiency index equal or less than the maximum efficiency index of $P$, then we gain more speedup by assigning the entire $P$ to a single loop than from any complex assignment of the factors of $P$ (including the optimal).

Thus, given any decomposition of $P$ into factors $P = p_1 \ldots p_k$, a necessary (but not sufficient) condition for a complex assignment to be better than the best simple assignment is $\epsilon < \epsilon_i$, for all $i = 1,2,\ldots,k$ (where $\epsilon_i$ is the maximum efficiency index for factor $p_i$ over all loops of $L$). Obviously if $\epsilon = 1$ then the optimal simple assignment is the overall optimal as well. An example of the application of Theorem 4.4 is shown in Figure 2(a), where the simple assignment of 32 processors to the outermost loop is also the optimal one.

**Corollary 4.5.** If $N = \prod_{i=1}^{m} N_i$, $\epsilon$ is the efficiency index of the optimal simple assignment, $\epsilon_i$, $i = 1,2,\ldots,m$ is the efficiency index for the $i$-th loop in a complex optimal assignment and $\mathrm{E}_L$ the corresponding compound efficiency index, then any optimal complex assignment should satisfy,

$$\epsilon < \epsilon_i \leq 1, \quad i = 1, 2, \ldots, m \quad \text{and} \quad \epsilon < \mathrm{E}_L \leq 1.$$

$$\text{Let} \quad \mathrm{E}_0 = \frac{N / P}{\lceil N/P \rceil} \quad \text{where} \quad N = \prod_{i=1}^{m} N_i.$$

Then any optimal assignment of $P$ to $L$ satisfies

$$\mathrm{E}_L \leq \mathrm{E}_0 \tag{4}$$

where $\mathrm{E}_L$ is the CEI of an optimal assignment. Only in special cases there would be an optimal assignment of $P$ to $L$ for which the equality in (4) holds. A compiler transformation called "loop-coalescing" can be applied to certain types of loops and always achieves $\mathrm{E}_L = \mathrm{E}_0$ [11].

Corollary 4.5 can be used to check whether a given complex assignment is better than an optimal simple assignment. It would be useful however to be able to answer the question about the existence of such assignment. That is, given a loop $L$ and a number of $P$ processors, is there an optimal complex assignment better than the optimal simple assignment? If for a particular loop the answer is negative, the optimal simple assignment is chosen and therefore the problem for that loop is solved in constant time, assuming the efficiency indexes have been computed. Proposition 4.6 below provides the test for the existence of an optimal complex assignment.

For each loop $N_i \in L$ we define the *critical capacity* $g_i$, of $N_i$ as the maximum number of processors that can be assigned to $N_i$ with its efficiency index remaining strictly greater than $\epsilon$ (the maximum efficiency index of $P$). In other words, for each $N_i$ $g_i$ is chosen to satisfy,

$$\epsilon_i^{g_i} > \epsilon \quad \text{and} \quad \epsilon_i^{g_i + r} \leq \epsilon$$

for any $r \geq 1$. Then we have the following proposition.

**Proposition 4.6.** A necessary condition for the existence of a complex assignment of $P$ to $L$ which is better than the corresponding optimal simple assignment is

$$\prod_{i=1}^{m} g_i \geq P.$$

The obvious approach for optimally solving the processor assignment problem is exhaustive search. For small nested loops and a very small number of processors exhaustive search would probably be tolerable at compile-time. For medium size loops and a few tens of processors however, the cost of exhaustive search becomes intolerable even at compile-time. For example, the number of different assignments of 50 processors to 15 nested loops is $4.8X10^{13}$. If it takes 1000ns (on a fast machine) to process each different assignment it would take more than 555 days CPU time to find the optimal assignment of 50 processors to 15 loops.

Using the results of this section however, we can design a branch and bound algorithm that greatly reduces the number of candidate optimal assignments. In several cases the tests of this section can prune all possible assignments but the optimal and in practice such a branch and bound algorithm would have polynomial complexity for most cases. The problem remains unsolved though since we can never guarantee polynomial complexity and we can always come up with an example loop which can make even the branch and bound algorithm run in exponential time.

In the next section we present an optimal processor assignment algorithm that has a low polynomial complexity and finds the optimal assignment for all types of loops and any number of processors.

### 4.2. Optimal Complex Assignments

In order to better illustrate the ideas of this section we start by considering perfectly nested DOALLs and $P = 2^k$ processors. As we proceed the concepts are generalized to include more complex loop structures such as nonperfectly nested combinations of serial, DOALL, and DOACR loops.

Let us consider an $m$-level nested DOALL $L = (N_1, N_2, \ldots, N_m)$ and a number of $P = 2^k$ processors.

```
DOALL 1 I1=1,63                       DOALL 1 I1=1,15
  DOALL 2 I2=1,7                        DOALL 2 I2=1,17
    DOALL 3 I3=1,31                       DOALL 3 I3=1,17
      DOALL 4 I4=1,20                       DOALL 4 I4=1,25
          . . .                                 . . .
(a)       . . .                     (b)         . . .
          . . .                                 . . .
4       CONTINUE                      4       CONTINUE
3     CONTINUE                        3     CONTINUE
2   CONTINUE                          2   CONTINUE
1 CONTINUE                            1 CONTINUE
```

Figure 2. (a) An application of Theorem 2.2.
(b) The nested loop of example 4.1.1.

Algorithm OPTAL which is analytically described below will give us the optimal assignment profile of the $P$ processors to the $m$ loops of $L$. For each loop $L$ we compute the *efficiency table* $M$. Each column $j$ of $M$ corresponds to a loop $N_j$ of $L$ and each row $i$ corresponds to a number of $2^i$, $i=0,1,...,k$ processors. An entry $(i,j)$ of table $M$ contains the efficiency index for assigning $2^i$ processors to loop $N_j$. This $(m \times k)$ efficiency table will be used repeatedly by OPTAL to obtain the optimal assignment of $P$ processors to loop $L$.

From Lemma 4.3 we observe that each column of $M$ is ordered in nonincreasing order. If the loops are ordered by size then each row of $M$ is also ordered in nonincreasing order. Therefore if $\epsilon_{ij}$ is the element of $M$ in the $i$-th row and $j$-th column, then

$$\epsilon_{ij} \geq \epsilon_{iw} \quad \text{for} \quad \text{w} \geq j.$$

It is clear that in any assignment of $P$ to $L$ there can be at most one entry of the lower half of $M$ involved in that assignment. Let us give an outline of the basic steps of the algorithm. We start by assigning the $P$ processors to the innermost or outermost loop, and let us always start from the innermost in our case. The second step finds the optimal assignment of $P$ to the two innermost loops. In the process we also need to compute the optimal assignment of $1, 2, 2^2, \ldots, 2^k$ processors respectively to the two innermost loops. These assignments however are computed only once for each loop and stored for later use by successive steps.

In general, after the $(m - i)$-th step OPTAL has found the optimal assignment of $1, 2, 2^2, ..., P$ processors to loops $L_i=(N_i, N_{i+1}, ..., N_m)$. The next $(m - i + 1)$-th step considers loop $N_{i-1}$ and finds the optimal assignment of $1, 2, 2^2, \ldots, P$ processors to loop $(N_{i-1}, L_i)$ possibly by reassigning processors from $L_i$ to $N_{i-1}$. All possible assignments for $N_{i-1}$ are considered. Note that all possible assignments for $L_i$ have already been computed. At the end of the $m$-th step OPTAL outputs the profile of the optimal assignment of $P = 2^k$ to loop $L=(N_1, N_2, ..., N_m)$. Based on Lemma 4.1 the optimal assignment of $P$ to $L$ would be the one that maximizes $\text{E}_L$. This is precisely what OPTAL does.

### 4.2.1. The Perfectly-Nested Loop Case

In this section we describe processor assignment for perfectly nested DOALLs and $P = 2^k$. We use this case as an example of the application of the general algorithm described in the next section. The simplicity of this case helps illustrate the algorithm clearly. It is followed by a simple example that describes the details of computing the optimal assignment. The heart of OPTAL is a recursive function $G$, that is defined as follows: Given $P=2^k$ and $L$ an $m$-way nested loop as previously, we define $G_i(q)$ as the product of efficiency indexes of the optimal assignment of $q$ processors to loops $(N_i, N_{i+1}, ..., N_m)$. More specifically a closed form expression of function $G_i(q)$ is given by,

$$G_i(q) = \max_{1 < p_j < q} \left\{ \prod_{j=i}^{m} \epsilon_j^{p_j} \right\}$$

and such that $q = \prod_{j=i}^{m} p_j \leq P$. The recursive definition of $G_i(q)$ that we will be using from now on is given by (5)

$$G_i(P) = \max_{0 \leq r \leq k} \left\{ \epsilon_i^{2^r} G_{i+1}(P/2^r) \right\} \quad \text{or} \qquad (5)$$

$$G_i(P) = \max \left\{ G_{i+1}(P), \epsilon_i^2 G_{i+1}(P/2), \epsilon_i^4 G_{i+1}(P/4), \right.$$

$$\left. \epsilon_i^8 G_{i+1}(P/8), \ldots, \epsilon_i^P G_{i+1}(1) \right\}$$

where $\epsilon_i^q$ is the efficiency index for assigning $q$ processors to loop $N_i$ (available from table $M$). The optimal assignment of $P$ processors to loops $(N_i, N_{i+1}, ..., N_m)$ can be found by selecting from all assignments of $2^r$ processors to loop $N_i$ and $2^{k-r}$ processors to $(N_{i+1}, ..., N_m)$, $r = 0, 1,..., k$, the one that maximizes $\prod_{j=i}^{m} \epsilon_j$ (from (5)).

The function in (5) is computed for $i=m, m\text{-}1, ..., 1$ and for each $i$ we also compute $G_i(1)$, $G_i(2)$, $G_i(2^2)$,..., $G_i(P=2^k)$. The optimal assignment of the $P$ processors to loop $L$ will be given at the end of the $m$-th step by $G_1(2^k)$. Initially (first step) for $i=m$ we have $G_m(q) = \epsilon_m^q$. For each $G_i(q)$ the corresponding processor assignment profile is stored and when $G_1(2^k)$ is computed the profile for the optimal assignment is available.

The algorithm completes in $m$ steps. In each of the $m$ steps, $k=logP$ function evaluations are performed and each of the $r=1,2,...,k$ function evaluations involves the computation of the maximum of $r$ values. The overall complexity of the algorithm is therefore $O(mlog^2P)$. Using the results of the previous sections we can easily avoid unnecessary computations and further reduce the complexity of OPTAL.

The explicit processor assignment vector (with the exact number of processors assigned to each loop) is computed as a side effect of the computation of $G_i$. When a particular $G_i$ is chosen as optimal the corresponding assignment vector can be trivially reconstructed. In order to illustrate the computational details of the algorithm we give below a simple example involving four DOALLs and $2^5$ processors. It should be noted that this approach not only finds the optimal assignment of the given $P$ processors to a particular loop nest, but it also finds the optimal assignments of $P/2$, $P/4$, $P/8$, $P/16$,..., 1 processors to the same loop. We can therefore determine the minimum number of useful processors with little extra cost.

**Example 4.1.1:** Consider the loop $L=(N_1 = 15,\ N_2 = 17,\ N_3 = 17,\ N_4=25)$ of Figure 2(b) and let $P=2^5$ be the available processors. The optimal assignment of $P$ to $L$ is computed as follows: First the 5X4 efficiency matrix $M$ is computed. At the first step for $i=4$ we have $G_4(2^r) = \epsilon_4^{2^r}$ for $r = 0, 1, \ldots, 5$. The computations for the remaining three steps are shown analytically below.

**Step 2**

$$G_3(2)=\max\left\{G_4(2),\epsilon_3^2G_4(1)\right\}$$

$$G_3(4)=\max\left\{G_4(4),\epsilon_3^2G_4(2),\ \epsilon_3^4G_4(1)\right\}$$

$$G_3(8)=\max\left\{G_4(8),\epsilon_3^2G_4(4),\ \epsilon_3^4G_4(2),\epsilon_3^8G_4(1)\right\}$$

$$G_3(16)=\max\left\{G_4(16),\epsilon_3^2G_4(8),\epsilon_3^4G_4(4),\epsilon_3^8G_4(2),\epsilon_3^{16}G_4(1)\right\}$$

$$G_3(32)=\max\left\{G_4(32),\ \epsilon_3^2G_4(16),\epsilon_3^4G_4(8),\epsilon_3^8G_4(4),\epsilon_3^{16}G_4(2),\epsilon_3^{32}G_4(1)\right\}$$

**Step 3**

$$G_2(2)=\max\left\{G_3(2),\ \epsilon_2^2G_3(1)\right\}$$

$$G_2(4)=\max\left\{G_3(4),\ \epsilon_2^2G_3(2),\epsilon_2^4G_3(1)\right\}$$

$$G_2(8)=\max\left\{G_3(8),\epsilon_2^2G_3(4),\ \epsilon_2^4G_3(2),\epsilon_2^8G_3(1)\right\}$$

$$G_2(16)=\max\left\{G_3(16),\epsilon_2^2G_3(8),\ \epsilon_2^4G_3(4),\epsilon_2^8G_3(2),\epsilon_2^{16}G_3(1)\right\}$$

$$G_2(32)=\max\left\{G_3(32),\ \epsilon_2^2G_3(16),\epsilon_2^4G_3(8),\epsilon_2^8G_3(4),\epsilon_2^{16}G_3(2),\epsilon_2^{32}G_3(1)\right\}$$

**Step 4**

$$G_1(2)=\max\left\{G_2(2),\ \epsilon_1^2G_2(1)\right\}$$

$$G_1(4)=\max\left\{G_2(4),\epsilon_1^2G_2(2),\epsilon_1^4G_2(1)\right\}$$

$$G_1(8)=\max\left\{G_2(8),\epsilon_1^2G_2(4),\epsilon_1^4G_2(2),\epsilon_1^8G_2(1)\right\}$$

$$G_1(16)=\max\left\{G_2(16),\epsilon_1^2G_2(8),\epsilon_1^4G_2(4),\epsilon_1^8G_2(2),\epsilon_1^{16}G_2(1)\right\}$$

$$G_1(32)=\max\left\{G_2(32),\epsilon_1^2G_2(16),\epsilon_1^4G_2(8),\epsilon_1^8G_2(4),\epsilon_1^{16}G_2(2),\ \epsilon_1^{32}G_2(1)\right\}$$

In each case the maximum element appears in bold letters. The optimal assignment in this example is therefore the one that assigns 16 processors to loop $N_1 = 15$ and 2 processors to loop $N_4 = 25$. The processor assignment profile is reconstructed as follows. The number of processors assigned to a loop $l$, is equal to the superscript of the $\epsilon$ factor of the maximum term in $G_l(P)$. If an $\epsilon$ factor does not exist, the corresponding loop receives 1 processor. First we look at the maximum element of $G_1(32)$. This element is $\epsilon^{16}G_2(2)$ which tells us that loop $N_1$ receives 16 processors, and the remaining processors are allocated to $G_2(2)$. The maximum element of entry $G_2(2)$ is $G_3(2)$ which indicates that loop $N_2$ receives 1 processor. Continuing in the same way, the maximum element of entry $G_3(2)$ is $G_4(2)$ which again tells us that loop $N_3$ is assigned 1 processor, and therefore loop $N_4$ is assigned the remaining 2 processors.

### 4.2.2. The General Algorithm

Although most real multiprocessor systems have $P = 2^k$ for some integer $k$, OPTAL can be used to generate optimal processor assignments for any integer $P$. It also handles arbitrarily complex nested parallel loops. Before we describe the details of the general algorithm however, we need to define the concepts of DOACR and loop nesting more precisely. The details about the DOACR [9], [1] construct are beyond the scope of this paper and we only define terms used in later discussion.

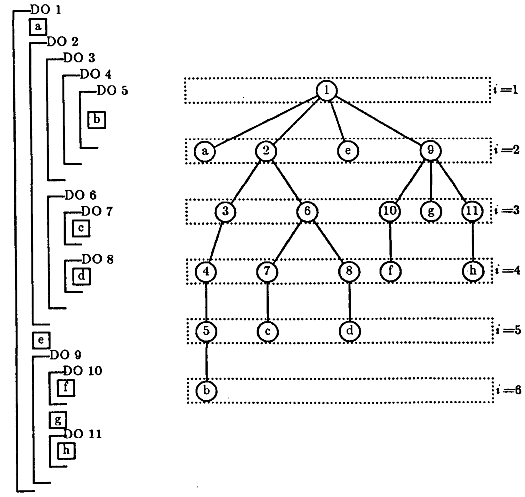

Figure 3. A nested loop and its tree representation. Squares and leaves denote BASs.

As mentioned in Section 2, a DOACR loop can be informally defined as a parallel loop in which data dependences allow for partial overlap of successive iterations during execution on an MES system. In other words, if iteration $i$ starts at time $t$ on a given processor, iteration $(i+1)$ can start at time $t + d$, where $d$ is a constant. Constant $d$ is called delay and represents the execution time of a subset of loop statements whose data dependence graph forms a cycle. If $B$ is the size (serial execution time) of the loop body, then $d/B$ is defined as the percentage of overlap, (or doacross percentage). When $d=B$ the loop is serial while if $d=0$ the loop is said to be DOALL. In DOALL loops all iterations may start execution simultaneously. DOALL and serial loops are therefore special cases of DOACR loops. The parallel execution time of a DOACR loop with $N_i$ iterations, $d_i$ delay and a body size of $B_i$ that executes on $P$ processors is given by the following [12].

$$T_P^i(B_i) = \left(\left\lceil\frac{N_i}{P}\right\rceil - 1\right) * \max\{B_i,\ Pd_i\} + d_i * \Big((N - 1) \bmod P\Big) + B_i \qquad (6)$$

To simplify the notation in the following discussion, we assume that a block of assignment statements (BAS) can be considered as a DOACR loop with $N_i = 1$, and $d_i = 0$.

An arbitrarily complex nested loop can be uniquely represented as a $k$-level tree where $k$ is the maximum nest depth. The leaves of the tree correspond to BASs and intermediate nodes correspond to (DOACR) loops. Obviously the total number of nodes in a loop tree is $\lambda + \mu$ where $\lambda$ is the number of individual loops in the structure and $\mu$ the number of BASs. An example of a nested loop and its tree representation are shown in Figure 3. Intermediate tree nodes at level $m$ correspond to loops at nest depth $m$. We assume that individual loops in an arbitrarily nested loop are numbered increasingly, in lexicographic order.

In the general case loops are not perfectly nested and therefore the efficiency index as defined in Section 4 is not useful. We can redefine the efficiency index for the general case but it is more convenient to define the assignment function so that it measures directly parallel execution time. Therefore the max term of the assignment function becomes min in this case since our objective here is to minimize execution time and thus maximize speedup.

The steps of the general algorithm are almost identical to the case of perfectly nested loops. The example of Figure 3 is used whenever it helps illustrate the computations involved. A $\lambda \times P$ table can be used to store intermediate values. ($\lambda$, $P$ are the numbers of loops and processors respectively). During the first step we compute the parallel execution time of the DOACR loops at level $k$ on the tree, where $k$ again is the maximum nest level. This is done as follows:

$$G_k^i(q) \;=\; T_q^i(B_i)\,, \qquad q \;=\; 1, 2, ..., P \qquad (7)$$

and for all leaves i.

where $T_q^i$ is given by (6). The general step is defined recursively as in the perfectly nested loop case. The optimal assignment of $P$ processors to loops in levels $i$ through $k$ ($i < k$), (assuming the optimal assignment of $P$ to loops at level $i$+1 is known), is then generated by:

$$G_i^j(q) \;=\; \min_{1 \leq r \leq q} \left\{ T_r^j \left( \sum_{n\ child\ of\ j} G_{i+1}^n(\lfloor q/r \rfloor) \right) \right\} \qquad (8)$$

and for $q$=1, 2, 3, ..., $P$

where (8) is computed for all nodes (loops) $j$ at level $i$, and $T(^*)$ is given by (6). The summation in (8) accounts for all nodes at level $i + 1$ that are descendants of node $j$, that is, all loops nested inside loop $N_j$. The optimal assignment of $P$ processors to a given loop is given by $G_1^1(P)$. Recall from the example of the previous section that the detailed processor assignment vector is automatically constructed during the evaluation of 8. For each loop the number of processors assigned to that loop correspond to the minimum term in 8.

It should be noted that all optimal assignments of 1, 2,..., $P$-1 processors to a loop $L$ are computed as intermediate results of the computation of $G_1^L(P)$. We therefore have the following.

**Lemma 4.7.** The maximum number of useful processors given $P$ for a loop $L$ is the minimum $Q$, such that $1 \leq Q \leq P$ and $G_1^L(Q) = G_1^L(P)$.

**Theorem 4.8.** For any loop $L$ of maximum nest depth $k$, and any integer $P$, OPTAL terminates after $k$ iterations and generates the optimal assignment of $P$ processors to $L$.

The complexity of the algorithm can be easily determined. The assignment function $G_i^j$ is computed $P$ times for each node (loop) in the tree, or a total of $\lambda P$ times. Each evaluation of the assignment function also involves finding the minimum of an average of $P/2$ terms. The complexity therefore (without counting additions) is $O(\lambda P^2 / 2)$. The complexity can be reduced to $O(\lambda P \log P)$, and OPTAL can be used to implement a systolic array control unit that consists of $P \log P$ nodes and determines the optimal assignment of $P$ processors to a given loop in $\lambda$ steps [11]. The speedup resulting from the optimal assignment of $P$ processors to a loop $L$ is given by, $S_P \;=\; G_1^L(1) \;/\; G_1^L(P)$.

An interesting point of this approach is that although loops at the same nest level are allocated the same total number of processors, each loop manages (assigns) its own processors in an independent way. For example, suppose that loops 3 and 6 of Figure 3 are allocated 8 processors each. A possible assignment then may assign 1 processor to loops 3 and 4, and 8 processors to loop 5, while in the second case we may have 2 processors assigned to loop 6, and 4 processors to each of the loops 7 and 8. It is clear that loops on the same nest level must be assigned the same total number of processors when executing on a parallel processor system. Otherwise we have suboptimal parallel execution times since some processors will be forced to remain idle.

## 5. EXPERIMENTS

We implemented this processor assignment algorithm as a pass in the Parafrase compiler. Processor assignment is performed after DOALL and DOACR loops are recognized and delays computed. In our experiments we measured speedup values for some subroutines of the EISPACK and IEEE DSP packages, even though analysis of the entire packages is under way.

Speedup values were computed as discussed in Section 2. In our case $T_P$, the parallel execution time, was measured for $P$=32, $P$=256, and $P$=2048 processors, and for loop bounds set to 40. In some EISPACK subroutines where loop bounds correspond to the bandwidth of band-matrices, we used loop bounds of 1 or 4. The speedup values measured for the three different numbers of processors are shown in Tables 1 and 2. The subroutines from the two packages used in these experiments were randomly selected.

From the speedup values we observe that for 32 processors the average speedup is almost linear for both EISPACK and IEEE subroutines. For 256 processors the average speedup for EISPACK subroutines is about 137, or more than $P/2$. In other words, we have an efficiency of more than 50% for $P$=256. For the IEEE subroutines we observe an even higher average efficiency for the same number of processors. The third column in the tables corresponds to an unlimited number of processors. Since most of the EISPACK subroutines deal with square matrices, for 40X40 arrays the the maximum expected speedup is 1600. Taking into account several loops with bounds of 1 or 4 and the number of one-dimensional loops, the average maximum speedup should be expected to be considerably lower than 1600. The average speedup of the third column of Table 1 is about 310, which corresponds to an average efficiency of about 15%. Since at most 1600 processors would be useful for most of the EISPACK routines, in reallity we would have an efficiency of about 20%. The corresponding values for the third column of Table 2 are quite higher than those of EISPACK. Generally, supercomputers deliver a wide range of performances from program to program. This is true of real machines [16], and has been observed in our earlier experimental work [7]. It appears, from the experiments we

Table 1: Speedup values for 32, 256, and 2048 processors for EISPACK (Table 1), and IEEE DSP subroutines (Table 2).

have conducted so far, that when OPTAL is used there is very little variation when programs are run with limited number of processors (i.e, when the number of processors is proportional to array sizes).

Considering the fact that efficiencies in the range of 20% are characterized very satisfactory in modern supercomputers, we can claim that optimal assignments to parallel loops result in high speedups for most cases. Processor allocations to independent code segments can increase the average speedup at least by a factor of two [14], [11].

## 6. CONCLUSION

The problem of coordinating several parallel processors to execute a parallel program as fast as possible is a key problem to the efficient use of large parallel processor machines, and the design of multiprocessors with hundreds or even thousands of processors. It is very important to be able to identify parallelism in a program and use all the available processors to maximize speedup. This problem however is complex and should not be shifted entirely to the user. Compilers, operating systems, and special hardware modules can be used to solve the problem satisfactorily with little or no user assistance.

In this paper we discussed issues of program parallelism and scheduling for parallel processor systems. We divided the scheduling process into three basic activities and focused on processor assignment to parallel loops. An algorithm was presented that gives an optimal solution at compile-time for processor assignments to complex parallel loops. This algorithm can be also implemented as a hardware device to perform processor assignment at run-time. We also presented some speedup measurements for EISPACK and IEEE subroutines, that result from the optimal assignment of processors to parallel loops. These measurements indicate that optimal processor assignments result in almost linear speedups on medium scale parallel processor machines.

# PROCESSOR SELF-SCHEDULING FOR MULTIPLE-NESTED PARALLEL LOOPS

Peiyi Tang and Pen-Chung Yew

Center for Supercomputing Research and Development
University of Illinois at Urbana-Champaign
Urbana, Illinois 61801

## Abstract

Processor self-scheduling is a useful scheme in a multiprocessor system if the execution time of each iteration in a parallel loop is not known in advance and varies substantially, or if there are multiple nestings in parallel loops which makes static scheduling difficult and inefficient. By using efficient synchronization primitives, the operating system is not needed for loop scheduling. The overhead for the processor self-scheduling is small.

We presented a processor self-scheduling scheme for a single-nested parallel loop, and extend the scheme to multiple-nested parallel loops. Barrier synchronization mechanisms in the processors self-scheduling schemes are also discussed.

## 1. Introduction

Processor scheduling is a problem that must be solved in order to run a program on a multiprocessor system efficiently. The multiprocessor system considered here is a collection of identical processors with a global shared memory. Cray X-MP [1], Cedar [2], Ultracomputer [3] and RP3 [4] are some examples of such systems.

Parallel loops in a program, whose iterations can be executed concurrently on different processors, provide the greatest potential of parallelism to be exploited by multiprocessor systems. It is called a DOALL-loop, if the iterations of a parallel loop are independent. If there are data dependences across iterations of a DO-loop, its iterations can still be executed concurrently on different processors provided that the data dependences are enforced by synchronization across the processors during the execution [8]. This kind of parallel loop is called a DOACROSS-loop [11]. Both DOALL-loops and DOACROSS-loops can be nested in many levels. In this paper, we only consider DOALL-loops.

DOALL-loops can either be recognized by an optimizing compiler like Paraphrase [10] or explicitly specified by a programmer. Processors need to be scheduled properly so that execution time of a DOALL-loop is minimized. A *task* of scheduling here is one or several iterations of a DOALL-loop. We will only consider non-preemptive scheduling schemes, i.e., once a processor is assigned an iteration, it will continue to execute the iteration until its completion.

If execution time of each iteration of a DOALL-loop is the same, the optimal scheduling is to assign iterations evenly among processors. This scheduling can be done before program execution and is called *static* scheduling.

If execution time of each iteration is different and is not known until program execution, the scheduling of iterations to processors is more efficient if it can be done dynamically during the program execution, i.e., assign a new iteration to a processor whenever it becomes available. The total number of iterations assigned to each processor may not be equal, but the workload of each processor tends to be balanced. This scheduling is called *dynamic* scheduling. In this paper, we only consider dynamic scheduling.

Dynamic scheduling will incur scheduling overhead at run time. One technique to reduce overhead is to schedule several iterations (called a *chunk* of iterations) to a processor at a time. As long as the number of chunks is large enough, workload among processors can still be balanced.

Scheduling overhead can be very large if dynamic scheduling is done by system calls to the operating system. One way to reduce scheduling overhead is to use processor self-scheduling [5] [6] [7]. Rather than issuing a system call to the operating system for scheduling, processors can schedule themselves by fetch-and-adding a shared variable to get loop indices of a chunk of iterations. If a multiprocessor system has efficient hardware-implemented synchronization primitives like those in Cedar [8], Ultracomputer [9] and RP3 [4], scheduling overhead for a chunk of iterations can be reduced quite significantly.

However, so far, all processor self-scheduling schemes only deal with the outermost parallel DO-loop [5] [6] [7]. The rest of the parallel loops nested inside are treated as serial DO-loops. Hence, parallelism of the nested DOALL-loops is not fully exploited.

In this paper, we present a self-scheduling scheme for nested DOALL-loops using Cedar synchronization instructions. Cedar synchronization instructions [8] are briefly introduced in section 2. In section 3, we describe barrier synchronization mechanism needed in processor self-scheduling and processor self-scheduling schemes for single-nested DOALL-loops. In section 4, we present a processor self-scheduling scheme for multiple-nested DOALL-loops. An estimation of overhead for scheduling an iteration and the performance of the proposed processor self-scheduling schemes are given in section 5. In section 6, we have some concluding remarks.

This work was supported in part by the **National Science Foundation** under Grant Nos. US NSF DCR84-06916 and US NSF DCR84-10110, and the **US Department of Energy** under Grant No. US DOE DE FG02-85ER25001.

## 2. Cedar Synchronization Primitives

In a Cedar Multiprocessor System, a variable can be declared as a synchronization variable. A synchronization variable x has two fields: KEY and DATA. The KEY field is for storing synchronization information (which is an integer) and the DATA field is for storing the value of the variable (which can be a floating point number). The format of a Cedar synchronization instruction is as follows:

```
{x; test on KEY;
  operation on KEY; operation on DATA}.
```

Here x is the name (or the address) of the synchronization variable. The "test on x.KEY" specifies the condition to be tested between the KEY field of x (denoted by x.KEY) and a key provided by the instruction (denoted by i.KEY). The test includes $>$, $\geq$ $<$, $\leq$ $=$, $\neq$and NULL. The NULL test means that no test is needed and therefore the result of the test is always true. The operation on x.KEY can be Increment, Decrement, Add, Fetch, Fetch & Add, Store, Fetch & Increment, Fetch & Decrement and No Action. The operation on DATA can be Fetch, Store and No Action. The execution of the whole synchronization instruction, i.e. test on x.KEY, operations on x.KEY and x.DATA, is done in globally shared memory modules and is indivisible [8]. The operation on x.KEY and the operation on x.DATA are executed only when the result of the test is true. The memory module will inform the processor of a "failure" if the condition of the test is not satisfied, or a "success" if the condition is satisfied and execution of the instruction is completed. For some application, test on x.KEY has to be done repeatedly until the test condition becomes true. A star on the test condition (as shown below) is used to indicate this situation. In other words,

```
{x; (test on KEY)*;
  operation on KEY; operation on DATA }
```

is equivalent to

```
1: {x; test on KEY;
     operation on KEY; operation on DATA }
   if failure then goto 1
```

Cedar synchronization primitives are very effective in handling low level synchronizations required in numerical computations like enforcing data dependences across loop iterations [8]. In those applications, KEY field stores loop iteration numbers and DATA field usually stores the value of the data (which is usually a floating point number). In this paper, we use this synchronization primitives mostly for non-numerical scheduling problems. Hence, only the KEY field is used.

## 3. Barrier Synchronization

Following are several assumptions used in our processor self-scheduling schemes:

(1) We assume that the operating system assigns certain number of processors, say P processors, to a program before its execution. After that, the operating system will not be involved in scheduling.

(2) Code for processor self-scheduling is embedded in a user's program, and each processor will execute the same program.

(3) For the simplicity of the discussion, we assume that a task in our scheduling is only one iteration. A task whicb has several iterations can be similarly implemented.

The iterations of a DOALL-loop are scheduled through a shared variable, and after all of the iterations are scheduled, a *barrier synchronization* is needed for the completion of the DOALL-loop. In this section, we present two barrier synchronization mechanisms and processor self-scheduling schemes for a single-nested DOALL-loop.

In the first barrier synchronization mechanism, processors will be blocked at the *barrier* until all of the processors complete their tasks and arrive at the barrier. After that, the barrier will open and all of the processors can pass through. There is a counter which counts the number of arriving processors, and it must be reinitialized before the barrier can be reused for the second time. Algorithm 3.1 is a processor self-scheduling scheme for a DOALL-loop using this barrier synchronization mechanism.

**Algorithm 3.1**

```
/* J: loop index for the DOALL-loop with M iterations
   A: a counter to count the number of processors
      that have arrived at the barrier
   B: a variable acting as a barrier */

/* Initially J=1, A=P and B=0, where P is the
   total number of the processors assigned to
   execute the program. */

$L_1$: {J; $\leq$M; Fetch(LOCJ)&Increment}
   if failure then goto $L_2$
     .
     .
     . /* Original Do loop-body with index LOCJ */
     .
     .
   goto $L_1$
   /* Processors go back to $L_1$
      to get another iteration. */

$L_2$: {A; $>$1; Decrement}
   if failure then
        begin
         J:=1; A=P; B:=P
        end
   {B; ($>$0)*; Decrement}
   /* B acts as a barrier and is reinitialized
      after P processors pass through. */
```

If a DOALL-loop is enclosed in an outer serial loop as shown in Figure 3.1, the implementation of the outer serial loop is quite simple. Since all of the processors are synchronized at the barrier of the second DOALL-loop $J_2$, each processor can have a local copy of loop index variable LOCI and update it after the execution of the DOALL-loop $J_2$. The processor self-scheduling code for the whole program is illustrated in Figure 3.2.

However, a barrier synchronization based on the number of arriving processors has a problem. If the actual number of processors assigned to the program is less than that specified in the program (i.e. P processors), the barrier of $J_1$ will never open and all of the processors will be stuck there. In other words, the operating system must assign exactly the same number of processors as specified in the program; otherwise, we will have a deadlock.

However, the precedence relation only requires that all of the iterations of the first DOALL-loop be completed before the second DOALL-loop can be started. In the following, a barrier is controlled by the number of completed iterations of the DOALL-loop instead of by the number of arriving processors. Counter A is initialized to M, the total number of iterations, instead of P. When all of the iterations are completed, the barrier will be opened. Thus, this barrier synchronization mechanism will work even if the operating system assigns fewer than P processors to the program. The processor self-scheduling scheme using this barrier synchronization mechanism is shown in Algorithm 3.2

**Algorithm 3.2**

```
/* C: a lock to block processors after P processors
      have entered the DOALL-loop
   J: loop index for the DOALL-loop with M iterations
   A: a counter to count the number of completed iterations
   B: a variable acting as a barrier
   T: a counter to detect the last processor,
      which is responsible for reinitializing
      all of the synchronization variables */
/* Initially C=P, J=1, A=M, B=0 and T=P.
   P is the number of processors assigned
   to the program.                 */

  {C; (>0)*; Decrement}
  /* This is to block processors after P processors
      have entered the DOALL-loop. */
$L_1$: {J; ≤M; Fetch(LOCJ)&Increment}
  if failure then goto $L_2$
     .
     .
     . /* Original Do loop-body with index LOCJ */
     .
     .
  {A; >1; Decrement}
  if failure then B:=1
  /* Counter A counts the number of completed
     iterations and controls the opening of
     the barrier.            */
  goto $L_1$
  /* Processors go back to $L_1$ to get
     another iteration. */
 $L_2$: {B; (>0)*; No Action}
  /* B acts as a barrier.    */
  {T; >1; Decrement}
  if failure then
  /* This is to reinitialize all of the
     synchronization variables. */
    begin
      T:=P; B:=0; A:=M
      J=1; C:=P
    end
```

Note that all of the synchronization variables in the algorithm will be reinitialized after P processors have passed the variable T. If there are fewer than P processors assigned to the program, some processors must come back and make up the discrepancy, and the synchronization variables will be reinitialized eventually.

Lock C in the beginning of the code is used to prevent the race problem caused by the delay in reinitializing the barrier. Note that there is a delay between the time when all of the P processors pass the barrier and the time it is reinitialized. During this period of time, it is possible that some processors may revisit this DOALL-loop again for the next iteration of the outer serial loop. If there is no such a lock to block those fast processors, they will pass the barrier for the second time and start executing the following DOALL-loop before this DOALL-loop is restarted.

The disadvantage of the barrier synchronization mechanism based on the number of completed iterations is that the implementation of the outer serial DO-loop is more complicated. Because processors are no longer synchronized after each iteration of the outer serial DO-loop, the number of the times each processor will traverse the outer serial DO-loop may be different. A shared index variable for the outer serial DO-loop is thus needed. The branch node needed to implement the outer serial DO-loop is given in Algorithm 3.3. Figure 3.3 illustrates the processor self-scheduling code for the entire program in Figure 3.1 using this barrier synchronization mechanism.

**Algorithm 3.3**

```
/* C: a lock to block processors after P processors
      have entered the branch node.
   S: a semaphore to guarantee that only one
      processor can control the outer serial loop
   B: a variable acting as a barrier
   T: a counter to detect the last processor,
      which is responsible for reinitializing
      all of the synchronization variables */

/* Initially C=P, S=1,B=0 and T=P, where P is
   the number of processors assigned to the program. */

  {C; (>0)*; Decrement}
  /* This is to block processors after P processors
      have entered the branch node. */
$L_1$: {S; >0; Decrement}
  if failure then goto $L_2$
  /* This is to allow only one processor
      to execute the following code. */
  if  I<N then
      begin
        COND:= true; I:=I+1
      end
     else
      begin
        COND:= false; I:= 1
      end
  /* Update the shared index variable I
      and resolve the branch condition,
      which is stored in COND */
  B:=1
  /* Open the  barrier B */
$L_2$: {B; (>0)*; No Action}
  MYCOND:=COND
  /* Save the branch condition */
  {T; >1; Decrement}
  if failure then
     begin
```

```
    T:=P; B:=0; S:=1; C:=P
  end
/* This is to reinitialize all of the
   synchronization variables. */
if MYCOND=true then goto START
/* START is the head of the serial DO-loop. */
```

## 4. Processor Self-Scheduling for Nested DOALL-loops

In this section, we extend the processor self-scheduling schemes to nested DOALL-loops. Before going further, we have to define a few terms which will be used later.

If each inner DOALL loop is surrounded immediately by an outer DOALL loop with no scalar code between them, this multiple DOALL loop nestings is a **perfectly-nested DOALL structure**.

Otherwise, a nested DOALL structure is called a **non-perfectly-nested DOALL structure.** Figure 4.1 shows an example of non-perfectly-nested DOALL structure. There, we use a left bracket "[" to denote each DOALL-loop nesting. In a non-perfectly-nested DOALL structure, each innermost DOALL loop nesting will contain a loop body. The loop-body with all of its surrounding DOALL-loop nestings form a **nested DOALL component**. For example, the non-perfectly-nested DOALL structure in Figure 4.1 has three nested DOALL components. A perfectly-nested DOALL structure contains only one nested DOALL component.

We only discuss self-scheduling scheme of a non-perfectly-nested structure. A perfectly-nested DOALL structure is a special case of a non-perfectly-nested DOALL structure.

Assume that a non-perfectly-nested DOALL structure like the one in Figure 4.1 consists of $m$ nested DOALL components. Each nested DOALL component can be characterized by two vectors: an index variable vector and a loop-bound vector. The index variable vector of a nested DOALL component $(I_1,I_2,...,I_d)$ is a vector which consists of the index variables of the loop nestings. Here, $I_1$ is the index variable of the outermost nesting and d is the depth of the loop nestings. The loop-bound vector $(N_1,N_2,...,N_d)$ is a vector of the corresponding loop-bounds. For example, the index variable vectors for the three nested DOALL components in Figure 4.1 are $(I_1,I_2)$, $(I_1,J_2,J_3)$ and $(I_1,J_2,K_3)$, respectively, and their corresponding loop-bound vectors are (3,7), (3,2,3) and (3,2,4).

For a nested DOALL component with index variable vector $(I_1,I_2,...,I_d)$ and loop-bound vector $(N_1,N_2,...,N_d)$, there are total of $N_1 \cdots N_d$ iterations for the component. Each of them can be identified by a sequence number from 1 to $N_1 \cdots N_d$. If we split the d loop nestings at level k $(1 \leq k < d)$ into $(I_1,...,I_k)$ and $(I_{k+1},...,I_d)$, we can notice that there are $N_{k+1} \cdots N_d$ iterations of the component that share common loop indices of the k outermost nestings $(I_1,...,I_k)$. An iteration with $I_1=i_1$, $I_2=i_2$, ..., $I_k=i_k$ is called an **iteration at level k.** The sequence number for the iteration is defined to be

$$i=(i_1\text{-}1)N_2 \cdots N_k + \cdots + (i_{k-1}\text{-}1)N_k + i_k.$$

There are $N_1 \cdots N_k$ iterations at level k, each of which can be identified by a sequence number from 1 to $N_1 \cdots N_k$.

Let $(I_1,I_2,...,I_{d_j})$ and $(N_1,N_2,...,N_{d_j})$ be the index variable vector and the loop-bound vector of the $j$-th component. It has two parameters $k_j$ and $l_j$ $(1 \leq j \leq m,\ 1 \leq k_j \leq d_j,\ 1 \leq l_j \leq d_j)$, defined as follows: if its deepest common loop nesting with the $(j\text{-}1)$-th component is at $(p\text{-}1)$ level, we will have $k_j=p$. Similarly, if the deepest common loop nesting it shares with the $(j+1)$-th component is at $(q\text{-}1)$ level, we have $l_j=q$. From the definition, we have $l_j=k_{j+1}$, $1 \leq j < m$. We also define that $k_1=1$ and $l_m=1$. For the non-perfectly-nested DOALL structure in Figure 4.1, we have $k_1=1$, $l_1=2$, $k_2=2$, $l_2=3$, $k_3=3$, $l_3=1$.

Assume that the deepest common loop nesting for the $(j\text{-}1)$-th and the $j$-th components is at level $p\text{-}1$, i.e. $l_{j-1}=k_j=p$ (See Figure 4.2). According to the semantics of nested DOALL-loops, an iteration at level p-1 for the j-th component can not be started until the corresponding iteration for the (j-1)-th component is completed. We use a variable $B^{j-1}$ to enforce this precedence constraint. When $B^{j-1}=t$, the first t iterations at level p-1 for the (j-1)-th component are completed, and, hence, we can start to schedule the j-th component for those iterations.

The components of a DOALL loop structure will be scheduled in sequence, and the iterations of each component will be scheduled in the order of their sequence numbers. Thus, the processor self-scheduling schemes proposed here for nested DOALL-loops can also be applied to nested DOACROSS-loops or mixture of nested DOALL-loops and DOACROSS-loops without causing deadlocks.

Processor self-scheduling for the j-th nested DOALL component is realized by fetch-and-incrementing an **index control variable $I^j$.** The initial value of $I^j$ is 1, which corresponds to the first index vector (1,1,...,1). The maximum value of $I^j$ is $M_j=N_1N_2 \cdots N_{d_j}$, which corresponds to the last index vector $(N_1,N_2,...,N_{d_j})$. Let $F_{N_1,N_2,\cdots,N_{d_j}}$ be a function that maps the sequence number of an iteration into its index vector. Table 4.1 shows an example of function $F_{2,3,2}$. Function $F_{N_1,N_2,\cdots,N_{d_j}}$ can be formulated as follows:

$$F_{N_1,N_2,\cdots,N_{d_j}}[x] \rightarrow (i_1,i_2,\cdots,i_{d_j}),$$

where for $1 \leq k \leq d_j$, we have

$$i_k = \left\lfloor \frac{x\text{-}1}{N_{k+1} \cdots N_{d_j}} \right\rfloor mod\ N_k + 1.$$

$\lfloor t \rfloor$ is the largest integer smaller than $t$. This computation can be done locally in a processor after it fetches a sequence number from $I^j$. However, as mentioned before, if the sequence number of an iteration at level p-1 for the j-th component is larger than $B^{j-1}$, it can not be started. Given a sequence number x of an iteration, the sequence number of the iteration at level p-1 is

$$y = \left\lfloor \frac{x\text{-}1}{N_p \cdots N_{d_j}} \right\rfloor + 1.$$

So, before starting to execute an iteration of the component, a processor needs to check if $B^{j-1} \geq y$. If $B^{j-1} < y$, a processor has to wait until $B^{j-1}$ becomes larger.

The processor self-scheduling code for the non-perfectly-nested DOALL structure is given in Algorithm 4.1.

**Algorithm 4.1**

```
{C; (>0)*; Decrement}
    .
    .
    .
/* The code for the j-th component starts here.
  Initially $I^j$=1, $B^j$=0,
  $A^j(i_1,i_2, \ldots, i_{q-1})=N_q N_{q+1} \cdots N_{d_j}$
       $(1\leq i_1\leq N_1, 1\leq i_2\leq N_2, \ldots, 1\leq i_{q-1}\leq N_{q-1})$ */
$L^j$: {$I^j$; $\leq M_j$; Fetch(x)&Increment}
   /* $M_j=N_1 \cdots N_{d_j}$. */
   if failure then goto $L^{j+1}$
   /* $L^{j+1}$ is the beginning of the next component */
   y:= $\lfloor (x-1)/(N_p \cdots N_{d_j}) \rfloor + 1$
   {$B^{j-1}$; $(\geq y)$*; No action}
   for k= 1 to $d_j$ do
     $LOCI_k := \lfloor (x-1)/(N_{k+1} \cdots N_{d_j}) \rfloor \bmod N_k + 1$
   /* Compute the index vector from the sequence
      number x using function $F_{N_1,\ldots,N_{d_j}}$ */
    .
    .
    . /* original Loop-body with index vector
    .    $(LOCI_1, LOCI_2, \cdots, LOCI_{d_j})$ */
    .
    .
   {$A^j(LOCI_1, LOCI_2, \ldots, LOCI_{q-1})$; >1; Decrement}
    if failure then
      begin
        $A^j(LOCI_1, \cdots, LOCI_{q-1}):=N_q \cdots N_{d_j}$
        z := $\lfloor (x-1)/(N_q \cdots N_{d_j}) \rfloor + 1$
        {$B^j$; (=z-1)*; Increment}
      end
    goto $L^j$
 /* The j-th component ends here.  */
    .
    .
$L^{m+i}$: {$B^m$; (=1)*; No action}
    /* $B^m$ acts as a barrier. */
    {T; >1: Decrement}
    if failure then
     begin
      T:=P
      $B^1$:=0; $I^1$:=1
      $B^2$:=0; $I^2$:=1
       .
       .
       .
      $B^m$:=0; $I^m$:=1
      C:=P
    end
```

Algorithm 4.1 consists of three portions. First portion is just a single statement

{C; (>0)*; Decrement}

which functions as a lock in the beginning of the code to prevent race problem. Lock C is initialized to P, the number of processors assigned to the program. The second portion is the main self-scheduling code for each nested DOALL component. They are the same except for the different parameters such as loop-bound vector, $k_j$ and $l_j$. We only present the code for the j-th component.

The main self-scheduling code for each component consists of three parts: loop self-scheduling, the original loop-body and bookkeeping of the completed iterations. We already discussed the "self-scheduling" part. In bookkeeping of the completed iterations, recall that for each iteration at level q-1, there are total of $N_q \cdots N_{d_j}$ iterations for the $(d_j-q+1)$ innermost loop nestings of the component. We use an element of array $A^j$ to record the total remaining iterations. It will be decremented by 1 after each iterations of the innermost $(d_j-q+1)$ loops has been completed.

When $N_q \cdots N_{d_j}$ iterations of the innermost $(d_j-q+1)$ nestings are completed, the element of $A^j$ is reinitialized. Given the sequence number x of the iteration fetched from $I^j$, the sequence number z of the corresponding iteration at level q-1 is

$$z=\left\lfloor \frac{x-1}{N_q \cdots N_{d_j}} \right\rfloor +1.$$

$B^j$, which is used to control the execution of the (j+1)-th component, is then updated. Note that $B^j$ is incremented only when its value is one smaller than the calculated sequence number. Thus, when $B^j$=s, it is guaranteed that the iterations at level q-1 with the sequence number from 1 to s have been completed.

The last portion of Algorithm 4.1 is for barrier synchronization and reinitialization. $B^m$ acts as a barrier for the entire non-perfectly-nested DOALL structure. In fact, since $l_m$=1, $B^m$ has only two values: 0 and 1. As in Algorithm 3.2, T is used to detect the last processor leaving the entire DOALL structure. That processor is responsible for reinitializing variables $B^j$, $I^j$ $(1\leq j\leq m)$, T and C. Array $A^j$ $(1\leq j\leq m)$ is reinitialized in the code for each component in the second portion. The barrier synchronization used here is based on the number of completed iterations. If the nested DOALL structure is within an outer serial loop, one has to use algorithm 3.3 to implement branch node.

Notice that iterations for the first nested DOALL component in a non-perfectly-nested DOALL structure can be scheduled without restriction. It is not necessary to check the value of $B^0$. This is why we set $k_1$=1 and $B^0$ is not used.

The entire processor self-scheduling code for the whole nested DOALL structure in Figure 4.1 is shown in Figure 4.3.

## 5. Overhead and Performance

Processor self-scheduling allows us to have better utilization of processors. During the program execution time, whenever a processor becomes available, it will grab another iteration and start executing the new iteration as long as the precedence relation in the program is not violated. Hence, the program execution time can actually be improved.

In a large multiprocessor system, global memory accesses will take very significant amount of time, hence, we will only consider global memory accesses (remember that Cedar synchronization primitives are global memory accesses) when we estimate the scheduling overhead. In Algorithm 3.1 and Algorithm 3.2, the overhead of scheduling an iteration of a single-nested parallel loop is only one Cedar synchronization instruction, which is one global memory access to the index control variable J. The overhead of scheduling an iteration of multiple-nested parallel loops is two global memory accesses as shown in Algorithm 4.1: one for testing and fetch-and-adding index control variable $I^j$ and one for checking variable $B^{j-1}$. The later is not needed in the case of perfectly nested parallel loops, i.e. the scheduling overhead for an iteration of a perfectly nested parallel loop is only one global memory access. This overhead is very small compared to the overhead that would incur if it is done by the operating system.

It is very important to note that the barrier synchronizations in the end of parallel loops are also needed in the static scheduling schemes. Hence, they are not extra overhead for the self-scheduling schemes.

Let us compare the self-scheduling scheme with the static scheduling scheme proposed in [12]. Assume that the execution times for each iteration of the nested DOALL structure is the same.

For a single-nested DOALL loop with N iterations, both schemes will schedule N iterations over P processors evenly. The program execution time will be the same for both schemes, i.e. it will be $\lceil N/P \rceil$ times the execution time of an iteration. However, processor self-scheduling will require one extra global memory access and, hence, it will have slightly more overhead than static scheduling scheme.

However, for multiple-nested DOALL loops, things can be quite different. Assume that we have a perfectly-nested DOALL-loop structure with loop-bound vector $(N_1, N_2, \cdots, N_d)$. Using static scheduling scheme, we have to find the optimal decomposition of $P = P_1 \cdots P_d$, where $P_i$ is the number of processors assigned to the i-th loop nesting, such that $\lceil N_1/P_1 \rceil \cdots \lceil N_d/P_d \rceil$ is minimized [12]. The completion time for this static scheduling is

$$T_{st} = \tau \lceil N_1/P_1 \rceil \cdots \lceil N_d/P_d \rceil \tag{5.1}$$

where $\tau$ is the execution time of an iteration. Using processor self-scheduling in Algorithm 4.1, we have

$$T_{sf} = (\tau + \sigma) \lceil N/P \rceil, \tag{5.2}$$

where $\sigma$ is the extra time needed for 1 extra Cedar synchronization instruction, and $N = N_1 N_2 \cdots N_d$. Note that

$$\lceil N/P \rceil \leq \lceil N_1/P_1 \rceil \cdots \lceil N_d/P_d \rceil \tag{5.3}$$

The equality in (5.3) holds only for some special cases. Let us ignore those special cases and assume that $(\lceil N_1/P_1 \rceil \cdots \lceil N_d/P_d \rceil) - \lceil N/P \rceil = k$, $k \neq 0$. $T_{sf}$ is less than $T_{st}$ when

$$\tau > \frac{\sigma}{k} \left\lceil \frac{N}{P} \right\rceil.$$

For the non-perfectly-nested DOALL-loop structure in Figure 4.1, assume that there are P=8 processors. Using the static scheduling scheme in [12], we get the optimal decomposition $P = 1 \times 2 \times 4$, i.e., using 1 processor for the outermost loop nesting, 2 processors for the second outermost loop nesting and 4 processors for the innermost loop nesting. The completion time is $9\tau$. Using self-scheduling, the completion time is $8(\tau + 2\sigma)$. In self-scheduling scheme, a processor is not tied to any specific loop nesting, thus, processors can be better utilized.

## 6. Concluding Remarks

We present processor self-scheduling scheme for both single- and multiple-nested parallel loops. Two different barrier synchronization mechanism are discussed. The scheduling overheads for these schemes are quite small if synchronization primitives are supported in the system as in Cedar [2].

Processor utilization can be improved over static scheduling scheme, which can lead to better program execution time if the execution time of each loop iteration varies substantially, or if there are multiple loop nestings.

## Abstract

This paper discusses some advanced topics related to interchanging DO loops in numerical programs. DO loop interchanging is used for many reasons; one well-known use of loop interchanging is to vectorize an outer DO loop when the inner DO loop must be left serial. In this paper we study loop interchanging as an end in itself. First, we describe the KAP/Design, a special program which, when given a nest of DO loops, prints out all the ways in which those DO loops can be interchanged. We describe some of the special transformations that are used by the KAP/Design. Second, a new type of loop interchanging, interchanging of imperfectly nested loops, is described.

## 1. Introduction

This paper discusses interchanging of DO loops in numerical programs. Loop interchanging is often used to uncover parallel operations in nested DO loops; when an inner DO loop cannot be vectorized, for instance, loop interchanging is used to bring a different loop to the innermost nest level which perhaps can be vectorized [1,2]. Loop interchanging has also been shown to be useful to modify the way arrays are accessed (to reduce bank conflicts or to reduce page faults [1,3,4]) or to change the way registers are allocated (vector registers in particular, allowing "super-vector" performance on vector pipeline machines [2]).

The KAP is a family of powerful retargetable vectorizers which use loop interchanging heavily [5,6,7]. We have studied loop interchanging and its applications extensively. This paper presents some of the results of this research.

The second section describes a special version of the KAP, called the KAP/Design, which prints out all legal ways to interchange a nest of DO loops. Examples of its use are given with an explanation of the problems we encountered while developing the KAP/Design. The third section describes a technique for interchanging imperfectly nested DO loops; this technique is not as simple as distributing the outer DO loop, but is something totally new.

## 2. KAP/Design

As pointed out in [8], different formulations of an algorithm sometimes differ only in having the DO loops interchanged. Some algorithm designers even stated that it might be useful to have a program source translator that printed out all the ways in which a DO loop nest might be interchanged. The KAP vectorizer includes a powerful loop interchanging algorithm, and it was a small matter to make a version that would interchange a nest of loops all possible ways and print each interchanged loop nest out. This became KAP/Design; an example of KAP/Design output on a simple matrix multiply program is shown in Figure 1. Normally the KAP/Design would be hardly noteworthy, but some of the problems that were encountered while designing and using the KAP/Design are interesting.

### 2.1 Simple Loop Interchanging

This section explains briefly how the KAP/Design tests for the legality of loop interchanging. A nest of DO loops, such as the two-nested loop in Figure 2(a), can be thought of as traversing a two-dimensional iteration space, shown in Figure 2(b). The arrows in Figure 2(b) represent how the serial DO loops execute the statements in the loop for iteration (I=1,J=1) first, then (1,2), (1,3), ..., (1,5), then incrementing the I index to go to (2,1), (2,2), ..., (2,5), ..., (5,1), ..., (5,5). Interchanging these two DO loops means changing the order in which the iteration space is traversed; by interchanging the loop as in Figure 3(a), the iteration space would be executed in the order shown in Figure 3(b).

There may also be data dependence relations between the iterations of a DO loop. Simple data dependence relations in scalar code are represented in the following program segment:

```
S1:    X = Z
S2:    Y = X
S3:    Z = Z + 1
S4:    X = 9.
```

In this short program segment, we say that statement S2 depends on S1 (flow-dependence) since the value of X used in S2 is assigned in S1; this means that statement S2 cannot be moved above S1 without changing the answers.

0190-3918/86/0000/0536 $01.00 © 1986 IEEE

We say that S3 depends on S1 (anti-dependence) since the value of Z assigned in S3 is not the value used by S1; this means that S3 cannot be moved above S1 without changing the answers. Finally, we say that S4 depends on S1 (output-dependence) since the value assigned to X in S4 is assigned after the value in S1 is assigned; again, S4 cannot be moved above S1 without changing the program. More on data dependence can be found in [9,10,11,12,13].

For interchanging loops, the KAP/Design is not so much interested in the data dependence relations between the statements in a loop as between the iterations of a loop. In the loop in Figures 2 and 3, the value of A(1,2) used in iteration (I=1,J=2) was assigned in iteration (I=1,J=1). In fact, the value used in iteration (i,j) was assigned in iteration (i,j-1) (except for boundary values); this relation is shown in the iteration space dependence graph in Figure 4. Notice that the pattern of the dependence flow in the iteration space can be characterized by the direction or the distance of the flow with respect to the loop index variables. In this example, the dependence distance would be called (0,-1), since the distance in the I loop is zero, and the distance in the J loop is -1. The KAP/Design saves the sign of the dependence distance; here it would save (0,-), or (=,<), to characterize the data dependence in the loop ((=,<) is the data dependence direction vector).

```

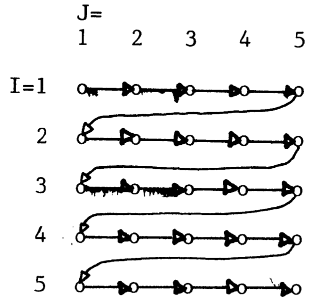
(a)



(b)

Figure 3.

The possible directions in a two dimensional iteration space (corresponding to a doubly-nested DO loop) are shown in Figure 5. Figure 5(a) shows the data dependence directions that are preserved by loop interchanging; Figure 5(b) shows the data dependence directions that prevent loop interchanging. A pair of loops with a (<,>) data dependence direction vector cannot be interchanged (without interaction from outer loops; see [1,2]).

The KAP/Design discovers all the data dependence relations in the DO loop, and saves the corresponding data dependence direction vectors. To perform DO loop interchanging on more than two loops, it does repeated pairwise interchanging.

## 2.2 Triangular Loops

One problem is that most studies of loop interchanging ignore the loop bounds [1,2,3]. Detailed discussions of how to test whether two loops can be interchanged explain the data dependence conditions, but assume that the inner DO loop bound is invariant in the outer loop. Many programs include triangular DO loop bounds, such as the loop nest in Figure 6(a). Here, the upper bound of the inner DO J loop is a simple function of the outer loop index. The iteration space traversed by this DO loop pair is drawn in Figure 6(b); it is easy to see why this is called a triangular loop. To properly interchange these loops it is necessary to modify the loop bounds, as in Figure 6(c). This is no more difficult than modifying the bounds of a double summation when interchanging the summations. The types of triangular loop bounds are classified by the shape of the triangle in the iteration space; the triangle in Figure 6(b) is a lower-left triangle. The four types of triangles are the lower/upper-left/right; four more types may be distinguished by including or excluding the diagonal (Figure 6(b) excludes the diagonal). These are characterized by the loop bounds:

```
              with diagonal:       without diagonal:

  lower left:
              DO 100 I = M,N       DO 100 I = M,N
              DO 100 J = M,I       DO 100 J = M,I-1

  upper right:
              DO 100 I = M,N       DO 100 I = M,N
              DO 100 J = I,N       DO 100 J = I+1,N

  upper left:
              DO 100 I = M,N       DO 100 I = M,N
              DO 100 J = M,N-I+M   DO 100 J = M,N-I+M-1

  lower right:
              DO 100 I = M,N       DO 100 I = M,N
              DO 100 J = N-I+M,N   DO 100 J = N-I+M+1,N
```

Interchanging a triangular loop can be thought of as transposing the iteration space about its major diagonal. Thus, a lower left triangle would be transposed into an upper right triangle, and vice versa. The lower right and upper left triangles would be transposed into themselves.

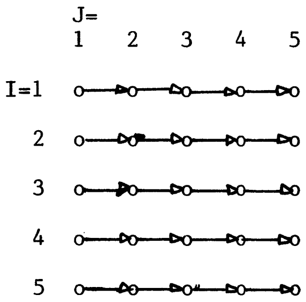

Figure 4.

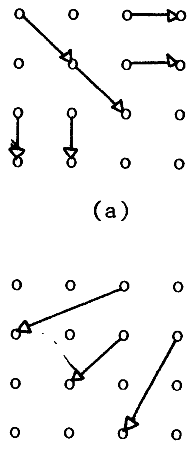

Figure 5.

```
      DO 100 I = 1,N
      DO 100 J = 1,I-1
  100 A(I,J) = A(I,J) + B(I,J)
```

(a)

```
      J=
      1   2   3 ...     N

  I=1

```

(b)

```
      DO 100 J = 1,N
      DO 100 I = J+1,N
  100 A(I,J) = A(I,J) + B(I,J)
```

(c)

Figure 6.

## 2.3 Data Dependence in Triangular Loops

Most triangular loops in real programs, however, are not so easy to interchange. Most triangular loops refer to both the triangle and the diagonal, as in Figure 7(a), or to the triangle and its transpose, as in Figure 7(b). In these cases, the fact that the loop bounds are triangular must be taken into account when the data dependence graph is built. If the inner loop bound were replaced by N in these two loops, for instance, then there would be a data dependence cycle which would prevent the loops from being interchanged. With the upper bound of "I-1", there is no dependence cycle, since J is always less than I for any I. A harder example, from a kernel of a real program, is shown in Figure 8(a). To find the dependence from A(I,J) to A(K,J), the I and K indices must be considered together with the J index, since both I and K are triangular in J.

To handle cases like this, the KAP/Design includes an exact data dependence algorithm; this algorithm either proves that a data dependence relation exists or proves independence, if the following common conditions are satisfied:

1. Loop increments are constant,
2. Array subscripts are a linear expression involving loop index variables and constants, and
3. Loop upper and lower bounds are linear expressions involving outer loop index variables and constants, or are unknown.

When loop bounds are unknown, this test may compute a data dependence relation that does not exist for the loop bounds used in a particular execution of the loop, but the dependence can be proven to exist for some possible values of the loop bounds. The new data dependence algorithm is an extension of the test in [9]. Figure 8(b) shows all the ways to interchange the loop from Figure 8(a), as discovered using this perfect data dependence test.

## 2.4 Trapezoidal Loops Interchanging

The triangular loop bounds shown above actually appear quite often in numerical algorithms. Less frequently, other loop bounds which are functions of outer loops appear; some of these have little hope of loop interchanging, as the one in Figure 9. Others can be interchanged, but not with the simple rules for triangular loops. Such loop bounds may not appear in the original formulation of the algorithm, but may show up after some triangular loops have been interchanged. For instance, the loop in Figure 10(a) is coded with some simple triangular loop bounds.

```
      DO 100 I = 1,N
      DO 100 J = 1,I-1
100   A(I,J) = A(I,J) / A(I,I)
```

(a)

```
      DO 100 I = 1,N
      DO 100 J = 1,I-1
100   A(I,J) = A(J,I)
```

(b)

Figure 7.

```
      DO 100 J = 1,N
      DO 100 I = J+1,N

C
C
      DO 105 K=1,N-1
      DO 105 I=K+1,N
      DO 105 J=K+1,I-1
105    A(I,J) = A(I,J) + A(I,K) * A(K,J)
      END
```

(b)

Figure 8.

After interchanging the DO K and DO J loops, the bounds are modified as shown in Figure 10(b); the inner DO I loop, which was originally triangular with respect to the DO K loop, no longer is. The DO K loop bounds were changed when it was interchanged with DO J. Even through DO I and DO K do not form a triangular loop nest, the loop bounds can be modified to allow the loops to be interchanged; the result is shown in Figure 10(c). Note the use of the MIN function in the upper bound of DO K (had the lower bound needed to be changed, a MAX function would have been used). The iteration space described by the inner two loops of Figure 10(b) (assume that J is fixed) is shown in Figure 10(d); this is a trapezoid. In order to interchange trapezoidal loop bounds, the same type of loop bound modifications as used in triangular loop interchanging is used, except that a MIN or MAX function is used to cut off the point of the triangle and make the trapezoid. The KAP/Design includes triangular loop bound interchanging and trapezoidal loop interchanging; the KAP/Design output for the loop in Figure 10(a) is shown in Figure 11.

```
      DO 100 I = 1,N
      DO 100 J = 1,LP(I)**2
  100  A(I) = A(I) + B(I,J)
```

Figure 9.

```

```

(d)

Figure 10.

3. Imperfectly Nested DO Loops

When imperfectly nested DO loops are to be interchanged, such as the loops in Figure 12(a), the usual process is to distribute the outer loop as in Figure 12(b); this creates perfectly nested DO loops, which can then be interchanged normally, as in Figure 12(c). The iteration space of the original loop can be drawn as shown in Figure 12(d); notice that there are two loop bodies that are important: statement s1, which is enclosed only in the DO I loop, and statement s2, which is enclosed in both loops. The execution order of the iterations is shown. Distributing and interchanging the loops as described modifies the execution ordering to the one in Figure 12(e); instead of execution flowing from left

      END
```

Figure 11.

to right, then top to bottom, it flows from top to bottom, then left to right. This is exactly the same as the modification to the execution ordering for interchanging of perfectly nested loops, as was shown in Figures 2 and 3.

Sometimes, however, the loop distribution that is required by this method is not legal. Take, for example, the loop in Figure 13(a); the value of A(I,K) used in s2 is assigned is sl, and the value of A(I-1,K+1) used in sl is assigned on the previous I iteration in sl. The iteration space dependence graph for this loop is shown in Figure 13(b); distributing the outer DO I loop would violate the data dependence conditions, since all the iterations of sl would be executed before any iterations of s2, changing the value used for A(I-1,K+1). These two loops can be interchanged, however; if the execution of statement sl could somehow be moved so it ran along the DO J axis, then the iteration space dependence graph would be as shown in Figure 13(c). In this iteration space, the DO I loop would have to be the inner loop; this corresponds to the program in Figure 13(d). Notice that not only have the DO loops been interchanged, but the references to the I loop index in sl have been replaced by J.

This type of loop interchanging is legal when no data dependence relations are violated. The data dependence relations that are preserved are:

(a) sl(i)   --> sl(i')      where i<=i'

(b) s2(i,j) --> s2(i',j') where i<=i', j<=j'

(c) sl(i)   --> s2(i',j') where i<=i', i<=j'

(d) s2(i,j) --> sl(i')      where i<i', j<i'

```
         DO 100 I = 1,N
sl:       X(I) = X(I) + 1.
         DO 100 J = 1,N
s2:  100  B(I,J) = X(I) + A(I,J)
```

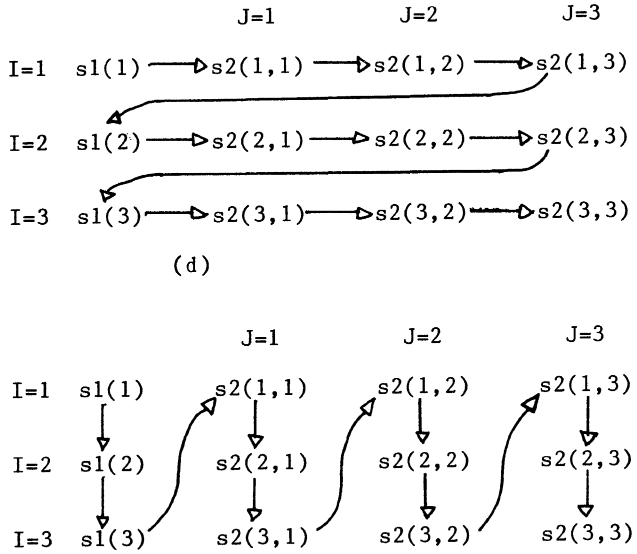
(a)

```
         DO 101 I = 1,N
sl:  101  X(I) = X(I) + 1.
         DO 100 I = 1,N
         DO 100 J = 1,N
s2:  100  B(I,J) = X(I) + A(I,J)
```

(b)

```
         DO 101 I = 1,N
sl:  101  X(I) = X(I) + 1.
         DO 100 J = 1,N
         DO 100 I = 1,N
s2:  100  B(I,J) = X(I) + A(I,J)
```

(c)



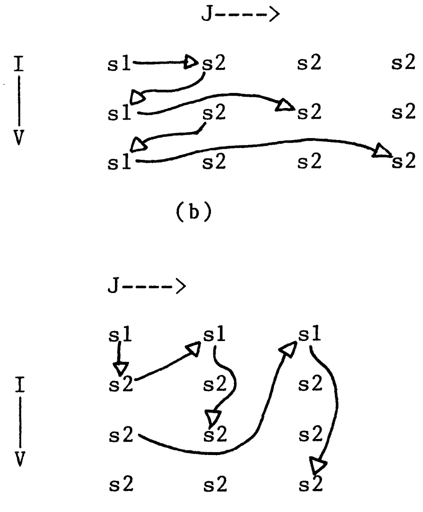
(d)

(e)

Figure 12.

```
         DO 100 I = K+1,N
sl:       A(I,K) = A(I-1,K+1) * A(K+1,K+1)
         DO 100 J = K+1,N
s2:  100  A(I,J) = A(I,J) + A(I,K)*A(K,J)
```

(a)



(b)

(c)

```
         DO 100 J = K+1,N
sl:       A(J,K) = A(J-1,K+1) * A(K+1,K+1)
         DO 100 I = K+1,N
s2:  100  A(I,J) = A(I,J) + A(I,K)*A(K,J)
```

(d)

Figure 13.

Test (a) above is obvious, and test (b) is the same as the test for normal interchanging.

These conditions divide the iteration space into two types of regions, as shown in Figures 14(a) and 14(b). These regions are subsets of each other: R1(2) includes R1(1) and is a subset of R1(3), and so on; for the R2 regions, R2(2) includes R2(3) and is a subset of R2(1), and so on. This new type of imperfectly-nested loop interchanging will preserve dependences in the iteration space dependence graph from s1(k) to any iteration of s2 in region R2(k), and dependences to s1(k) from any iteration of s2 in region R1(k-1). Figures 15(a) and 15(b) shows data dependences in the iteration space that will be preserved by this type of loop interchanging, and Figures 15(c) and 15(d) shows data dependences that will be violated.

Testing for legality of this type of loop interchanging is easier when the loop bounds are triangular, as in Figure 16(a); the iteration space for this loop is shown in Figure 16(b). Since the relation I < J is always true for any iteration of s2 (since the DO J loop starts at I+1), the interchange conditions (c) and (d) above becomes

(c') s1(i) --> s2(i',j') where i<=i'
(since i'<j', i<=i' implies i<=j')

(d') s2(i,j) --> s1(i') where j< i'
(since i<j, j<i' implies i<i')

```
               J---->

             R1(1)| R1(2)| R1(3)| R1(4)...

Figure 16.

A future version of KAP/Design will include interchanging of imperfectly nested DO loops.

In conclusion, loop interchanging is an interesting subject for its own sake. Loop interchanging has many applications in optimizing compilers for high speed computers, and further studies in this field will certainly prove useful in the long run.

# COMPILER GENERATED SYNCHRONIZATION FOR DO LOOPS

*Samuel P. Midkiff and David A. Padua*

Center for Supercomputing Research and Development
University of Illinois at Urbana-Champaign
Urbana, Illinois 61801

Abstract -- This paper presents methods for the compile time generation of synchronization instructions for parallel loops running on a multiprocessor. A synchronization instruction set and architecture are defined, and using these it is shown how to synchronize FORTRAN source loops so that dependences on the parallel loop are enforced. Construction of an applicable dependence graph is covered. A program transformation is given that increases the parallelism that can be utilized in a parallel loop containing nested loops. Finally, a generalizable technique is presented for reducing the number of dependences needing synchronizing in a parallel loop.

## Introduction

When programs are executed on a multiprocessing computer, parallelism can be supported at several levels. The University of Illinois Cedar Project machine [7], the CRAY XMP series [3] (using micro-tasking) and the NYU Ultra-Computer [6] among others allow intra-loop parallelism, i.e. parallelism that exists between different iterations of a loop, to be exploited. This parallelism is realized by allowing different iterations of a loop to run simultaneously on different processors of the multiprocessor. When one iteration of a loop produces data that another iteration uses, or there is a danger of an iteration overwriting data prematurely, it is necessary to constrain the execution order of iterations so that the hazards are avoided. In this paper, we show how this can be done automatically, at compile time, using synchronization instructions. Strategies are presented for the placement of synchronization instructions in a FORTRAN source program loop, to increase the amount of parallelism realized from the source program, and to reduce the amount of synchronization necessary.

It is assumed that programs that are synchronized by the methods presented here have been passed through an automatic program restructurer such as Parafrase [17], [11] and [10]. We do not discuss parallel loop detection, but rather the synchronization of dependences in loops that have previously been recognized as parallel.

Although some of the transformations and optimizations mentioned in this paper are applicable to a wide range of architectures, for brevity's sake we restrict ourselves to a single architecture.

The target architecture, and the sorts of parallelism that can be exploited by it are the first topic of this paper. We then turn to a discussion of *dependences* and *dependence graphs* (DG), which form the basis of the actions of this paper. Since we are concerned only with synchronization within a loop, a DG will be built in turn for each loop to be synchronized in the program. The loop is then transformed, and the next loop in the program is dealt with until the entire program is transformed.

Next we define the synchronization instruction set used, and show how it can be used to synchronize dependences. Because of the semantics of the synchronization instructions, the DG can now be modified to reduce the amount of parallelism in inner loops lost to the synchronization scheme.

After nested loops have been dealt with, the DG is appropriate to guide the generation of synchronization instructions, and we give an example of a loop nest with synchronization instructions added. We can choose, however, to remove from the DG redundant dependence arcs, thereby reducing the amount of synchronization needed. We give a method to reduce the number of dependence arcs, and by examples show its effects on synchronization.

Although we use a single synchronization instruction set in this paper, the methods used can be extended to other instruction sets. In particular, the method presented in this paper for removing redundant dependence arcs is extensible to any architecture.

## Architecture

The architecture of this paper is a multiprocessor. Figure 1 shows a block diagram of the target architecture. Neither processor nor memory modules are distinguishable from their neighbors.

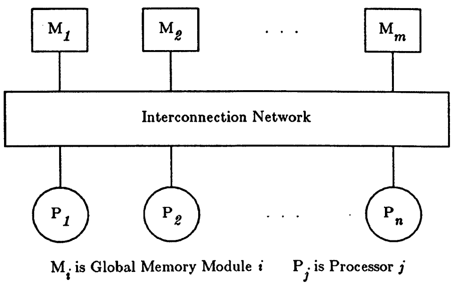

Figure 1. System Architecture

Each memory module is capable of being accessed by any processor through the interconnection network. Access is assumed to be deterministic in that either fetches and stores from a single processor are processed in the order they are issued, This means that either fetches and stores within a processor are done serially, or that an equivalent ordering is imposed on data accesses.

Parallelism is realized by spreading iterations of a loop across multiple processors. A loop so executed will be referred to as a *dospread* loop. All other loops will be referred to as DO loops. A *dospread* loop can be either a *doall* [5], [13], [15], or a *doacross* loop [4], [15], [16]. We place the following restriction on *dospread* loops: they may contain no nested dospread loop. In [14] and [16] algorithms are given for deciding what loop in a nest of potential *dospread* loops should be run as a *dospread* loop.

*Dospread* loop iterations are either spread horizontally [8] across processors or self scheduled. Horizontal spreading means that given $P$ processors, processor $p$ will execute iterations $p, p+P, p+2 \cdot P, \cdots$. Figure 2 shows an example of horizontal spreading on a loop with sixteen iterations. Horizontal scheduling can be accomplished through loop blocking [8]. Self scheduling means that whenever a processor becomes idle it will execute the next iteration of the *dospread* loop.

## Dependences and Dependence Graphs

The restrictions on program execution mentioned previously are necessary to enforce dependences. We now informally define four types of dependences. For more formal definitions and discussion of dependence testing, see [2], [9] and [17]. In the definitions that follow, $S_i$ refers to a statement in the program. If there are two statements, $S_i$ and $S_j$, and $i < j$, then $S_i$ lexically precedes $S_j$.

i *flow* dependence: If data fetched by $S_{si}$ may be generated by $S_{so}$, then a flow dependence exists from $S_{so}$ to $S_{si}$.

ii *output* dependence: If $S_{si}$ may write to some memory location after $S_{so}$ has written to that same memory location, then an output dependence exists from $S_{so}$ to $S_{si}$.

iii *anti* dependence: If $S_{so}$ fetches from a memory location that is may subsequently be overwritten by $S_{si}$, then $S_{si}$ is anti dependent on $S_{so}$.

iv *control* dependence: If whether $S_{si}$ executes depends on the outcome of the execution of $S_{so}$, then a control dependence exists from $S_{so}$ to $S_{si}$.

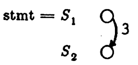
In each of the four cases, $S_{so}$ is called the *source* of the dependence and $S_{si}$ the sink. If the sink of a dependence is after the source, i.e. $so < si$, the dependence is a *lexically forward dependence* (LFD). Otherwise the dependence is a *lexically backward dependence* (LBD).

Dependences extend over zero or more iterations. The number of iterations a dependence extends across is known as the dependence *distance*, $\Delta$ [17]. Figure 0a shows a loop nest. Values of $A$, in $S_1$, written in an iteration are read three iterations later by $S_2$. Therefore a flow dependence exists from $S_1$ to $S_2$, and $\Delta = 3$.

A dependence can be thought of as a relation between two statements. This relation can be represented graphically on a DG, where nodes are statements and a directed arc from $S_{so}$ to $S_{si}$ represents a dependence. The arcs are labeled with the value of $\Delta$ for the dependence. Nested DO loops are considered to be a single statement, and are represented by a single node in the DG. Control cycles caused by backwards GOTOs are also represented by a single node in the DG. Figure 3b gives a DG for the loop of Figure 3a. If two or more dependences, all with the same source and sink, but with different distances, exist, we can remove all the dependence arcs except for the one with the minimum distance. The reason for this is that all arcs but the one with the shortest distance are redundant when using the synchronization instructions of this paper. An example showing this is given in the section Dependence Arc Elimination. An arc is considered redundant if the dependence it enforces will be honored even if it is not explicitly synchronized. What arcs are redundant is dependent on the synchronization instruction set and control structure of the architecture.

```
        DOSPREAD 10 I = 1, N
                A(I) = B(I) + C(I)      S1
                D(I) = A(I-3) + E(I)    S2
10      CONTINUE
```

(a) A Loop Nest



(b) DG for the Loop of (a)

Figure 3. A Loop and Its DG

Dependences can have $\Delta$s that are greater than zero, less than zero, and equal to zero. If $\Delta > 0$, as in Figure 3b, the dependence is from an earlier iteration to a later iteration. If $\Delta = 0$, then the dependence is from the same iteration to a later one. If $\Delta < 0$, the dependence is from a later iteration to an earlier one. This can only happen if the dependence is on a loop nested within another loop. Figure 4a shows such a loop nest, and Figure 4b shows the DG. There are two distances attached to the dependence arc. The first, 1, is the distance of the dependence on the outer $I$ loop and the second, -2, is the distance on the inner $J$ loop.

```
        DOSPREAD 20 I = 1, N
                DO 10 J = 1, N                          L1
                        A(I,J) = B(I,J) + C(I,J)
                        D(I,J) = A(I-1, J+2) - E(I,J)
10              CONTINUE
20      CONTINUE
```

(a) A Loop Nest

(b) The DG for (a)

Figure 4. A Loop Nest with >0 and <0 Dependences

The DG is the major data structure for determining the location of synchronization instructions in a program. For our architecture, when the dependence graph is built only dependences with $\Delta > 0$ are included. $\Delta$ less than zero has to be considered only if two nested loops are to execute as *dospread* loops. Since *dospread* loops cannot be nested, these types of dependences will not need to be synchronized. If $\Delta = 0$, then the dependence is within an iteration. Since data stores and fetches are serial within an iteration, these dependences are forced to be honored by the hardware, and need not be synchronized.

All control dependences have $\Delta = 0$, except for control dependences caused by branches out of the loop, called *exit-if*s. If an exit-if occurs, the loop terminates. Therefore, in loops with an exit-if, each statement of an iteration is dependent on the execution of the exit-if in the previous iteration. Thus a control dependence exists between the exit-if and every statement in the graph. Every dependence arc but the one from the exit-if to the first statement of the loop body is redundant and can be removed. Therefore we only include this dependence arc in the DG. Which exit-if dependence arcs are redundant is strongly dependent on the the control structure of the architecture, so adding only one control arc for an exit-if is not generally valid. Figure 5a shows a loop nest that will be used throughout this paper as an example, and Figure 5b the DG for the loop. Note that a data dependence with distance zero exists from $S_4$ to $S_5$ and is not included on the DG.

## Synchronization Instructions

Three synchronization instructions are needed to synchronize *dospread* loops. We first give the semantics of these instructions, and then show how they are used to synchronize loops. All three instructions operate on a fixed set of synchronization registers accessible to all processors. The synchronization instructions assume that the DO loops being synchronized are normalized [2], i.e. they run from 1 to some upper bound in increments of 1. This can be done automatically.

The *testset* instruction has the syntax *testset*$(r)$, where $r$ is a synchronization register. It performs two functions. The first is iteration. Having done so, it alters the value of *r* to signal later iterations it has executed. Figure 6a gives the semantics of the ***testset*** statement. One important feature of the ***testset*** instruction is that all executions of a ***testset*** after the first, for some synchronization register ***r***, within an iteration, act as no-ops.

```
          DOSPREAD 50 I = 1, N
                  S(I) = S(I) + 1.0                        S1
                  IF (S(I).GT.0.0) GOTO 60                 S2
                  DO 10 J = 1, N                           L1
                          A(I,J) = B(I,J) + C(I,J)
10                CONTINUE
                  IF (D(I).GT.0.0) GOTO 20                 S3
                          E(I) = F(I-1)+G(I)               S4
                          F(I) = E(I) + H(I)               S5
20                CONTINUE                                 S6
                          P(I) = 2.0*P(I)                  S7
                  DO 40 M = 1, 8                           L2
                          Q(I,M) = R(I,M) + A(I-1,M)
                          R(I,M) = Q(I-1,M+2)*2.0

                $r := i$
        else if $r < i - 1$ then
                goto $l$
```

(a) Semantics of the *testset* Instruction

```
        if $i - \Delta > 0$ then
l:      if $r < i - \Delta$ then  goto $l$
```

(b) Semantics of the *test* Instruction

```
l:      if  all iterations $j$, $j < i$, have completed  then
                halt execution of all other processors executing the loop
        else
                goto  $l$
```

(c) Semantics of the *terminate* Instruction

Figure 6. Semantics of the *testset* and *testset* Instructions

The *test* instruction has the syntax $test(r)\ \Delta$. The *test* instruction in an iteration waits until a *testset* instruction has executed $\Delta$ iterations previously.

The final synchronization instruction is the *terminate* instruction. Its syntax is simply *terminate*. Its purpose is to halt execution of a *dospread* loop when an iteration branches out of the loop during execution of an exit-if. The *terminate* waits until all previous iterations of the loop have finished executing, and then halts the execution of the loop. Figure 6c summarizes its semantics.

This instruction set involves several tradeoffs. The primary advantage of the instruction set, as discussed when building the DG, is that dependence distances can safely be assumed to be any distance less than or equal to the minimum distance of a dependence. Therefore, one can always be assumed as the distance of a dependence. This is important for two reasons. First, it allows simpler dependence testing routines to be used. Secondly, in cases where the dependence distance is unknowable at compile time, as with sub-scripted subscripts, the dependence can still be safely synchronized by assuming the dependence distance is one, the minimum distance that the dependence can take.

One disadvantage is that the *testset* instruction partially serializes the loop since each *testset* must wait until a *testset* in the previous iteration has executed. Therefore no loop can execute completely in parallel. This serializing effect, however, has an important advantage. It increases the number of dependence arcs that are redundant. In doing so it allows the aforementioned assumptions to be made about the distance of a dependence.

Another disadvantage is the use of a fixed number of registers. If a loop has more dependences to synchronize than there are registers available, we can be forced to resort to dependence folding [14] to reduce the number of dependence arcs present. Dependence folding usually leads to loops being more serial. Only having a fixed number of registers also causes problems with nested loops, which are discussed later in this section. The advantage of a fixed number of registers is that they can be accessed faster than global memory, and special hardware can be set up, if desired, for accessing these registers, thereby taking traffic off the interconnection network.

We now show how to synchronize LFDs and LBDs using the above synchronization instructions when no nested loops are present in the body of the loop. With any dependence it is necessary that executing the source of the dependence notify the sink, in a later iteration, that it can execute. It is also necessary that the sink of a dependence wait until notified that its source has executed. With an LFD this is simple. If a *testset* is placed after the source of the dependence, and before the sink of the dependence, the dependence will be enforced.

For example, consider the loop in Figure 7a, and its DG in Figure 7b. The dependence from $S_1$ to $S_2$ extends over two iterations. Figure 7c shows a *testset* placed between $S_1$ and $S_2$. Before the sink of a dependence executes in iteration $i + 2$ the *testset* preceding it must complete execution. The *testset* in iteration $i + 2$ cannot execute before the *testset* in iteration $i + 1$, which, in turn, cannot execute before the *testset* in iteration $i$. The *testset* in iteration $i$ cannot execute, however, until the source of the dependence in iteration $i$ has executed. Thus the dependence is forced to be honored.

```
          DO 10 I = 1, N
                  A(I) = B(I) + C(I)         S1
                  D(I) = E(I) + A(I-2)       S2
10        CONTINUE

                  A(I) = B(I) + C(I)         S1
                  testset(1)                 TS1
                  D(I) = E(I) + A(I-2)       S2
10        CONTINUE
```

(c) The Loop Nest of (a) Synchronized

Figure 7. Synchronizing a LFD

To synchronize a LBD, such as is seen in Figure 8a, a *testset* is placed after the source of the dependence to signal that the source has executed in this iteration. A *test* is then placed before the sink of the dependence. Thus the sink of the dependence cannot execute until after the source, since the *test* instruction will not finish executing until after the *testset* following the source has completed. Figure 8c shows the synchronized loop.

```
        DO 10 I = 1, N
                A(I) = B(I) + D(I-2)    $S_1$

                A(I) = B(I) + D(I-2)    $S_1$
                D(I) = E(I) + A(I)      $S_2$
                testset(1)              $TS_1$
10      CONTINUE
```

(c) The Loop Nest of (a) Synchronized

Figure 8. Synchronizing a LBD

If control branches are present in the *dospread* loop further actions must be taken. In particular, we must insure that a *testset* be executed for every register used in the loop, on every iteration of the loop. Consider again the loop nest of Figure 5. To synchronize the LBD from $S_5$ to $S_4$ a *testset* would be placed between $S_5$ and $S_6$. If the IF statement at $S_3$ takes the true branch, then the *testset* would not be executed on that iteration. The *testset* of the next iteration in which the false branch of the IF is taken would then deadlock waiting for its synchronization register to be updated. Therefore a *testset* should be placed along the flow of control path through the loop containing the true branch.

This problem is handled as follows. The loop is broken up into basic blocks, (BAS) [1], and a flow of control graph [1] is built that represents the control structure of the program. This graph can be represented by a matrix $reach(i, j)$, such that $reach(i, j) =$ **true** if an arc from $BAS_i$ to $BAS_j$ is in the flow of control graph. The $(i, j)$ element of the transitive closure of *reach*, $reach^*(i, j)$, is true if a path exists from $BAS_i$ to $BAS_j$.

Each arc in the DG is handled in turn. A *testset*, $TS_{so}$, is placed after the source of the dependence. At each branch, *reach* can be checked to see if any target of the branch is the block containing $TS_{so}$. If this is so, every other target BAS of the branch is checked (using $reach^*$) to determine if it can also reach the block containing $TS_{so}$. If it cannot, a *testset* is placed in that BAS. Thus every branch that can reach $TS_{so}$ must either reach the original *testset* or an added *testset*, and deadlock cannot occur.

Two other flow of control problems remain: the presence of nested DO loops within the *dospread* loop, and exit-ifs. The former case is handled in the next section. We deal with the latter case now.

Consider the exit-if of statement $S_2$ in Figure 5. The control arc from $S_2$ to $S_1$ forms a LBD that will cause *test*(1) 1 to be placed before $S_1$, and *testset*(1) to be placed after $S_2$. The *test* instruction will wait until the *testset* in the previous iteration has executed before allowing $S_1$ to execute, and the *testset* will not execute if the exit branch of the exit-if is taken. If the exit branch is taken in iteration $i$, all iterations less than $i$ must be allowed to finish, and the deadlocked iterations greater than $i$ must be terminated.

To halt the loop, a block of code is added to the loop that executes a *terminate* instruction. As will be seen, placement of this block is unimportant but in this paper it will be added to the end of the loop. For every exit branch to some label $l$, the block:

```
$l'$      terminate
          GOTO $l$
```

is added to the loop, and all branches to $l$ in the loop are changed to branches to $l'$. The *terminate* instruction checks if all iterations of the loop less than the current one have finished. If so, it halts all processors executing the loop and the GOTO makes the exit branch. To prevent other statements in the loop from falling through to this added block, a GOTO to the CONTINUE at the end of the *dospread* loop is added immediately before the *terminate* instruction. Figure 9 shows the program with these statements added.

```
        DOSPREAD 50 I = 1, N
                test(1) 1                               $T_1$
                S(I) = S(I) + 1.0                       $S_1$
                IF (S(I).GT.0.0) GOTO 61                $S_2$
                testset(1)                              $TS_1$
                DO 10 J = 1, N                          $L_1$
                        A(I,J) = B(I,J) + C(I,J)
10              CONTINUE
                IF (D(I).GT.0.0) GOTO 20                $S_3$
                        E(I) = F(I-1)+G(I)              $S_4$
                        F(I) = E(I) + H(I)              $S_5$
20              CONTINUE                                $S_6$

60      CONTINUE
```

Figure 9. Loop Nest with Exit-if Synchronized

## Nested Loops

If the source and sink of a dependence are both within the same nested loop, the dependence forms a self cycle on the DG node representing the loop. $L_2$ in the DG of Figure 5b is an example of this. This loop is reproduced in Figure 10a If a *test* is placed before the loop, and a *testset* is placed after the loop, the loop forms a large chunk of serial code in the *dospread* loop. It is therefore desirable that some parallelism be extracted from this nested loop. Figure 10b gives the iteration space [17] for this loop nest. Each node in the iteration space represents an iteration of the loop, and arcs represent dependences from iteration to iteration. Dependences on the $M$ loop span two iterations of the $M$ loop, while dependences on the *dospread* loop span one iteration. Our goal is to allow some iterations of $L_2$ in iteration $i + 1$ of the *dospread* to execute before all iterations of $L_2$ execute in iteration $i$ by placing synchronization instructions so that dependences on both the *dospread* and $L_2$ loops are satisfied.

To do this a transformation called *loop splitting* is performed. Loop splitting breaks the inner loop into $n$ different sub-loops, and places synchronization instructions between the sub-loops. Each sub-loop executes a contiguous set of iterations from the original loop. Thus if the $M$ loop of our example is broken into four sub-loops, the first would run from 1 to 2, the second from 3 to 4, the third from 5 to 6 and the fourth from 7 to 8. Each sub-loop contains two iterations, therefore if the first sub-loop of iteration $i$ of the *dospread* loop waits until the second sub-loop in the previous iteration of the *dospread* loop has executed, dependences to it will be honored. That this is true can be seen by examining the sources of dependences in the iteration space diagram that have their sinks in the second sub-loop. The second sub-loop must wait until the third sub-loop of the previous iteration has finished, and the third sub-loop must wait until the fourth sub-loop of the previous iteration has finished. The fourth sub-loop contains no dependence sinks whose sources are in other sub-loops, therefore it does not need to wait on any other sub-loop. These dependences can be detected by splitting the inner loop and recomputing the dependences between the sub-loops. The synchronization of these dependences will give the execution ordering specified above.

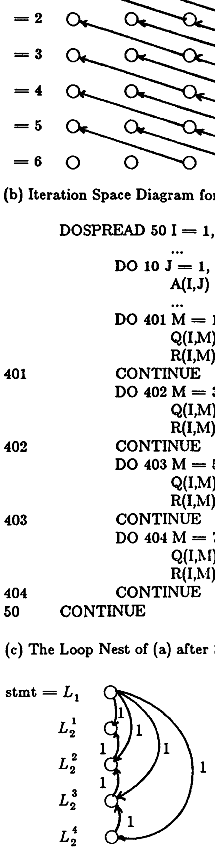
(c) The Loop Nest of (a) after Splitting



(d) DG for the Split Loop

Figure 10. A Loop Splitting Example

When this synchronization has taken place, the execution of the third and first, and fourth and second sub-loops of adjacent iterations of the *dospread* loop can overlap, salvaging some of the parallelism present before loop spreading.

The only other problem that remains is what to do with dependences whose sources are outside the loop being split, but whose sink is in the loop being split, or whose sink is outside the loop being split but whose source is the CONTINUE statement of the loop being split. The dependence should be replicated over every copy of the loop created by loop splitting. The dependence routines used to build the original DG should then be queried to see if the dependences exist to or from each sub-loop of the split loop. If the dependence no longer exists to or from a particular sub-loop, it should be removed from the DG. In our example, the dependence does exist to every sub-loop.

Figure 10c shows the $M$ loop split, and Figure 10d shows the DG for the loop nest with dependences resulting from loop splitting added.

In [14] a method is given for determining analytically the placement of dependences for split loops as a function of the maximum dependence distance on the split loop and the minimum number of iterations in a sub-loop.

## Dependence Arc Elimination

After nested loops have been taken care of, as in the previous section, synchronization instructions can be inserted into the source program using the methods of the second section. Adding synchronization instructions now can result in more instructions being added than is necessary to insure the legal execution of the program. We now discuss a method of reducing the number of dependences needing synchronization in a DG. As the number of dependences needing synchronization is reduced, the amount of synchronization added to the loop is reduced, and consequently the overhead associated with synchronization is reduced. The goal of dependence arc elimination is to determine what dependences are redundant, i.e. what dependences are implicitly synchronized by a combination of the control structure of the architecture and the synchronization of other dependences. Related work in this area is discussed in [12].

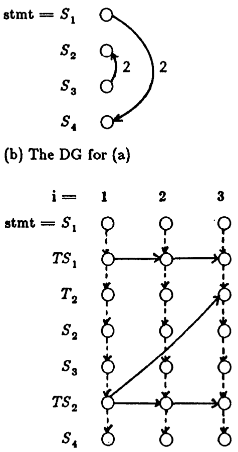
We present our dependence arc elimination method with the instruction set defined in this paper in mind. The technique is usable, however, with a wide range of architectures. Details of this are given in [14].

A dependence arc can be eliminated if a combination of the control structure of the target architecture, and synchronization added for other dependences, force the dependence to always be synchronized. To eliminate a dependence arc, a simple way of representing the total control structure of a loop nest is required. We use a *controlled path graph*, or CPG, to give this representation. A CPG contains nodes, each of which represents a *statement instance*. A statement instance is the occurrence of a statement within an iteration of the *dospread* loop. At least a source and sink of any dependence arc to be eliminated must be included in the CPG. Thus, if $\Delta_{max}$ is the longest distance of any dependence in the *dospread* loop, the CPG must contain at least $\Delta_{max} + 1$ iterations (columns). That no more columns than this are needed is proven in [14]. Arcs in the CPG represent the execution order of the statement instances: the statement instance at the head of an arc will execute after the statement instance at the tail of an arc.

Figure 11a gives a *dospread* loop without branches and with synchronization instructions added. Figure 11b gives the DG for the loop that led to this synchronization, and Figure 11c gives the CPG for this loop. The dashed lines in the CPG represent control exercised over the program execution by the architecture. As stated before, statements within a single iteration execute serially on a single processor. Each statement within an iteration must execute after the previous statement in that iteration, and therefore is at the head of an arc whose tail is the previous statement. Next, we know a *testset* on a certain register must follow the *testset* on that same register in the previous iteration. Therefore an arc is drawn from each *testset* in the first iteration to the *testset* in the second iteration using the same synchronization register. Finally, we know that a *test*($r$) $\Delta$ instruction must follow the *testset* instruction $\Delta$ iterations back. Therefore we draw arcs from each *testset* to its corresponding *test*, if one exists.

```
        DOSPREAD 10 I = 1, N
            A(I) = B(I) + C(I)          S1
            testset(1)                  TS1
            test(2) 2                   T2
            B(I) = A(I) + E(I-2)        S2
            E(I) = D(I) + F(I)          S3
            testset(2)                  TS2
            F(I) = A(I-2) + E(I)        S4
10      CONTINUE
```

(a) A DOSPREAD Loop



(b) The DG for (a)

(c) The CPG for the (a)

Figure 11. Example of a CPG

Constructing the CPG is the architecturally dependent portion of this method. If it is desirable to do dependence arc elimination with another architecture, all that is necessary is that the dashed arcs accurately reflect the control exercised by the target architecture, and that arcs are added to reflect the effects of synchronizing the loop.

Deciding if an arc should be removed from the DG is trivial once the CPG has been built. We need only to find a path from the source to the sink of the dependence in the CPG without using any arcs in the CPG that result from synchronizing that dependence. It is possible to eliminate the dependence arc since if a path exists through the CPG from the source to the sink of the eliminated dependence, then the sink of the dependence must execute after the source of the dependence without explicitly synchronizing the dependence.

The dependence arc from $S_1$ to $S_4$ can be removed from the DG for this loop. Starting at $S_1$ in iteration one, $TS_2$ in the same iteration can be reached. Its arcs can be followed to $TS_2$ in iteration 3, and from there the dotted lines can be followed to $TS_4$ in iteration 3. Therefore we can travel from the source to the sink of the dependence without going through any arcs resulting from $TS_1$, which synchronize the dependence whose arc is being eliminated.

After deciding that an arc can be removed from the DG, we do so. As well, all nodes in the CPG used to synchronize the arc are removed, and the arcs associated with them are removed. This insures that the dependence arc just removed is not used to eliminate any other dependence arc.

We give another example that shows that only the dependence arc with the minimum distance needs to be retained when two or more dependence arcs with different distances exist between two statements. Figure 12a gives a loop nest with both dependences from $S_2$ to $S_1$ synchronized. Figure 12b gives the CPG for this loop nest. The *testset* and *set* on register 2 synchronizes the dependence of length two, while the *testset* and *test* on register 3 synchronizes the dependence of length three. Starting at $S_2$ in iteration one, the dashed arcs can be traveled to reach $TS_2$. The arc leaving $TS_2$ in iteration one, and traveling to $TS_2$ in iteration two is taken, followed by the arc to $T_2$ in iteration three. From there the dashed arcs can be taken to $S_1$ in iteration three, showing that the dependence arc with distance three can be eliminated.

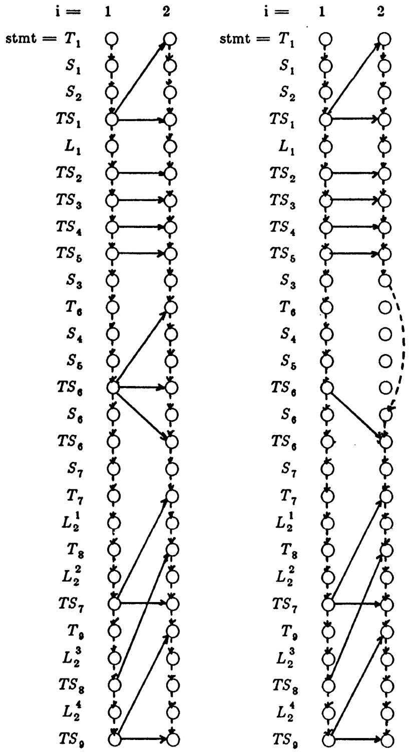
different iterations. The first assumes that the false branch of the IF of $S_3$ is taken in both iterations. The second assumes that the false branch is taken in the first iteration, and the true branch is taken in the next iteration. The third assumes that the true branch is taken in the first iteration, and the false branch is taken in the second. Finally, the fourth assumes that the true branch is taken in both iterations. The CPGs are built the same as when no flow of control branches are present with two exceptions. When a statement is a branch, an arc is only placed from the branch to the statement that will execute after the branch, and not to every target of the branch. Finally any synchronization instruction that is not executed in the flow of control path for an iteration does not have any synchronization arcs coming in or going out of it.

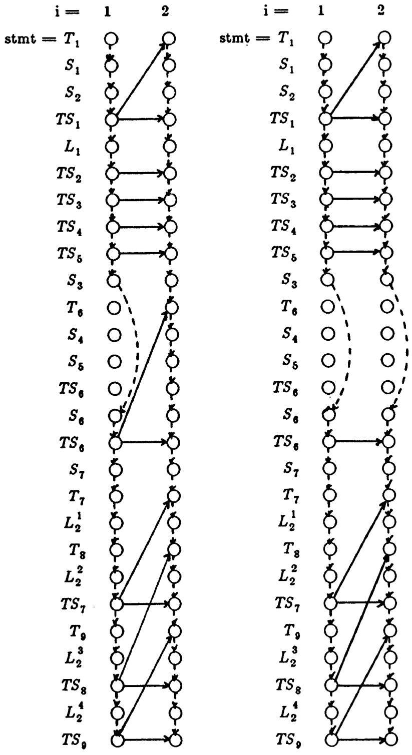


(b) CPGs for (a)

Figure 13. Continued

Eliminating a dependence arc is the same as with the CPG of Figure 11c except that it is necessary to find a path through every CPG constructed for the loop. This is necessary since the dependence arc must be redundant regardless of the flow of control path taken through the graph. It is possible to eliminate the dependence arc since if a path exists through all the CPGs, then the sink of the dependence must execute after the source of the dependence, without synchronizing the dependence, regardless of what branches are taken.

Consider, as an example, the dependence from $L_1$ to $L_2^4$, synchronized by the *testset* instruction, $TS_5$. Using the arcs in the CPGs provided by $TS_2$, and the architecturally dependent arcs, we can travel from the source to the sink of the dependence without using any arcs supplied by the $L_1$ to $L_2^4$ dependence, in this case those arcs connecting $TS_5$. Therefore we can eliminate this arc from the graph, since it is synchronized by other arcs. As each arc is eliminated in the DG, the corresponding synchronization instruction nodes in the CPG are eliminated so that they are not used when eliminating other dependence arcs. Likewise, the arcs representing dependences from $L_1$ to $L_2^3$ and $L_1$ to $L_2^2$ can be eliminated.



(c) CPGs for (a)

Figure 13. Continued

The dependence arc in the DG from $L_1$ to $L_2^1$ is eliminated by the backward dependence from $S_5$ to $S_4$, and the arcs provided by its *testset*, $TS_6$. After this arc is eliminated from the DG, no more arcs can be eliminated. Figure 14a shows the DG after dependence arc elimination, and Figure 14b shows the synchronized program after dependence arc elimination.

         ...
60       CONTINUE
```

(b) Loop of Figure 5 Synchronized

Figure 14. Continued

Finding a path through all the CPGs for a loop is necessary and sufficient for eliminating a dependence arc. This is proven in [14]. It is also shown in [14] that dependence arc elimination is NP-hard, and a polynomial time algorithm for dependence arc elimination in loops without control branches is given. An exponential algorithm is given for loops with control branches. The exponential nature of the algorithm is shown to be not too bad in practice because of the small number of branches and the short dependence distances present in most loops.

If one is willing to not eliminate as many dependence arcs as possible, an easy but conservative approach is possible. By putting in arcs representing control exercised by the architecture only for non-branching statements, it will not be possible to go from the source to the sink of a dependence that is separated by a control flow branch. This means only dependences whose sources and sinks lie within a basic block will be eliminated. Therefore, only one CPG can be built and the dependence elimination can be done in polynomial time. Using this method, the dependence arcs from $L_1$ to the $L_2$ sub-loops would not have been eliminated in the example of Figure 13.

## Conclusions

We have shown that the automatic generation of synchronization instructions is not only practical, but straightforward. Many of the techniques discussed in this paper have been implemented in a pass for the Parafrase program restructurer, demonstrating their practicality. We have also shown that a set of synchronization primitives that allows fairly primitive dependence testing to take place can be used effectively to synchronize DO loops.

Several of the techniques discussed can be easily extended to other instruction sets. The algorithm used to place *testset* instructions can be used with any set instruction. The method of dependence arc elimination we have discussed can be immediately extended to most if not all architectures by modifying the placement of arcs in the CPG. Finally, loop splitting can be used effectively with any instruction set in which the number of synchronization registers is limited.

# EFFICIENT EXECUTION OF PROGRAMS WITH PIPELINE CONFIGURATION OF A RECONFIGURABLE MULTIPROCESSOR*

Karam Mossad and Chuan-lin Wu

Department of Electrical and Computer Engineering
The University of Texas at Austin
Austin, Texas 78712

Abstract -- In this paper we introduce a program graph model for sequential programs. We then present two algorithms which can assign any program graph to be executed on a pipeline configuration having the minimum number of processors of a reconfigurable multiprocessor. We show that the time complexity of these algorithms is polynomial for large and practical classes of program graphs that include r-ary trees and serial/parallel graphs. We conject that the problem of assignment is NP-complete. Consequently, the complexity of the algorithms is the best that one can hope to achieve.

## 1. INTRODUCTION:

One of the main reasons of not being able to achieve the potential gain of concurrent and parallel systems is that the architecture is not well matched to the application of interest or vise versa [1]. In this paper an effort is made to match the sequential programs to a pipeline configuration of a reconfigurable multiprocessor [2]. The reconfigurable multiprocessor can be reconfigured to connect processors into commonly used topologies such as pipeline, tree, mesh, loop, and their composite [3]

There will be a transition from the normally known pipeline architecture [4,5,6] to a new one which will be called program pipelines, in which, each stage will be a processor, or many processors. To execute a sequential program concurrently on a program pipeline, the program is divided into a sequence of blocks. Each block is executed by one stage of the pipeline. It is assumed that the program will be executed frequently, and hence a reduction of total execution time will result if compared to the total execution time of the same program on a uniprocessor. A compiler program is a practical example which can be divided and which can repeatedly receive compilation tasks [7,8].

## 2. PROGRAM GRAPH MODEL

Definition 1:

An acyclic directed graph G is called Program Graph iff the following three conditions are satisfied:

1) Exactly on node in G has no in going edges; this node is called the entry node of G
2) Every node in G is reachable by a directed path from the entry node
3) Every node V in G is assigned a positive integer d(V) called the delay of node V

Definition 2:

Let G be a program graph. The delay of G, denoted d(G), is as follows:

$d(G) = \max [d(V_1), d(V_2), \ldots.., d(V_n)]$, such that V is in G.

Definition.3:

A program graph is called linear iff it consists of only one directed path.

Definition 4:

A linear program graph is called a pipeline with delay K iff for every node V in the graph, d(V) = K.

Definition 5:

Let G be a program graph and P be a pipeline with delay K. An assignment f of G into P is a function that assigns each node V in G to a node f(V) in P such that the following two conditions are satisfied:

1) For every two distinct nodes V and V' in G, if there is a directed path from V to V' then either f(V) and f(V') are the same node in P or there is a directed path from node f(V) to node f(V') in P.
2) The max value in the set

$\{ \sum_1^r d(V_1)\ V_1, \ldots\ldots V_1$ constitute a directed path in G,

and are assigned to the same node in P} is at most K, the delay of P.

The next lemma follows immediately from the above definitions.

Lemma 1:

If there is an assignment from a program graph G into a pipeline P, with delay K, then $d(G) \leq d(P)$, i.e., $d(G) \leq K$..

**Problem:** It is required to design an algorithim that takes any program graph G and any positive integer K, where K $\geq$ d(G), then defines a pipeline P with delay K and an assignment f of G into P such that the number of nodes in P is minimum.

Let us comment on the fact that our model program graph does not allow cycles, while sequential programs do have cycles. If a sequential program has a cycle, as shown in Fig. 1 - a as an example, then its execution can be pipelined only if there is an upperbound on the number of times the cycle is to be executed. In this case, we suggest two solutions on how to represent a cycle in our program graph model as follows:

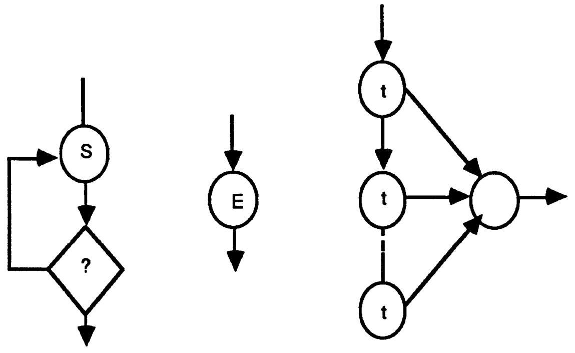
1 Collapse the cycle into one node in the program graph model. The execution time of the node equals t x s, where t is the time to execute the cycle once, and s is the upper bound on the number of times the cycle is executed. Collapsing is as shown in Fig. 1 - b

2 Unfold the cycle into a sequence of s nodes, each with execution time t, in the program graph model. Where t and s are as defined above. Unfolding is as shown in Fig. 1 - c.

Notice that the first solution will produce a program graph with a smaller number of nodes but the execution time of such nodes is bigger than those in the second solution.

An efficient assignment of linear program graphs into pipelines is given in the next section.

Fig. 1. Cycle Problem Solution



a) Cycle b) Collapsing method c) Unfolding method

## 3. EFFICIENT ASSIGNMENT OF LINEAR PROGRAM GRAPHS INTO PIPELINES:

In this section, we present an algorithm that takes any linear program graph G, and a positive integer K, where d(G) ≤ κ, then computes:

a) The minimum number p of nodes in a pipeline P with delay K such that there is an assignment of G into P, and
b) The assignment function F: G ------>P

Algorithm 1:

```
Input: G and K (as defined above)
Output: An integer p, and an array f (as defined above)
Variables:
    sum: integer;
    Node: (1, . . . . . ,g, g + 1)
Steps: node: = 1;
       p: = 0;
       While node ≤g
       do  p = p + 1;
           sum: = 0;
           While  node ≤ g and sum + d(node) ≤ K
              do  f [node] : = P;
              sum: = sum + d (node);
              node: = node + 1
              endwhile
          endwhile
End of Algorithm 1
```

The following theorem estabishes the correctness of Algorithm 1

Theorem 1:

Let G be any linear program graph, and K be any positive integer such that K ≥ d(G). And let p and f be the output of applying Algorithm 1 to G and K:.

a) f is an assignment of G into a pipeline with delay K that has p nodes.
b) If there is an assignment of G into a pipeline with delay K, then this pipeline must have at least p nodes.

## 4. EFFICIENT ASSIGNMENT OF GENERAL PROGRAM GRAPHS INTO PIPELINES:

We present in this section an algorithm that takes any (general) program graph G, and a positive integer K, where d(G) ≤ K, then computes:

a) The minimum number p, of nodes in a pipeline P with delay K such that there is an assignment of G into P, and
b) An assignment f of G into P.

Algorithm 2:

```
Input:  G and K (as defined above)
Output: An integer p, and an array f (as defined above)
Variables:
        node: (1, . . . . . ,g)
Steps:
    1.  p: = O
    2.  for node = 1 (1, . . . . . ,g) do f [node]: = O endfor
        3.  for each complete path T in G do
            *  Recall that T is in fact a linear
            *  Program graph
               a) Apply algorithm 1 to T and K, and let the
                  output be q and h respectively.
            *  By theorem 1, q is the minimum number
            *  Of nodes in a pipeline Q with delay K
            *  Such that there is assignment h of
            *  T into Q.
               b) p: = max (p,q)
               c) for every node in T do
                     f [node]: = max (f [node], h [node])
        endfor
    endfor
```

The following theorem estabishes the correctness of Algorithm 2

Theorem 2:

Let G be any linear program graph, and K be any positive integer such that K ≥ d(G). And let p and f be the output of applying Algorithm 2 to G and K.

a) f is an assignment of G into a pipeline with delay K that has p nodes.
b) If there is an assignment of G into a pipeline with delay K, then this pipeline must have at least p nodes.

## 5. TIME COMPLEXITY ANALYSIS:

In this section we present some results concerning the time complexity of algorithms one and two. In particular we show that:

1) Algorithm 1 has a linear time complexity.
2) Algorithm 2 has a polynomial time complexity for large (and practical) classes of program graphs.
3) Algorithm 2 has an exponential time complexity in general.

Theorem 3:

The time complexity of Algorithm 1 is 0(n), where n is the # of nodes in the linear program graph G.

Next we discuss the complexity of Algorithm 2 for some practical classes of program graphs, namely, and serial parallel graphs.

Definition 6: An r-ary tree is a directed rooted tree where each nonleaf node has at most r children.

Definition 7: A serial/ parallel graph is a program graph that has one entry node, one exit node, and a block in between as shown in Fig. 2, where a block is defined recursively as follows:

1) One node as shown in Fig. 3 a
2) One node followed by a block as shown in Fig. 3 b, or
3) One node that branches to two blocks as shown in Fig. 3 c

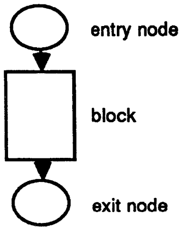


Fig. 2 serial/parallel graph

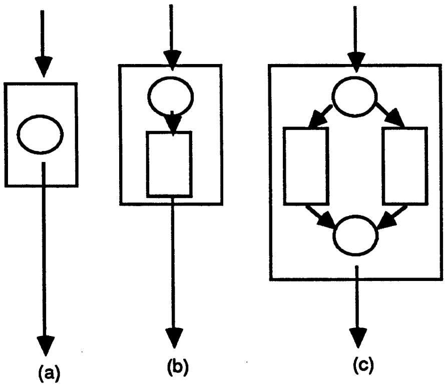

Fig. 3 The recursive definition of a block

Corollary 1:

The time complexity of Algorithm 2 is

$0 ( 1/r [n (r - 1) + 1] \log_r [n (r - 1) + 1])$ i.e.

$0 (n \log_r n )$ when applied to

program graphs in the shape of an r - ary tree with n nodes.

Corollary 2:

The time complexity of Algorithm 2 is $0 (n^2)$ when applied to a program graph in the shape of a serial/parallel program graph with n nodes.

Unfortunately, the time complexity of Algorithm 2 is not always polynomialas demonstrated by the following theorem.

Theorem 4:

There is a class of program graphs, namely, complete acyclic, for which the time complexity of Algorithm 2 is exponential.

## 6. CONCLUSION:

The execution of sequential programs can be speeded up by executing them on reconfigurable architecture. Specifically, we have introduced a program graph to model sequential programs and presented two algorithms which can be used to assign any program graph to a pipeline having the minimum number of processors. We proved the correctness of both algorithms and discussed their time complexity. The complexity analysis showed that the complexity of Algorithm 1 is linear, and the complexity of Algorithm 2 is polynomial when applied to program graph on the shape of r-ary trees or serial/parallel graphs. It is, also, shown that there exists a class of program graphs for which the complexity of Algorithm 2 is exponential. We suspect that the problem is NP - complete in general, and if it is so, then the time complexity of Algorithm 1 and 2 is the best that one can hope to achieve.

# SIMULTANEOUS BROADCASTING IN MULTIPROCESSOR NETWORKS

*K. N. Venkataraman*
*George Cybenko*
*David W. Krumme*

Department of Computer Science
Tufts University
Medford MA 02155

## Abstract

The problem of *simultaneous broadcasting* in multiprocessor networks is studied in this paper. This problem, in which every processor has a token that must be broadcast to every other processor in the network, arises in the development of applications programs for multiprocessor networks. The main result of this paper is that the optimal algorithm for the token broadcast problem (under a restricted model of communication) for a complete graph network with N processors runs in $\lceil 1.44 \log_2 N + 4 \rceil$ steps. It is also shown that the same problem can be solved on a hypercube in $\lceil 2 \log_2 N \rceil$ steps.

## 1 Introduction

In writing applications programs to run on the INTEL iPSC/d5 hypercube multiprocessor [2], we have found a number of uses for the following construct. Every processor has a token that must be broadcast to every other processor and these tokens can be combined so that the effective size of combined tokens is the same as the size of the original tokens. This assumption that tokens can be combined applies where communication or packet-size overhead is the dominating factor; or where tokens can be combined arithmetically or otherwise. This construction is useful for synchronizing the starting times of the actual applications code on all processors for accurate timing measurements. Another equally important use for such a construct is in the computation of a global sum where each processor is storing one of the summands and the sum must be computed and communicated to all processors. This situation has arisen, for example, in sparse eigenvalue and linear equations solving techniques with which we have been experimenting [1]. In general, the communications requirements demanded by this problem are necessary and sufficient to evaluate any function of all the tokens at all of the nodes in the network, and the assumption that tokens can be combined yields a simple yet reasonable abstraction of the problem.

Using realistic models for interprocessor communication in a local memory, message passing multiprocessor network, we have studied good and optimal algorithms for performing this task on hypercubes and other multiprocessor networks. It appears that the minimal time parallel algorithm for solving this global token passing problem provides a useful criterion for evaluating a multiprocessor network topology. It is quite distinct, as our examples show, from previously used characteristics such as diameter, girth, density and connectivity [7].

## 2 Token Broadcast Problem

In this section we shall state our version of the *token broadcast problem* and the two different models of communication that we shall focus on in this paper.

**Definition:** Given a network N, specified by the interconnection graph G=(V,E), and a token $t_i$ associated with each of the nodes $p_i$, $1 \le i \le n = |V|$, the *token broadcast* problem is that each node should broadcast its token to all the other nodes in G and as a result at the end of the broadcast each node should contain the tokens $t_1, \cdots, t_n$.

This version of the broadcast problem is different from the *routing problems* that have been studied [3,4,8,10]. We require that all tokens be available at all of the nodes at the end of the broadcast.

We are interested in efficient algorithms for solving the broadcast problem for different interconnection graphs that have been proposed [7,8,9]. In the current paper we shall focus our attention on the *hypercube* and the *complete graph.* We shall investigate the algorithms for the broadcast problem under the two models of communication described below. In both the models we assume that it takes the same amount of time to transmit one token or a collection of tokens across the communication link from a node to its neighbour and we shall use that measure as our unit of time. This assumption is realistic to a large extent on the INTEL iPSC multiprocessor system due to packet-size effects and further, makes it easier to analyze the properties of optimal algorithms for the broadcast problem.

**Model A:** In each step of the computation, messages can be transmitted on any links but only in one direction along each link in the network. In other words, any number of edges can be active but each edge can be used only in one direction at a given step. This is a good model of

This work was partially supported by NSF Grant DCR-8505634 and US-Spain Joint Committee for Scientific and Technological Cooperation Grant CCA8411019.

certain architectures, including the iPSC, if one assumes that actual communication time dominates.

**Model B:** In each step of the computation, a processor can either receive a message from one of its neighbours or send a message to one of its neighbours. In effect, in a given step at most half the processors communicate with the other half. This model describes virtually any architecture under the assumption that the overhead or setup time at each node is great compared with the actual communication time. On the iPSC, this is often the best model.

For an architecture like that of the Ncube [5] with bidirectional channels, a bidirectional version of model A could apply, and in that case the graph-theoretic questions that we ask have easy answers, while model B if appropriate would still most naturally use unidirectional communication.

## 3 Optimal Algorithms for Complete Graphs

In this section we shall study the token broadcast problem for the complete graph interconnection pattern. We will present an algorithm for each of the communication models and we will also show that the algorithms are optimal in terms of number of steps.

It is easy to see that we can solve the problem in two steps under model A. We pick a distinguished node $p$ and in the first step, every node (except $p$) sends its token to $p$ and in the second step $p$ sends all the accumulated tokens to each of the other processors. It is also clear that this algorithm is optimal in terms of number of steps.

For model B, we shall first establish a lower bound on the number of steps and then present an algorithm which runs at that speed. Let us assume that there are $N = 2^d$ nodes in the network. We shall introduce a measure on the amount of information at a given node and study the maximum rate of growth of the total information over all the nodes in the network. At first, one may try the number of tokens $\nu_i$ at processor $p_i$ as a measure of information content at that processor with $\Sigma_{i=1}^{n}\nu_i$ being the total information over all the nodes in that network. A simple analysis shows that the maximum rate of growth of information is 2 and the resulting lower bound on the number of steps is $d$. Instead, let us use $\nu_i^k$ as the measure and find that $k$ which will give us the best lower bound. A careful analysis shows that $k = 2$ is the best choice; given $k = 2$ a straightforward calculation establishes the following theorem.

**Theorem 1:** For a network of N processors whose interconnection pattern is a complete graph, any algorithm that solves the token broadcast problem under model B takes at least

$$\left( \frac{\log_2 N}{\log_2(\frac{1+\sqrt{5}}{2})} \right)$$

steps. (This translates to roughly 1.44 $\log_2 N$ steps.)

The following theorem shows that the lower bound is actually matched by the optimal algorithm to the broadcast problem.

**Theorem 2:** There exists an algorithm that solves the token broadcast problem under model B for a network of N processors whose interconnection pattern is a complete graph in

$$\left\lceil \frac{\log_2 N}{\log_2(\frac{1+\sqrt{5}}{2})} \right\rceil + 4$$

steps.

*Proof:* The general description of the actual algorithm which achieves this bound is as follows. After $k \geq 2$ steps of the algorithm half the number of nodes have accumulated $2 \cdot fib(k)$ tokens and the other half have accumulated $2 \cdot fib(k-1)$ tokens where $fib(k)$ is the $k^{th}$ element in the *Fibonacci* sequence with $fib(0) = 0$ and $fib(1) = 1$ . At each step, the nodes with larger number of tokens send their tokens to the other half of the nodes; care should be taken so that the tokens that a node receives is disjoint from the tokens that it already has. The actual protocol is given below.

We assume $N$ is even; if not, choose any one node and send its token to another site, solve the problem on all nodes but the one, and lastly send from some site to the chosen node. Let $n = N/2$ and label the nodes $p_0, p_1, \cdots, p_{n-1}, q_0, q_1, \cdots, q_{n-1}$.

*Step 0*: Transmit from $p_i$ to $q_i$ for all $i$, $0 \leq i \leq (n-1)$.

*Step 1*: Transmit from $q_i$ to $p_i$ for all $i$, $0 \leq i \leq (n-1)$.

*Step k, $k \geq 2$*: If $k$ is even transmit from $p_i$ to $q_{i+fib(k-1)}$ for all $i$, and if $k$ is odd, transmit from $q_i$ to $p_{i+fib(k-1)}$ for all $i$, where + denotes addition modulo $n$.

It is easy to verify that this strategy has the following properties: after step $k$, for each $i$ either $p_i$ or $q_i$ has all tokens from all nodes $p_j$ and $q_j$ for $j = i, i-1, \cdots, i - fib(k+1)+1$ where − denotes subtraction modulo $n$; the other one ($p_i$ or $q_i$) has all tokens from nodes $p_j$ and $q_j$ for $j = i, i-1, \cdots, i - fib(k) + 1$; after step $k$, nodes $p_i$ and $q_i$ ($k$ even) or nodes $q_i$ and $p_i$ ($k$ odd) have $2 \cdot fib(k)$ and $2 \cdot fib(k+1)$ tokens respectively; each step involves transmitting from the sites with the larger number of tokens to the sites with the smaller number. Then it can be seen that when $fib(k) \geq n$, every node has all tokens and the broadcast is finished. It is well known that $fib(k) \geq \left(\frac{1+\sqrt{5}}{2}\right)^{k-2}$, and from this inequality it is straightforward to count steps and arrive at the above bound.

It is not obvious that this algorithm is optimal, and our only proof of its optimality is that it asymptotically takes exactly the same number of steps given by the lower bound. In fact this algorithm achieves at each step very close to the maximum rate of growth of information as we defined it in establishing the lower bound, and it solves the broadcast problem efficiently (usually within 1 step of the lower bound) even for small values of $N$.

The optimal algorithm does not make use of all the links in the complete graph. The communications required by this algorithm define a network whose interconnection pattern is a regular graph of valence O(log N). Further this algorithm would be optimal even if one were to charge for the transmission as a linear function of the size of the message.

## 4 Broadcast Problem on a Hypercube

The hypercube $H_d$ of dimension $d$ has (0,1)-vectors of length $d$ as nodes, with an edge between two nodes if they differ in exactly one coordinate [7]. It is easy to observe that any algorithm under either model of communication will take at least $d$ steps to solve the broadcast problem since the *diameter* of the hypercube $H_d$ is $d$.

It is not too difficult to find algorithms that under model A solve the broadcast problem in $d+1$ steps. The simplest was first presented in [6] and can be described in this way. In the even numbered steps, nodes labelled with even parity send their collection of tokens to their respective neighbours labelled with odd parity and during odd numbered steps, the nodes with odd parity send their collection of tokens to their respective neighbours with even parity. But we have recently discovered for $d \geq 3$ a way to merge two different strategies of this sort into a combined strategy that solves the problem in $d$ steps which is optimal.

Let us look at the broadcast problem for model B. Let $T_i^+$ ($T_i^-$) denote the computation step where each node whose $i^{th}$ bit is 0 (1) transmits all its accumulated tokens to its neighbour whose corresponding bit is 1 (0). Now consider the sequence $\sigma = T_1^+, T_1^-, \cdots, T_d^+, T_d^-$. It can be shown that any permutation of $\sigma$ is a solution to the broadcast problem, and furthermore if any step is omitted from such a permutation then it is no longer a solution. Thus this algorithm runs in $2d$ steps but no faster. We have tried a number of different direct approaches, and they all resulted in algorithms that run in $2d$ steps. However, we have recently discovered an extremely complicated algorithm that solves the problem in 17 steps on the 9-cube, so we know that $2d$ is not optimal. But we believe there will be no simple algorithm that is better than $2d$, and we also suspect that the optimum is closer to $2d$ than to $1.44d$, so for practical purposes we consider the permutations of $\sigma$ to be the recommended algorithms for the broadcast problem under model B.

## 5 Other Multiprocessor Networks

Given an arbitrary interconnect network, it is interesting to consider the minimal number of steps needed by an algorithm to solve this token broadcast problem for either of the models we consider here. Especially in the case of Model B, the minimal number of steps appears to effectively capture the speed at which a network can perform a global synchronization. This measure is quite distinct from diameter or other common measures.

Restricting our attention to Model B (which is arguably most realistic and in fact models the performance of the INTEL iPSC family), our results demonstrate that a complete graph (diameter of 1) is less than 50% more efficient than a hypercube with the same number of nodes. Another way of viewing our result is that there exist interconnection networks with about 50% more communications channels than a hypercube that are optimal among all networks for this token passing problem. Our understanding of these optimal networks is extremely rudimentary at present.

A good example to illustrate this new measure is a star network with one central node and $n$ spokes. Each of the $n$ spokes is connected to the central node only. The diameter of this graph is 2 but the optimal algorithm under Model B requires $2n$ steps. This observation captures precisely the common wisdom that a star network encounters too much contention at its central node.

A linear array of nodes requires either $n$ or $n+1$ steps for an optimal algorithm (depending on the parity of $n$) and this does in fact correspond closely to the diameter in this case. We have shown that for an $n_1 \times n_2 \times \cdots \times n_k$ multidimensional grid, the problem can be solved in $\Sigma_{i=1}^{k} p(n_i)$ steps, where $p(2m) = 2m$, and $p(2m+1) = 2m+2$. However, the diameter of such a grid is $\Sigma n_i - k$ and so this solution is always within 2k of the diameter which is a lower bound. We have also shown that for a ring of $n$ nodes it can be solved in $n/2 + \sqrt{2n}$ steps. In both cases, the solution is optimal and the number of steps is close to the diameter. We do not know what the optimum is for the hypercube.

## 6 Conclusions

The main result of this paper is that the optimal algorithm for the token broadcast problem (under a restricted model of communication) for a complete graph network with N processors runs in $\lceil 1.44 \log_2 N + 4 \rceil$ steps. We observe that the hypercube network is not very much slower as the same problem can be solved on a hypercube in $\lceil 2 \log_2 N \rceil$ steps. There are two immediate questions that one would like to solve. What is the optimal algorithm for the hypercube network? Is there a structural property of the interconnection graph that totally captures the difficulty of the token broadcast problem?

## Abstract

The Alliant FX/8 multiprocessor implements several high-speed computation ideas in software and hardware. Each of the 8 computational elements (CEs) has vector capabilities and multiprocessor support. Generally, the FX/8 delivers its highest processing rates when executing vector loops concurrently [5]. In this paper, we present extensive empirical performance results for vector processing on the FX/8. The vector kernels of the LANL BMK8a1 benchmark are used in the experiments. We execute each kernel on 1 and 8 CEs and show the measured execution rate (in MFLOPS) as a function of vector length. We assess the performance of 1 CE as a vector processor by finding the vector lengths where vector processing exceeds that of scalar processing and calculating Hockney's $n_{1/2}$. For 8 CEs, we give upper/lower bounds on the achieved speedups and on the multiprocessing overhead. We also show the speedup variation as the number of CEs increases from 2 to 8. Our results reveal some interesting phenomena. Vector processing performance in a machine with a multi-level memory hierarchy, such as the FX/8, depends significantly on where the referenced vectors reside. Execution from memory, rather than from cache, degrades performance by a factor up to 3.7. Although speedups around 7 can be achieved for most stride-1 kernels when executed on 8 CEs, the maximum execution rates occur only for a narrow range of vector lengths ($O(1000)$). Performance drops rapidly when the vector lengths deviate slightly from the optimal values. This phenomena is not observed when executing on a single CE; the peak performance is obtained when the vectors are 32 elements long and remains close to the maximum for longer vector lengths ($O(1000)$). The kernels do not gain any appreciable speedup when the number of CEs is increased beyond 4 for short ($O(100)$) or long ($O(10{,}000)$) vectors. Multiprocessing of some indexed vector kernels results in almost no speedup due to the synchronization necessary to enforce output dependencies.

## 1. Introduction

The Alliant FX/8 is a shared memory multiprocessor system with a maximum advertised performance of 94.4 millions of floating point operations per second (MFLOPS) for single precision computations [5]. Each of its 8 computational elements (CEs) has vector processing capability with a peak advertised execution rate of 11.8 MFLOPS. The FX/8 is one of the several machines which have been announced in the last few years that use different forms of parallelism to exceed the performance attainable from the technology used in the implementation[a]. The FX/8 combines several interesting high-speed computation ideas in both software and hardware [12], [20], [21], [19], [13], [17]. It has an interactive optimizing Fortran compiler which transforms loops in subroutines to execute in vector mode on a single CE, vector-concurrent mode on multiple CEs, or scalar-concurrent mode on multiple CEs [5]. The operating system, Concentrix, is a multiprocessor Unix based on Berkeley 4.2 BSD. Multiprocessing is realized by concurrency control hardware in each CE which is accessed using special concurrency instructions. The 8 CEs of the system are crossbar connected to a shared, direct mapped, cache. The cache is connected to the shared memory via a bus. A more detailed description of the FX/8 is presented in the Section Two.

The performance assessment of a vector multiprocessor machine, like the FX/8, is important because of the great amount of effort that was spent in the last decade to develop vector algorithms for different applications and to enhance the capabilities of vectorizing preprocessors to detect vector loops in dusty deck codes [19]. In addition, there is little empirical data in the literature modeling the behavior of vector multiprocessors [7], [11]. This paper presents empirical results on the vector performance of the Alliant FX/8 multiprocessor. The thirteen vector kernels of the Los Alamos National Laboratory benchmark **BMK8a1** (for double precision computations) were used in our experiments [14].

In Section Three we report and discuss the experimental results. We show the delivered performance for each kernel when executed on one CE. A single CE demonstrates the classical performance behavior of a vector processor where the maximum performance is sustained over a wide range of vector lengths. However, as cache misses increase for longer vector lengths, the performance drops sharply to a rate where the cache hit ratio is at a minimum. To characterize the vector performance of 1 CE, we determine the vector length where each kernel starts executing faster in vector mode than in scalar mode and calculate $n_{1/2}$, the vector length at which the CE is supposed to deliver half of its peak performance ($r_{\infty}$), as described by Hockney in [16]. These results indicate that a single CE processes short vectors efficiently.

For 8 CEs, we present the delivered performance, speedup, and multiprocessing overhead for each kernel. We observe that the

execution rate increases as the vector length increases and then drops significantly to a minimum rate. The results show that the maximum performance for each kernel on 8 CEs is sustained over a significantly smaller range of vector lengths than for 1 CE. This is reflected in the speedup and multiprocessing overhead calculations. Speedup, $S_p(n)$, is defined as $t_1/t_p$ where $t_1$ and $t_p$ are the execution times of a kernel for vector length $n$ executed on 1 and $p$ CEs, respectively. We define the **machine efficiency**, $E_m(n)$, as the maximum delivered execution rate divided by the peak advertised execution rate of the machine and **multiprocessor efficiency**, $E_p(n)$, as $S_p(n)/p$. Multiprocessing overhead, $OV_p(n)$, is equal to $1\text{-}E_p(n)$. Our results indicate that only modest improvements in speedup are achieved when processing short ( $<=100$) and long ($\geq 10{,}000$) vectors on more than 4 CEs.

To determine the effect that the cache has on performance, we repeat the experiments for each kernel such that cache misses will be encountered whenever possible. Our measurements show that the performance decreases by a factor up to 3.7 when the vectors are referenced from memory instead of from the cache.

The BMK8a1 benchmark contains kernels with subscripted vectors. These vector kernels run slower than the stride-1 kernels. In Section Three, using one of the indexed kernels, we briefly discuss issues which affect the performance of such kernels. In Section Four we make some concluding remarks.

## 2. The Experimental Environment

We performed our experiments at the Center for Supercomputing Research and Development (CSRD) of the University of Illinois[b]. The configuration of the FX/8 used for these experiments is shown in Figure 1. The computational complex of the FX/8 contains 8 CEs. When executing concurrency instructions, the CEs communicate via a concurrency control bus. Each CE has a computational clock period of 170 nsec with a peak execution rate of 11.8 MFLOPS and 5.9 MFLOPS for single and double precision computation, respectively [5], [9]. With the 8 CEs working concurrently, the FX/8 advertised peak performance is 47.2 MFLOPS for double precision computations. The CEs are connected by a crossbar switch to a direct-mapped, write-back, shared cache of 16K double precision words[c]. The cache is implemented in 4 quadrants with a peak interleaved bandwidth to the CEs of 47.125 MW/sec. It is connected to a 4 MW shared memory via a bus with a peak bandwidth of 23.5 MW/sec. The system also contains 6 interactive processors (IPs) connected to their own caches as shown in Figure 1. The IPs primarily perform operating system related functions and I/O operations.

A computational element has vector processing capabilities as well as multiprocessing support. It has a rich set of arithmetic, logical and comparison vector instructions plus vector move instructions including scatter, gather and merge. There are 8 32-bit data registers, 8 address registers, 8 double precision floating point registers, and 8 32-element, double precision vector registers in each CE. Operands of vector instructions can come from vector registers, vector and floating point registers, or vector registers and the cache. Chaining is also supported for vector add-multiply and vector multiply-add instructions. Multiprocessing is supported by concurrency instructions which permit iterations of a loop to be executed concurrently across multiple processors in the CE complex.

The Alliant FX/8 Fortran compiler provides automatic detection of vector and/or multiprocessed loops. It optimizes code for scalar, vector and concurrent execution. Based on data dependency analysis, loops are optimized to execute in one of four modes: vector, scalar-concurrent, vector-concurrent, or concurrent-outer/vector-inner [5]. The FX/8 operating system, Concentrix, extends Berkeley Unix 4.2 to provide support for multiple processors and a large virtual space.

The FX/8 system maintains timing information for each program which is accessible through Fortran library routines and can be used for measurement purposes. Our experimentation procedure attempted to remove any inconsistencies that might result in the performance measurements due to the resolution of these timing tools by assuring a long running time relative to the granularity of the timed event. This was achieved by enclosing each kernel in a serial timing loop which repeats the execution of the kernel as many times as needed to obtain reliable timing data. All measurements were performed in standalone mode. Each vector kernel was executed five times for vector lengths varying between 1 and 100,000. The repetition of the experiments was necessary due to significant variations in the execution rates from one run to another for certain regions of vector lengths.

The Los Alamos National Laboratory benchmark BMK8a1 contains thirteen vector kernels designed to reflect the vector statements which are widely encountered in scientific codes [14]. Each kernel is a different combination of add and multiply operations of vectors and scalars that stores the outcome into a result vector. Some kernels use an additional vector to index an operand or result vector. In our notation used to identify the different kernels, $v$ is a vector, $s$ is a scalar, $p$ denotes addition, $t$ denotes multiplication, and $i$ denotes an indexing vector[d]. For instance, ***vts*** is the kernel $v1 = v2 * s$ and ***vi=vtv*** is the kernel $v1(i+k) = v2 * v3$ where $i$ is the indexing vector and $k$ is a constant. The complete list of vector kernels is:

***vps***
***vts***
***vpv***
***vtv***
***vtvps***
***vpvts***
***vtspvts***
***vtvpv***
***vtvpvtv***
***vips***
***vi=vtv***
***vpvtvi***
***vi=vipvtv***

## 3. Experimental Results

The performance of a one CE system is measured in order to calculate speedup and other performance metrics for multiple CEs. Examining the one CE results reveals interesting characteristics of the behavior of a vector processor when accessing data in a multi-level memory. The 8 CEs results show the performance improvement obtainable from vector-concurrent operation. The vector length region where maximum execution rate is achieved using 8 CEs is narrower than for one CE. However, the speedup in this region is around 7 for most stride-1 kernels. Comparing the performance for one and multiple CEs reveals important observations on the number of CEs which can be

[b] At the time the work reported in this paper was performed, the machine did not run production releases of the OS and the compiler. However, we believe that our conclusions will not change significantly when these releases are available.

[c] A double precision word is 64 bits wide.

[d] ***vi*** denotes a vector, $v$, indexed by another vector, $i$.

efficiently employed in a vector multiprocessor system. The performance results for the indexed kernels provides qualitative measure of the difficulties encountered when attempting to improve the performance of some codes using multiple vector processors.

### 3.1. One CE Performance

Figure 2 shows the maximum measured execution rate as a function of vector length for each kernel running on 1 CE. We observe that the behavior of all the kernels is similar; the computational rate increases as the vector lengths increase and reaches a maximum at vector length $n_{peak}$. For each kernel, the execution rate stays within a small percentage of the maximum until the vector length reaches a value denoted by $n_{drop}$. The computational rate then starts to fall until a vector length denoted by $n_{min}$ is reached. For vectors longer than $n_{min}$ the execution rate remains rather constant. These three vector length points are shown for the ***vtspvts*** kernel in Figure 2. We identify four regions for each performance curve: the **cache rate region** $(1 \leq n \leq n_{drop})$, **maximum rate region** $(n_{peak} \leq n \leq n_{drop})$, the **falloff region** $(n_{drop} < n \leq n_{min})$, and the **minimum rate region** $(n > n_{min})$. In the cache rate region, the size of the data referenced by each kernel is small enough such that the cache hit ratio is maximized. The performance in this region is characteristic of vector processors where the execution rate rapidly increases to a maximum point which is sustained as the vector length increases. The wide range of vector lengths where the execution rate stays within a small percentage of the maximum identifies the maximum rate region. The falloff region begins when the cache hit ratio starts decreasing. As the cache hit ratio continues to decrease for longer vector lengths, the number of the references to the shared memory increases and the performance drops until the cache hit ratio reaches its minimum at $n_{min}$. In the minimum rate region, the size of the referenced data is so large that a cache miss occurs whenever the kernel accesses the first word of a cache block[e].

Several factors affect the delivered performance for a given kernel at a particular vector length. These factors include the number of memory references, the number of floating point operations performed, the types of floating point operations, and the degree of chaining in the kernel. The ***vps*** kernel runs faster than the ***vts*** kernel because of operation type; ***vtvps*** runs faster than ***vtv*** due to the number of floating point operations performed and chaining; ***vtspvts*** runs faster than ***vtvpvtv*** due to the difference in the number of memory references. Table 1 shows the maximum MFLOPS measured for each kernel on 1 CE. The maximum execution rate occurs at vector length 32 for all kernels. This is expected since the vector registers are full at this vector length. Table 2 shows the execution rate for each kernel in the minimum rate region. Performance in the maximum rate region can be two times greater than the performance in the minimum rate region.

In order to determine how efficiently one CE processes short vectors, we found the vector length where execution in vector mode starts to be faster than in scalar mode. More performance can be achieved in vector mode for vector lengths > 2 for the stride-1 kernels and >6 for the indexed kernels. Hockney's $(n_{1/2}, r_{\infty})$ model can also be used to characterize the vector performance for one CE [16]. Table 3 shows that all kernels have an $n_{1/2} \leq 4$. This indicates that short vectors will be processed efficiently on the FX/8. However, most kernels deliver only around 1/3 of the measured peak execution rate at $n_{1/2}$ when executed on 1 CE instead of half the peak rate as expected by Hockney's model. It can be shown that Hockney's two parameter model $(n_{1/2}, r_{\infty})$ is simplistic when used to model real vector processors [4], [22].

### 3.2. Eight CEs Performance

Delivered Execution Rate

Figure 3 shows the maximum performance results when executing in vector-concurrent mode on 8 CEs. We observe that the execution rate rises more slowly and reaches the maximum rate region for much longer vectors than in the 1 CE case ($O(1000)$ compared to 32). This is partially due to the fact that vector-concurrent execution partitions the vector operation equally among the 8 CEs and longer vectors are required before the vector registers of each CE are maximally utilized[f]. Multiprocessing overhead associated with starting and sustaining vector-concurrent operations accounts for the further increase needed in vector length before the maximum rate is achieved. The performance of a kernel on 8 CEs is affected by the multi-level memory hierarchy for the same reasons as in the 1 CE case. In fact, we observed that the falloff region in the 8 CE performance curves coincides with the falloff region in the 1 CE performance curves for each kernel. However, the percentage drop in MFLOPS in the falloff region is greater with 8 CEs. Due to the initial slow performance increase to the maximum rate and the fixed falloff region, the maximum rate region spans a much smaller vector length interval than in the 1 CE case. This result has ramifications on how codes should be structured, with respect to vector length, so as to maximize the vector-concurrent performance when running on 8 CEs. In particular, we notice that if vector lengths deviate slightly from the maximum rate region, performance degrades rapidly.

Table 1 shows the maximum peak MFLOPS measured for each kernel when executing on 8 CEs, the vector length where the peak performance is delivered, and the machine efficiency $(E_m)$ at this vector length[g]. The machine efficiency is less for 8 CEs than for 1 CE due to multiprocessing overhead. All the kernels achieve < 50% machine efficiency and 10 kernels are < 30% efficient for 8 CEs. Table 2 is analogous Table 1 except the data for the MFLOPS in the minimum rate region is presented. It can be seen from the MFLOPS and the machine efficiency that a low cache hit ratio significantly reduces the performance. This subject is discussed in more detail in the section 3.3.

Speedup Results

Speedup is defined as $S_p(n) = t_1/t_p$ where $t_1$ and $t_p$ are the execution times of a kernel for vector length $n$ executed on 1 and $p$ CEs, respectively[h]. Since there were variations in measuring $t_1$ and $t_8$ over the five runs, we define the lower bound on the speedup of a kernel with vector lengths $n$, $L_{S(n)}$, to be the ratio of the smallest of the five $t_1$'s and the largest $t_8$. The upper bound on the speedup, $U_{S(n)}$ is calculated as the ratio of the largest measured $t_1$ to the smallest $t_8$. Figure 4 shows the upper and lower bound speedup curve for the ***vtv***

[e] A cache block contains four double precision words.

[f] This analysis is supported by the observation that the execution rate has a local maximum at vector length 256 for almost all of the kernels. At vector length 256, the vector registers for each CE are full.

[g] By definition, the maximum $E_m$ occurs at this vector length.

[h] In the remainder of the paper, $S(n)$ will be used to denoted $S_8(n)$.

kernel[i]. We observe that for all kernels the speedup upper bound is less than 4 for vector lengths smaller than 500 and less than 5 for vector lengths greater than 10,000. The maximum upper bound speedups for all the kernels are shown in Table 4. Eight of the 13 kernels have a maximum upper bound speedup greater than 7. The speedup of 4 of the remaining kernels is between 5 and 7. The indexed kernels have the smallest speedups; ***vi=vtv*** has a maximum upper bound speedup of only 1.32.

By comparing the vector lengths in Tables 1 and 4 we observe that the vector lengths where the peak MFLOPS and maximum speedup occur are not necessarily the same for a given kernel. Table 5 shows the speedup upper bound at the vector lengths where each kernel runs at its peak execution rate. We notice from Figure 4 and Tables 4 and 5 that the lower and upper bounds on speedup can differ significantly (up to 57%). This variation occurs in the falloff region and is primarily a result of the nondeterministic behavior of the cache in this region from one run to another. However, this variation is insignificant for short and long vector lengths ($n<500$ and $n>10{,}000$).

Figure 5 shows the speedup as a function of the number of CEs for stride-1 kernels. The envelopes in the figure enclose the speedup curves for all kernels at vector lengths 100, 1K and 100K. The speedup curve for ***vtvps*** is shown as a dashed line and roughly represents the median speedup within each speedup envelope. We observe that for both short and long vectors the speedup gained by increasing the number of processors beyond 4 is modest for most kernels. As the number of CEs increase from 4 to 8, the speedups approach 4.5 and 4 for vector lengths of 100 and 100K, respectively. For vector lengths of 1K, speedups are close to being linear in the number of CEs. These speedup results could be very useful to designers of multi-million dollar multiprocessor vector machines (e.g., the new Cray multiprocessors) in light of the mean vector lengths encountered in application codes ($\leq$468 in the Lawrence Livermore National Lab workload [24]).

Multiprocessing Overhead

The percentage multiprocessing overhead of a machine with $p$ processors when executing a kernel with vector length $n$, $OV_p(n)$, is given by $(1\text{-}S_p(n)/p)$*100%; $OV(n)$ denotes the overhead when $p$=8. We let $U_{OV(n)}$ denote the upper bound on the overhead and $L_{OV(n)}$ denote the lower bound. Figure 6 shows the upper and lower bound overhead curve for the ***vpvts*** kernel[j]. For all kernels, $U_{OV(n)}$ is greater than 50% for short ($n\leq$ 100) and long ($n\geq$ 10,000) vectors. For six of the nine stride-1 kernels, $U_{OV(n)}$ is less than 25% for vector lengths in the region $1000\leq n\leq 2000$. The overheads of the indexed vector kernels are greater than 30% for all vector lengths.

Table 6 identifies the vector lengths where the minimum $U_{OV(n)}$ occurs for all the kernels. We note that for the 9 stride-1 kernels the minimum $U_{OV(n)}$ is between 10-20%. For the indexed kernels, the minimum $U_{OV(n)}$ is close to 30% for 1 kernel, 40% for 2, and 85% for the fourth kernel.

### 3.3. Execution from Memory

In order to measure the vector-concurrent execution rate for a kernel with vector length $n$ ($1\leq n\leq 100{,}000$) such that the the maximum number of cache misses occurs, we reference the vectors as columns of two-dimensional arrays. The kernel is executed for the first column (of length $n$), then the second column, and so on. Since every column is distinct, new vectors are always being referenced. Also, the two-dimensional array sizes are declared such that when a column is referenced again by the timing loop, none of the data from the previous reference of that column will be present in the cache. We refer to the running of a kernel in this fashion as **execution from memory**. When a kernel is not restricted to execute in this manner and is able to take full advantage of the cache, we say that the kernel is **executing from cache**.

Figure 7 shows the execution rate from memory and from cache for the ***vtspvts*** kernel using 8 CEs. When the kernel executes from memory, the execution rate rises slowly as the vector length increases and reaches a maximum that coincides with the rate obtained in the minimum rate region when the kernel executes from cache. The same behavior is observed for the other kernels [3]. Table 7 shows the maximum performance degradation factors when kernels execute from memory instead of from the cache. This factor ranges between 1.35 and 2.26 when running on 1 CE. When executing on 8 CEs and using stride-1 kernels, the degradation factor is larger and ranges between 3.03 and 3.67. For indexed kernels, the degradation factor is between 1.49 and 2.08.

It is obvious that if the memory speed were increased, the execution performance from memory would increase. It is also expected that by increasing the size of the cache, the maximum rate region of the execution from cache curve would be extended. A current limitation to increasing the performance in the minimum rate region of the two curves is the bandwidth available on the Data Memory Bus [3]. Improving the data memory bus bandwidth would have the effect of shifting the minimum rate region of the two curves upward.

### 3.4. The Behavior of Indexed Kernels

When running on a single CE, the execution rate of a kernel will drop if one or more of the referenced vectors are addressed indirectly. This is mainly due to an increase in the number of vector instructions generated by the compiler for an indexed kernel (scatter/gather instructions, etc.). Moreover, the memory access pattern of the indexed vector elements might result in an appreciable decrease in the utilization of the bandwidth of the interleaved memory modules.

The execution rate of a multiprocessed vector kernel could degrade significantly if the result vector is addressed indirectly. This can be seen clearly in Figure 3 when comparing the execution rate curves for kernels ***vtv*** and ***vi=vtv***. Examing the assembly code generated for the two kernels reveals that while the ***vtv*** kernel is executed as a single concurrent vector loop, the concurrent loop of the ***vi=vtv*** kernel encloses two vector loops. Each CE first executes the vector statement ***temp←vtv***, where ***temp*** is a temporary vector. While $\mathrm{CE}_0$ continues by executing a second vector loop to scatter the contents of ***temp*** to the specified elements of the result vector, each $\mathrm{CE}_i$ (i=1,...,7) waits for a synchronization signal from $\mathrm{CE}_{i-1}$ indicating that it has finished scattering its results. In this fashion, any output dependence relationships between different instances of the original statement ***vi=vtv*** will be preserved. Figure 8 shows the execution scheme of this kernel using 8 CEs. This explains the lack of any speedup when this kernel is executed concurrently. Synchronization is not required in kernels with no potential output

[i] The speedup curves for the other kernels are found in [3].

[j] The overhead curves for the other kernels are found in [3].

dependencies. Kernels with output dependencies will gain speedup if the time spent evaluating the right hand side expression of the kernel is significantly larger than the time spent in the scattering loop by each CE. This is the case for the kernel ***vi=vipvtv*** where it is possible to attain a maximum speedup of 5.86 compared to 1.32 for the kernel ***vi=vtv***.

### Conclusion

Using the vector kernels of the LANL BMK8a1, this paper assesses the performance of the Alliant FX/8 multiprocessor for vector processing. One CE of the FX/8 shows the classical vector processor behavior where the performance increases as the vector length increases to a maximum which is maintained for larger vector lengths. However, because of the memory hierarchy, the vector performance of 1 CE falls to a rate dependent on the shared memory access speed when the cache size is not large enough for the referenced vectors to be cache resident. Although vector processing performance on 8 CEs shows the same rise and fall as vector length increases, parallel execution accentuates this behavior. First, the increase in execution rate is slower for short vectors due to the partitioning of the vectors across multiple processors and the multiprocessing overhead. Second, although speedups greater than 7 are achieved for most stride-1 kernels for vector lengths of $O(1000)$, the region of maximum performance is narrower than for 1 CE. Third, the speedup gain by increasing the number of computational elements beyond four is small for short ($O(100)$) and long ($O(10{,}000)$) vectors. The multiprocessing overhead exceeds 50% for short and long vectors for all kernels. It is less than 25% for most stride-1 kernels for vector lengths of $O(1000)$. Lastly, the performance of the FX/8 on stride-1 kernels can drop by a factor greater than 3 if the vectors are referenced from the shared memory.

The lower performance of the machine for kernels with indexed vectors is partially due to the increase in the number of vector instructions needed to execute the kernel. However, interprocessor synchronization to satisfy potential output dependencies is the major reason for performance degradation of indexed kernels.

The successful use of an 8 CEs FX/8 for vector processing depends on observing the principle of locality of reference [8]. This implies that the programmer (or optimizing compiler) should structure the code such that once certain sections of the program's data are resident in the cache, as much computation as possible is performed using this data before processing other sets of data [1], [2], [6], [18]. Some of the other factors that enhance the delivered performance are reducing the number of memory references in the vector statement, increasing the number of floating point operations performed using the same operands, and taking advantage of the chaining capabilities of the processors.

# SUPRENUM: THE GERMAN SUPERCOMPUTER ARCHITECTURE - RATIONALE AND CONCEPTS

P.M. Behr, W.K. Giloi, H. Mühlenbein

Gesellschaft für Mathematik und Datenverarbeitung (GMD)
Birlinghoven and Berlin
W. Germany

Abstract -- Supercomputer architectures for numerical applications can be based on either of two major principles, SIMD vector machines or MIMD multicomputer systems. In the paper both solutions are compared in terms of performance, cost-effectiveness, and software problems involved, thus providing the rationale for the decision to develop a MIMD/SIMD multiprocessor supercomputer, configurable to up to 1024 nodes, where each node contains a floating-point vector processor. The crucial issues of such an architecture are the need for a bottleneck-free interconnection structure on the hardware side and for the appropriate program development environment on the software side. The solutions envisioned for the SUPRENUM MIMD/SIMD supercomputer presently under development are presented.

## The Choice of Supercomputer Architecture

In this paper the term "supercomputer" refers to very high performance machines for numerical applications; though our considerations to some extent hold true as well for non-numerical supercomputers. Supercomputers obtain their performance from two contributing factors. Firstly, they operate at the highest possible speed technology can provide. Secondly, additional performance is gained through a large amount of parallel processing.

An algorithm may be generally defined as a partial order of operations, the partial order being determined by the data dependencies between the operations. We call the parallelism of an algorithm explicit if the data dependencies are well-defined by the nature of the data types to be processed and, consequently, are known a priori. We call the parallelism implicit if it is not a priori known but must be determined through data dependence analysis.

What makes dataflow principle so attractive is its property to enable the machine to perform the data dependence analysis at run time and, thus, to provide a convenient way of exploiting implicit parallelism. Since implicit parallelism includes explicit parallelism, dataflow is a most general operational principle for parallel processing. The forte of the dataflow solution however, comes at the price of considerable overhead and, therefore, is not cost-effective in parallel processing applications where the simpler and more efficient SIMD or MIMD control scheme of handling explicit parallelism suffices.

Figure 1 presents a taxonomy relating the nature of parallelism to the appropriate control structures, processor structures, and communication structures.

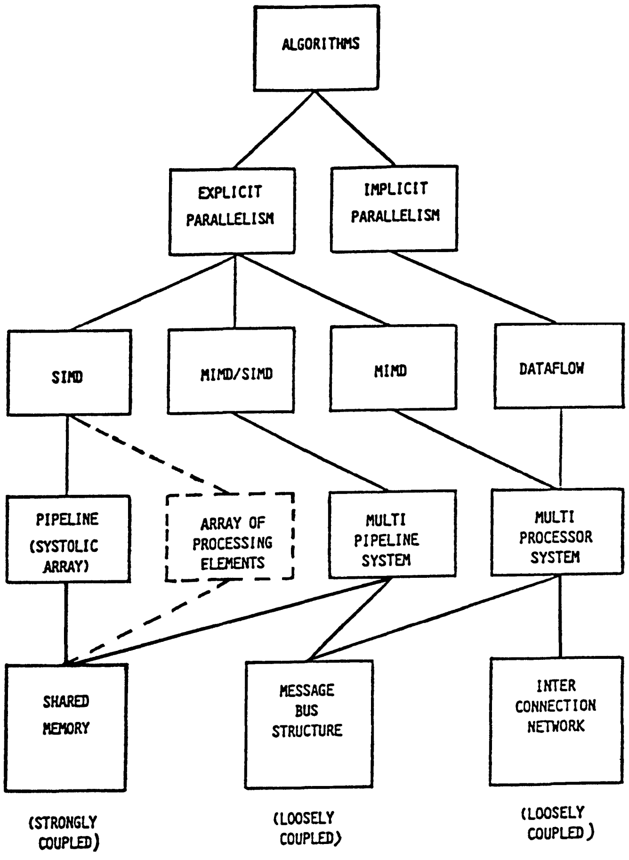

Figure 1 Taxonomy of parallel computer architectures

Figure 2 lists some of the major trade-offs between SIMD pipeline architectures and MIMD multiprocessor architectures. In the supercomputer domain, only the SIMD vector machine has found a larger market penetration. Recently, the first MIMD multiprocessor systems have become available in product form; their use at present still being more that of experimental systems rather than 'production machines'. However, two decades of research in innovative computer architecture have produced enough insight into all four forms of

0190-3918/86/0000/0567 $01.00 © 1986 IEEE

parallel architectures listed in Figure 1 to make it safe venturing the following statements.

1. SIMD machines consisting of an array of processing elements cannot compete in cost-effectiveness with SIMD pipeline machines, since they do not provide the parallel processing gain of a multi-stage pipeline processor.

2. In MIMD machines for numerical applications, the cost-effectiveness can be increased by as much as an order of magnitude through performing the floating point operations in each node in the vector mode rather than the scalar mode.

3. In the realm of numerical supercomputers, pure dataflow architectures have no chance to become a competitive solution; the reason being twofold. Firstly, since the parallelism in large numerical (array processing) problems is predominantly explicit and, thus, can be handled by the extremely efficient SIMD control scheme, the ability of the dataflow machine to handle implicit parallelism, which leads to its high control overhead, does not pay. Secondly, the pure dataflow scheme is based upon the notion that the firing of an operation consumes the tokens that are the "carriers" of the operands. Consequently, a value can be used as operand only once. This is counter-productive in all numerical algorithms in which values occur as operands of a number of operations. Both, the high control overhead and the inability of the pure dataflow scheme to handle data structure objects, result in an unfavorable MIPS/MFLOPS rate. By special measures (e.g., the introduction of the 'structure memory' in the manchester machine (Gürd, 1985), this rate can be much improved. However, it should not be overlooked that such measures in effect constitute a deviation from the pure dataflow scheme by introducing beneath the dataflow control level an SIMD control level for handling data structure objects. The performance gain obtained by such measure therefore is to be attributed to the SIMD execution of complex operations on data structure objects, while the dataflow control now synchronizes only the complex procedures and not the operations inside the procedures and, thus, becomes tolerable.

As conclusion of the discussion above we dare stating the following CONVERGENCE THEOREM: Numerical supercomputers of the future will be predominantly MIMD/SIMD machines.

The convergence will happen from the side of the vector machines by adding more and more pipelines; from the side of the MIMD architectures by pipelining the floating point coprocessor in the node. The SUPRENUM architecture is of the latter type.

SIMD PIPELINE ARCHITECTURE

PROCESSOR PERFORMANCE:

- SIMD GAIN
- PARALLEL PROCESSING GAIN OF MULTISTAGE PIPELINE FOR LARGE, ORDERED SETS OF DATA
- "SCALAR GAP"

PERFORMANCE LIMITATION DETERMINED BY:

- EFFECTIVE DATA MEMORY BANDWIDTH

POTENTIAL FOR PARALLEL PROCESSING:

- LOW TO MEDIUM

COST-EFFECTIVENESS:

- HIGHER

PROGRAMMING STYLE:

- PREDOMINANTLY FUNCTIONAL

CONFIGURABILITY AND FLEXIBILITY OF APPLICATION:

- LOW

MIMD MULTIPROCESSOR ARCHITECTURE

PROCESSOR PERFORMANCE:

- NO SIMD GAIN
- NO OR LITTLE PARALLEL OPERATION
- NO "SCALAR GAP"

PERFORMANCE LIMITATION DETERMINED BY:

- NODE INTERCONNECTION BANDWIDTH

POTENTIAL FOR PARALLEL PROCESSING:

- HIGH TO VERY HIGH

COST-EFFECTIVENESS:

- LOWER

PROGRAMMING STYLE:

- COOPERATING PROCESSES OR SINGLE ASSIGNMENT

CONFIGURABILITY AND FLEXIBILITY OF APPLICATION:

- HIGH

Figure 2 Trade-offs between SIMD and MIMD architectures

## The Choice of Technology

For the sake of discussion, two main technologies called "microcomputer technology" (MCT) and "main frame technology" (MFT) shall be characterized.

Microcomputer Technology:

- TTL or MOS, highly integrated low-power logic and memory (some $10^4$ to $10^5$ transistors per chip);

- predominant use of standard ("off-the-shelf") components, therefore lower design cost;
- low cost of packaging and cooling (forced air only);
- lower operating speed.

Main Frame Technology:

- ECL, less highly integrated high-power logic (some $10^3$ transistors per chip); ECL or CMOS memory;
- predominant use of custom gate array logic, therefore higher design cost;
- higher cost of packaging and cooling;
- higher operating speed.

Of course, the cost-effectiveness of a computer depends not only on the technology but also on the architecture. Two examples shall illustrate that fact.

(A) A microcomputer with floating-point coprocessor has about the same cost per FLOPS as the MFT based vector machine. Hence, the conclusion can be drawn that the higher cost-effectiveness of MCT compensates for the lower efficiency of the conventional architecture.

(B) Comparing MCT vector machines with MFT vector machines, the former exhibit a much higher cost-effectiveness. The reason why nevertheless MFT is the dominating supercomputer technology is the much higher absolute performance MFT may provide.

This discussion can be summarized by stating that a supercomputer development based on MCT is less costly and risky. However, if one wants to reach the same performance as with MFT, a higher degree of parallel processing is required to make up for the lower operating speed of MCT. Whether the MCT solution is more cost-effective than its MFT counterpart is a question that can be answered affirmatively only if the vector machine architecture is chosen. In the case of a MIMD machine one will be quite satisfied if the cost-effectiveness of a MFT-based vector machine can be met. In this case the MIMD machine is the better choice, for it is more flexible and does not exhibit the "scalar gap".

The relationship between the two technologies, MCT and MFT, and the two architectural forms, SIMD and MIMD, can be summarized as follows:

> MIMD multiprocessor systems with a larger number of nodes (as needed to achieve supercomputer performance) can be realized only in MCT.
>
> SIMD vector machines may be realized in both, MCT and MFT.

To conclude this section, we shall take a look at the absolute performance obtainable in either technology by contrasting the two cases, SIMD vector machine and MIMD multiprocessor system, respectively.

SIMD Vector Machine - MFT

As paradigm for maximal performance obtainable in ECL technology (MFT), we take the vector machines of CRAY Research Inc. (CRAY-1, CRAY-X MP, CRAY-2). The following table presents the major parameters of these machines.

| Model | Clock Time $T_p$ | Max. number of pipelines | Max. Performance | Year |
|---|---|---|---|---|
| CRAY-1 | 12.5 ns | 1 | 160 MFLOPS | 1977 |
| CRAY-X MP | 9.5 ns | 2 | 400 MFLOPS | 1983 |
| CRAY-2 | approx. 5 ns | 4 | 1000 MFLOPS | 1986 |

SIMD Vector Machine - MCT

Highly integrated dynamic memory allows a stream of up to 16 million words per second to be moved to and from the memory. Static CMOS memory has become available with an access time of down to 15 - 25 nanoseconds. The paradigm of a highly integrated floating-point pipeline processor is the Weitek WT 2264/2265 chip set (Weitek, 1986), which is designed to satisfy the following performance specifications:

- IEEE single precision operations (ADD, SUBTRACT, MULTIPLY): 20.0 MFLOPS
- IEEE double precision operations (ADD, SUBTRACT, MULTIPLY): 15.5 MFLOPS

The Weitek processors form a 7-stage pipeline. This, in connection with the pipelining of the data moves, results in a pipeline gain of about 10, a gain that is lost in the case of scalar operations. Chaining multiplication and addition (accumulation), e.g., for the inner vector product, doubles the vector mode performance. Several such pipeline processors could be cascaded to obtain a "macro pipeline" with a multiple of the performance of one processor set, provided the memory bandwidth is not already exhausted by one single pipeline.

MIMD Multiprocessor Machine - MCT

The maximal performance of an MIMD multiprocessor system with N nodes, obtained under most favorable conditions, is

$$P_{max} = q \cdot N \cdot P_n$$

if $P_n$ is the performance of a node and q is an overhead factor, $q < 1$.
The conditions under which $P_{max}$ can be reached are:

1. The algorithms executed by the machine must have a sufficiently high inherent parallelism in order to allow for the linear performance increase.

2. There exists no communication bottleneck in the system.

The first condition must be satisfied by the application; the second condition must be satisfied by the architecture. Violation of the conditions may result in a dramatic performance decrease.

It was pointed out above that SIMD machines provide more MFLOPS per cost unit, while MIMD machines provide a higher flexibility of use by virtue of the fact that parallel processing is not restricted to vectors. Hence, the decision between the two architectural principles involves a tradeoff between the higher cost-effectiveness of SIMD and the higher flexibility of MIMD. However, the MIMD flexibility exists only if it is not unduly constraint by the system's communication structure. For example, a communication structure that allows each node to communicate only with its nearest neighbors would be such a constraint and, thus, handicap the MIMD machine's competitiveness in comparison to the SIMD machine. Consequently, the communication structure of a general purpose MIMD multiprocessor architecture should provide total internode connectivity.

### MIMD/SIMD Machine - MCT

Going after the order of magnitude in node performance gain by "vectorizing" the node operations is a temptation hard to resist to. The result is an MIMD/SIMD architecture, i.e. a MIMD multiprocessor architecture in which each node contains a floating point pipeline processor. To preserve the flexibility of the MIMD approach, the nodes of such a machine must be connected through a communication structure with a very high communication bandwidth. I.e., a certain proportion must be maintained between node performance (in MFLOPS) and communication bandwidth (in MBytes), the factor of proportionality being application dependent. If this condition is satisfied, than vectorizing the nodes pays even in non-vector applications such a multigrid PDE solvers. In this case, even the small sets of data that must be interchanged between grid point can be treated as (small) vectors and, consequently, lead to a vector gain.

It must be mentioned that by attempting to combine the advantages of SIMD and MIMD, one also combines the software complexity of both approaches, namely the need for either a vectorizing compiler (SIMD) or a vector language (e.g. FORTRAN 8X).

## Communication Structures in Parallel Computers

### SIMD Vector Machines

SIMD vector machines process operand data streams flowing from a storage to the pipeline processor, thereby producing result data streams flowing back to the storage. Thus their performance is determined either by the memory bandwidth or the processor bandwidth limitation, whichever comes first, and no further communication bottleneck exists. The same holds true for multipipeline machines in which the tasks running on the different processors are only "loosely coupled" (i.e., in which there is little data dependency,between the tasks).

### MIMD Multiprocessor Systems

To overcome the memory bandwidth limitation problem, each processor of a MIMD multiprocessor system must have its private memory. Such a processor-memory combination usually is called a "node". This approach puts the emphasis on the problem of providing an adequate interconnection structure (IS) to handle the internode communication.

An adequate IS should satisfy the following conditions:

(1) It must provide total connectivity to maintain the potential flexibility of a MIMD machine.

(2) It must exhibit a sufficiently high bandwidth to avoid communication bottlenecks.

(3) It must be technically and economically feasible.

(4) It must be highly reliable.

### The Problem With Interconnection Networks

Interconnection networks (IN) that are capable of connecting a number of source nodes with a number of destination nodes are considered by many as the solution to the interconnection problem in large scale SIMD multiprocessor systems. Many papers have been published dealing with such structures, their complexity, and their interconnection properties. Hardly any of these many papers is addressing the topic of the technical feasibility and the interconnection bandwidth obtainable in view of such mundane parameters as pin limitation, packaging problems, driving power limitation, cost, etc.

INs come in two major categories: single-stage (permutation) and multi-stage networks. In single-stage networks, a data packet may have to travel through the network several times in order to reach a given destination from a given source. In contrast, in a multi-stage network the data can flow directly from the source to the destination. Another distinction is that between circuit switching, where a physical connection is provided from source to destination, and packet switching, where a logical connection is provided for a packet travelling through the network. Furthermore, control may be centralized or decentralized.

If one takes a closer look, the seemingly large variety of INs proposed can be identified as variants of one of the 4 basic classes listed in the following table (Ermel, 1985).

| CLASS | NETWORK TYPE | COMPLEXITY |
|---|---|---|
| A | CROSSBAR SWITCH | 0 $(n^2)$ |
| B | BENES NETWORK | 0 (n·log n + n/2) |
| C | N-CUBE, BASELINE, BANYARD, OMEGA, FLIP, DELTA | 0 ((n/2) log n) |
| D | DATA MANIPULATOR, INVERSE DATA MANIPULATOR | 0 (n + n log n) |

Networks with (N·log N)-complexity are not suitable for circuit switching, since they exhibit at any time a large incidence of mutual blockages of data paths. This leaves the crossbar switch, which provides total point-to-point connectivity, as the only viable solution for a circuit switching network. Packet switching networks, on the other hand, can readily deal with blockages, since the nodes have the capability of storing and keeping a packet for the duration of a blockage.

The switching elements of a circuit switching crossbar network are extremely simple (simple bus connection by tri-state logic). In addition, some hardware is needed to arbitrate the access to the crossbar busses. The switching elements of packet switching networks, on the other hand, must be intelligent communication processors that are orders of magnitude more complex than the simple switching elements of a circuit switching network. By the same token, they are also much slower, as they have to execute a complex microprogram to handle a packet. Therefore, if one compares only the switching complexity of different networks, one may be comparing apples with oranges.

A more detailed feasibility study conducted by Ermel (1986) has shown that the size of a crossbar network should not exceed that of a 32 x 32 switching matrix in order to be packagable in a reasonable manner; and 64 x 64 would absolutely be the technical limit. This means that the direct interconnection of, say, 256 or more nodes through a crossbar switching network is technically not feasible. Packet switching networks for the interconnection of an equally large number of nodes, even if still feasible in terms of pin limitation and packaging constraints, would be too slow for supercomputers.

The way out of this dilemma is a two-stage approach by forming clusters of nodes and connecting these clusters either via a crossbar network or an equally fast packet switching network. The interconnection of the nodes of a cluster may be performed through either a very high-speed cluster bus or, again, a crossbar network.

## Software Problems

Historically the parallel processing user has been a rather knowledgeable scientist or engineer who is willing to assume the burden of creating application programs using rudimentary environments. Detailed architectural and operating system knowledge as well as the intricate ability to manually map parallel algorithms onto a virtual parallel architecture are some of the hurdles such users had to overcome.

### Programming of Single-Pipeline Vector Machines

The programming of single pipeline vector machines usually is carried out in FORTRAN. A number of vectorizing compilers have been developed which map the inner loops of conventional, sequential FORTRAN programs onto the vector operations of the machine. The conditions under which such a mapping is possible and the techniques involved have become a well-understood topic.

### Programming of Multi-Pipeline Vector Machines

Presently, multi-pipeline vector machines are programmed in a multitasking manner. Typically, a task is a part of a program that can be run in parallel with some other parts of the program. The work to be done is partitioned into at least as many tasks (processes) as there are pipelines. The system then maintains a task queue, to which an unoccupied pipeline can go in order to find a task to execute. This "task attraction" scheme works only in strongly coupled systems, i.e. systems with shared logical memory.

The primary tools for multitasking can be classified into three categories. They are: task creation, critical sections monitoring, and task synchronization. The most advanced tools can be found in the Denelco HEP system, whereas for example the Cray computers offer only low-level constructs such as LOCK and EVENT variables. The following little example demonstrates some of the problems:

```
SERIAL PROGRAM:     DO 1  I=1, NPIPES
                    1 CALL COMPUTES (I)
PARALLEL PROGRAM:   DO 1  I=1, NPIPES
                    1 CALL TASKSTART
                    (ID, COMPUTES, I)
```

The two programs do not produce the same results. The reason is that FORTRAN calls are made by reference and the main task with the I-loop and the other tasks are running asynchronously.

Despite this and other classical "multitasking" problems the simple "task partitioning" approach works on the presently existing vector machines with a small number of pipelines. The application programmer is assumed to be a knowlegdeable system programmer capable of using the low-level multitasking tools.

This approach will not be acceptable when the number of pipelines becomes larger. The above mentioned low-level multitasking tools are fare too error prone for problems of higher complexity.

### Experiences with MIMD Multi-Processor Systems

The experiences with multitasking programming so far gained were made by system programmers and can be summarized as follows:

(1) The behavior of even short parallel programs may be astonishingly complex.

(2) Tracking down a bug in a parallel program can be exceedingly difficult. This results from the combination of logical complexity, nonrepeatable behavior, and the lack of existing tools.

At best, only partial solutions can be expected. The following postulates can be given:

(1) Whenever possible, rewrite at least the "skeleton" of the parallel program from scratch.

(2) Given the great difficulty of finding bugs, much greater emphasis must be placed on writing code which is correct from the beginning.

(3) Use high-level synchronization policies wherever possible and hide (encapsulate) them as much as possible.

## Programming of MIMD Multiprocessor Systems

The problem of programming a MIMD multiprocessor system with a very large number of nodes has been attacked only lately. Realistically, we see four different ways how applications software may be written during the next 5 - 10 years. Each of them currently has some severe drawbacks that limit their usefulness. McGraw/Axelrod (1984) discuss the following four approaches:

(1) Extend existing languages, like FORTRAN, with new operations that allow users to express concurrency and synchronization.

(2) Extend existing compilers to identify concurrent operations wherever it can and insert the necessary synchronization (automatic parallelization).

(3) Add a new "language layer" on top of an existing language that describes the multitasking and the desired concurrency, while allowing the basic applications program to remain "relatively" unaltered (metalanguage approach).

(4) Integrate new languages and appropriate compilers which incorporate the concepts of concurrency and synchronization (e.g., a very high object-oriented and process-oriented procedural language of a functional language).

These four ways do not represent totally orthogonal approaches, and therefore there can be no hard lines drawn between them. All of them involve some amount of language and compiler alteration.

## SUPRENUM-1: A MIMD Supercomputer

### Rationale for SUPRENUM-1

SUPRENUM-1 is a MIMD/SIMD supercomputer development project funded by the Ministry of Research and Technology (BMFT) of the German Federal Government. To carry out the project a task force has been formed consisting of several research institutions and companies. Specifically the Gesellschaft für Mathematik und Datenverarbeitung (GMD) is involved in the following tasks:

- development of a first prototype hardware and system software (in close cooperation with the participating industry)
- development of specific program development environments
- development of application software, e.g., multigrid partial differential equation solvers (Trottenberg, 1984).

The rationale for the decision to build a MIMD/SIMD multiprocessor system rather than a super fast SIMD vector machine is multifold:

(1) The market for SIMD vector machines is highly competitive, whereas the market for MIMD/SIMD supercomputers is just beginning to evolve.

(2) The higher flexibility of the MIMD principle allows for a broader application application spectrum.

(3) The "scalar gap" problem of SIMD vector machines is mitigated in MIMD/SIMD multiprocessor systems.

(4) It is expected that the MCT-based MIMD/SIMD multiprocessor system will eventually become more cost-effective than the MFT-based vector machine of comparable performance.

(5) Given the appropriate hardware solution, the development cost of the MCT-based multiprocessor system is lower than would be the cost of developing a MFT-based vector machine.

(6) The MIMD multiprocessor system development will produce technological spin-offs that will benefit a whole spectrum of products (such a general spin-off effect could not be expected from the more specialized pipeline machine development).

The SUPRENUM-1 research and development project is product-oriented. This means that, in contrast to pure research, additional market-oriented requirements must be satisfied such as:

- the desired absolute performance must be obtained at competitive cost-effectiveness;
- the program development environment provided must find user acceptance;
- the machine must be manufacturable, testable, and maintainable;
- there exists a time window during which the research and development project must lead to a production model.

In order to meet the time window requirement, the architectural design of SUPRENUM-1 will be based upon already proven yet highly innovative concepts and solutions. In this sense, the SUPRENUM-1 will be based upon already proven yet highly innovative concepts and solutions. In this sense, the SUPRENUM-1 development is influenced in many ways by the solutions and experiences gained by the preceding UPPER-project (Behr/Giloi, 1984).

## SUPRENUM-1 Hardware Architecture

In order to obtain a manageable, bottleneck-free interconnection structure, SUPRENUM-1 has a hierarchical hardware structure consisting of nodes, clusters, and hyperclusters.

As indicated in Figure 3, the basic processing node of SUPRENUM-1 is a single board computer consisting of the following major components:

- powerful 32-bit ('front end') microprocessor, to function as program execution machine as well as scalar processor, in connection with 8 MByte of high-speed dynamic memory and an objectoriented memory management unit;
- powerful floating-point vector processor (MFLOPS, IEEE standard single and double precision), performing a variety of complex numerical operations under microprogram control;
- microprogram controlled dedicated communication coprocessor, to support the object-oriented message passing and to allow the objects of application-specific data types to be copied at high-speed from node to node.

Each node has a local operating system whose task is to boot-up the node on power-on, manage and schedule the processes in the node, exchange communication objects with other nodes, manage the local memory, and perform comprehensive self-testing and fault diagnosis routines.

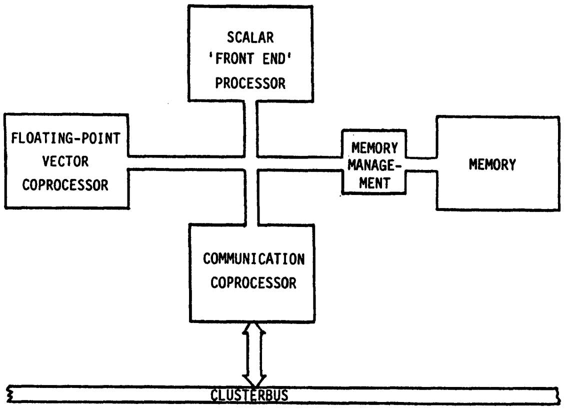

Figure 3 Structure of a node

Figure 4 depicts a block diagram of the cluster. The cluster contains up to 16 nodes plus a disk controller for local disks, the diagnosis node, and the communication unit for inter cluster communication. A cluster is accommodated in one 19" rack. The processors of the cluster communicate via an ultra-fast, duplicated parallel backplane-bus, which allows several communication partners to exchange messages simultaneously. The overall communication bandwidth of the cluster bus is 256 MByte/s a value that can hardly ever been exhausted.

Smaller systems may consist of one hypercluster ring, comprising up to 4 clusters (64 nodes) which are interconnected by one slotted ring bus (modified UPPERBUS, Zuber 1984) with a transmission bandwidth of 560 MBit/s.

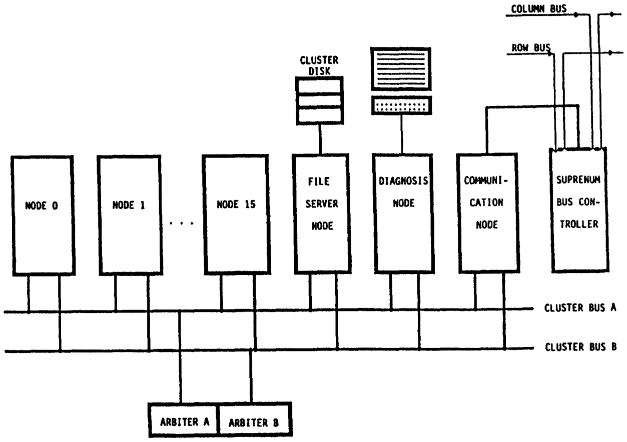

Figure 4 Structure of a cluster

Larger systems are structured in the form of a matrix of clusters whose rows and columns, respectively, are hypercluster rings. That is, each cluster belongs to two hyperclusters, row and column. The hypercluster bus is not fault-tolerant itself; rather, fault tolerance is achieved by alternate routing in the matrix. The hypercluster bus controller provides a gateway between the row and column each cluster belongs to, and it is intelligent enough to handle the alternate routing task arising in the case of bus transmission faults. The bus controller takes care of the protocol hierarchy that regulates the exchange of packets or larger logical entities, formed by a number of packets, via the slotted ring bus.

The SUPRENUM-1 system includes a separate operating system machine, whose tasks are to manage the global system resources such as global disk storage, take care of the workload distribution and system initialization, and control the recovery procedures required in the case of fault detection. The operating system machine, however, is not involved in the actual program execution. Program execution is strictly handled by the collective of local node operating systems. In addition to the operating system machine, SUPRENUM-1 contains a dedicated diagnosis and maintenance machine. Moreover, additional 'peripheral computers' can be added such as: one or more program development machines and special graphic processors for graphical representation of results. Note that these additional machines can be arbitrarily inserted into any of the rings of the orthogonal network of ring busses and that it is specifically the (ultra high bandwidth) ring bus structure that allows for the wide-range configurability of the system.

Figure 5 illustrates the matrix structure of a SUPRENUM-1 configuration with 256 nodes and a maximum processing power of 4 GFLOPS.

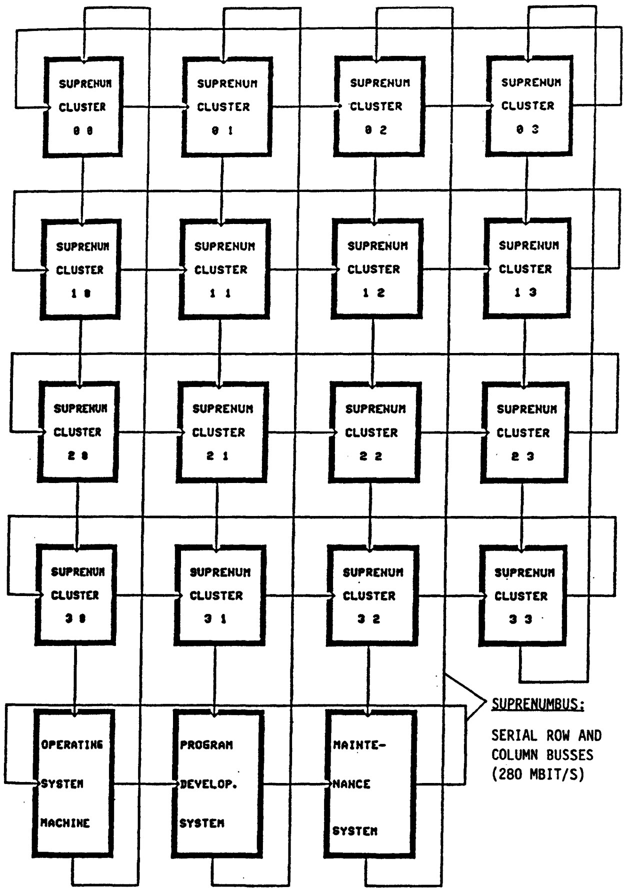

Figure 5 SUPRENUM System With 16 Clusters (256 Nodes)

## SUPRENUM-1 Software Architecture

### The SUPRENUM Software Environment

The SUPRENUM software system forms a hierarchy consisting of:

- 'firmware' (PROMed software) and software for node monitoring, process management, and inter process communication
- operating system machine software providing the language interface as well as the central database management
- appropriate parallel processing languages
- program constructor
- application constructor.

Every layer provides services to the upper layers. The language layer will be based upon the services of an abstract SUPRENUM machine.

The abstract SUPRENUM machine specifies the run-time environment the (distributed) 'global operating system' (collective of node operating systems) will support. Its basic features can be characterized as follows:

- The logical entity of computation is the process.
- The logical entity of communication is the communication object.
- Only communication objects can be shared by several processes; all other objects are local to the process who owns it.
- A structure is provided for aggregating processes with communication objects. This structure is called a task.
- The task provides the scope of protection.
- Multiple users may be given partitioned access to the machine.

The following basic features of the abstract SUPRENUM machine will be reflected in the programming languages:

- dynamic creation of explicit processes;
- asynchronous inter process communication (IPC);
- messages received at a single process entry point.

Asynchronous communication through messages received at multiple entry points have been explored by Behr/Giloi (1984) and Mühlenbein/Warhaut (1985). The approach is reflected in appropriate extensions of PASCAL (Hänisch, 1984) and MODULA 2 (Warhaut, 1986). In the SUPRENUM system, the languages extended for program decomposition into cooperating processes with data-driven synchronization will be FORTRAN and MODULA 2.

### The SUPRENUM Program Constructor

The program constructor consists of language-specific syntactic editors and interpreters. The constructor is based on the programming system generator "PSG" developed by Bahlke/Snelting (1985). The constructor can deal with incompletely specified program templates, called fragments, and comprises a 'hybrid' editor, which accepts textual input and/or prompted input from an abstract syntax tree.

Program fragments called program templates will be implemented for specific types of generic interprocess communication. One example is a program template for a ring process structure, where every process sends messages only to its left and right neighbor. Another example is the 2D-mesh, where each process can send messages to its four neighbors, etc.

Other components of the programming environments are run-time debuggers of different flavors. For example, language interpreters may be used for debugging small modules, simulators may be used for debugging larger programs, and a performance monitor may be used for performance-related debugging on the physical SUPRENUM machine.

### The SUPRENUM Application Constructor

The SUPRENUM Application Constructor will allow users who do not want to do low-level programming to implement applications by using existing application software packages.

The development of the SUPRENUM Application Constructor is a very research-oriented topic. The constructor will have to contain specialized application languages for restricted application domains, as well as a knowledge base for guiding the user in the task of generating applications by some heuristics.

First examples will be a very high level language for specifying the resolution of partial differential equation solving and an expert system for creating the appropriate multigrid programs.

## ABSTRACT

Reliability and availability are two common measures used to evaluate the dependability of computer systems. In this paper we analyze the reliability and Computation-Communication Availability of multicomputer networks for multiple faults with and without repair. Simulation models are developed based on task requirements, graceful degradation and computation and communication capability of the system. The effect of component failure rate and repair rate on the dependability of the multicomputers are also presented. The model accepts the adjacency matrix of a multicomputer graph as the input and hence is suitable for all types of networks. Typical results are presented for 16-node loop, complete connection, hypercube, mesh and tree structures on a comparative basis.

## 1. INTRODUCTION

Based on interconnections, parallel and distributed computer architectures can be broadly divided into two categories, namely: multiprocessors and multicomputers[1]. A multiprocessor consists of a large number of processors connected to a number of memory modules through a circuit switched interconnection network. In a multicomputer, however, each processor has its own private memory and message/packet switching is used for communication between the processors (nodes). Reliability issues of multiprocessor systems were presented in [2, 3]. This paper is concerned with those issues of multicomputer systems. Multicomputers are also sometimes referred to as computer networks. Normally the former is used in conjunction with centrally located systems while the later is used in case of geographically distributed computers. We will, however, use these two terms without distinction. We will also use processors and nodes interchangeably.

Several structures such as loops, trees, full connection and hypercubes, etc. [4-6] have been proposed to interconnect a network of computers in a message/packet switching environment. Each structure possesses some unique advantages and disadvantages compared to another. For example, a bi-directional single loop (ring) structure has only two I/O ports per node, but the diameter (maximum number of hops between any two nodes along the shortest path) is $\frac{N}{2}$ in a system with $N$ nodes. Any two non-adjacent faulty nodes or links disconnect the loop. On the other hand a completely connected structure has ($N$-1) I/O ports per node, but the distance between any two nodes is unity. The structure is highly fault tolerant, but due to its high cost the structure is unsuitable for systems with large number of nodes. The cost and performance of other structures such as chordal ring, tree and hypercube, etc. lie between these two [4-7]. The performance of the multicomputers is usually measured in terms of the average distance between the nodes and the average traffic density on a link. These measures usually decide the average queueing delay or the saturating load of a computer network [5-7].

All these performance evaluations assume that the components of the systems are fault free. In a real situation, however, the nodes and links will fail randomly depending on their failure rates. Hence, certain dependability measures like, reliability, availability etc. [8, 9] of these multicomputer systems are also important. These dependability measures can also be quantified based on the performance requirement at the user level or system level [11-13]. For a degradable multicomputer one measure is the *task based dependability* . In this case the failures are tolerated as long as the minimum number of nodes for the execution of a task are available and the reliability and availability of a system are computed based on this task requirement. The following example clarifies this idea.

*Example-1*

Consider a bidirectional single loop structure with 16 nodes where a node and a link have failed in (0, $t$ ). Assuming a task requires 12 nodes for computation, the structure in Fig. 1.a is good enough, but the structure in Fig. 1.b is not. The former has a linear array of 13 nodes sufficient for computation while the later has two arrays of 8 and 7 nodes both of which are insufficient for the task.

The reliability at time $t$ is defined as the probability that the system is operational during (0, $t$ ) [10]. The aim of this paper is to compare the reliabilities of different multicomputer structures under similar task requirements. From *example* 1, it is clear that the reliability not only depends on the number of faults during (0, $t$ ), but it heavily depends on the exact location of the faults which is random in nature. The situation becomes more and more complicated with progress of time, not to mention other difficult structures such as trees, meshes and hypercubes, etc. Hence it is unlikely that an analytical solution to compute the reliability exists; we therefore resort to simulation.

The reliability, as discussed above, does not reveal the performance degradation due to failure of various components in (0, $t$ ). The computation availability ($CA$) of a gracefully degrading multicomputer is defined as the expected value of available computation at time $t$ [9]. This is directly proportional to the number of processors (nodes) operational at time $t$. Many other similar measures have been suggested by different authors to capture the dependability of

degradable computer systems [13, 14]. We develop an availability model for computation and communication as described in the next section.

We will consider only hard failure of the nodes and links and compare the fault-tolerant properties of various multicomputers for both repairable and non-repairable conditions. By non-repairable we mean that there is no on-line maintenance facility available to repair/replace the failed components. The failed elements are detected and isolated by the maintenance processor and are repaired only when the system goes to the failed mode. A more optimistic situation is to consider on-line repair which means a component is repaired/replaced whenever it fails. In this case the system dependability is greatly influenced by the repair rate. The effect of the failure rate and repair rate on the dependability of the systems are also analyzed.

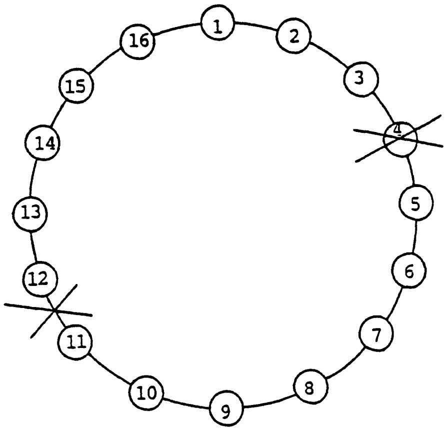

Fig. 1.b - A 16 node ring network after node 4 and link 11 have failed.

## 2. COMPUTATION AND COMMUNICATION

The most critical issues in the design of a distributed system are concerned with interprocess and interprocessor communication. It has been widely recognized that communication is at least as important as computation [15]. Hence, the communication capability of the degraded multicomputer must be considered with an equal weight taking into account both the node and link failures. It is also important to note that the component failures may bring in a structural change of the system. The loop structure of *example 1* , illustrated before, reduces to linear arrays after a node and a link failures. This structural change will result in a significant degradation in the communication ability of the network. Therefore, the previous availability models [9] do not represent the system performance adequately. Cherkassy et. al. [16] have considered both node and link failures in a tree network. However, because of the analytical complexity, they restrict their studies to single failures. Recently Tsuchiya [17] has presented a mathematical model for the availability analysis of distributed networks. But he does not consider performance degradation due to node and link failures. In this paper, we will study performance degradation with multiple failures and that too for various types of networks. Naturally, simulation seems to be the only way to accomplish this formidable task.

First, we have to determine a suitable measure for the computation and communication in a multicomputer system. The computation capability of a network is directly proportional to the number of operational nodes. The communication capability is usually measured in terms of the average delay of a message between a source and a destination. Under the usual assumptions of uniform traffic generation, fixed routing, etc. [5, 7], the delay is proportional to $\frac{\bar{d}}{1-\rho\bar{d}}$ [5], where $\bar{d}$ is the average number of hops a message passes through its route and $\rho$ is the utilization factor. Here $\rho = \frac{\gamma}{\mu C}$, where $\gamma$ is throughput in messages/sec, $\frac{1}{\mu}$ is the average message length in bits/message and $C$ is the total capacity of the network in bits/sec. When $\rho$ approaches $\frac{1}{\bar{d}}$ , the delay approaches infinity corresponding to a saturation traffic of $\gamma_{sat}$ . Then $\gamma_{sat} = \frac{\mu C}{\bar{d}}$ truly represents the communication capacity of a network. Here $\mu$ being a constant and $C$ being directly proportional to the number of links ($L$ ), $\gamma_{sat} = k_1\frac{L}{\bar{d}}$ for some constant $k_1$ . Although this is a good measure for the communication capability of the links, the number of nodes may be insufficient to handle that amount of traffic. In a network with $N$ nodes, $k_2N$ messages can be generated or processed in unit time for some constant $k_2$ . Hence, the actual communication capability is *Min* ( $k_1\frac{L}{\bar{d}}$, $k_2N$ ). With unit constants, we can safely assume *Min* ( $\frac{L}{\bar{d}}$,$N$ ) as a figure of merit. A similar measure was considered for the performance comparison of various multicomputers [7]. For simplicity (we guess), only the number of links ($L$ ) was chosen as the performance metric in [16].

The computation capability being proportional to $N$, we can define the computation-communication capability of a network as $N$.*Min* ( $N$, $\frac{L}{\bar{d}}$ ). The cost of a multicomputer system includes the cost of processors (nodes), links and I/O ports. If we start with the same number of nodes for all the structures we can assume that the cost is proportional to the number of links *(L)* . Taking performance and cost into account, we define the computation-communication availability of the system ($CCA_s(t)$) as:

$$CCA_s(t) = \frac{1}{L}\sum_{i=1}^{x} N_i .Min( N_i, \frac{L_i}{\overline{d}_i} ), \qquad (1)$$

where at time $t$, the network contains $x$ disjoint segments with the ith segment having $N_i$ nodes, $L_i$ links and average distance $\overline{d}_i$. $L$ is the total number of links of the initial configuration. We will consider disjoint segments that have more than two connected nodes [11]. Hence,

$$\sum_{i=1}^{x} N_i \leq N \quad \text{and} \quad \sum_{i=1}^{x} L_i \leq L$$

for $N_i \geq 2$. Note from the above CCA (t) expression that a completely connected structure will be node deficient where as a loop structure will be link deficient.

*Example-2*

Consider the situation depicted in Fig. 1. The $CCA_s(t)$ for Fig. 1.a is 1.63 and the $CCA_s(t)$ for Fig. 1.b is 1.38.

Computation-Communication Availability ($CCA$) as defined above can be interpreted differently for different applications. If the multicomputer only executes tasks that need a minimum of $I$ nodes, the $CCA$ is obtained by summing over the disjoint sets that satisfy this minimum requirement. When $I=2$, the availability is same as that denoted by the equation above. On the other hand for batch processing environments, where the multicomputer executes one task at a time, the $CCA$ of the system will be the maximum of the available computation-communications over all the disjoint multicomputer sets. The task can then be executed on any set that has at least $I$ connected nodes. If none of the disjoint sets has $I$ nodes the $CCA$ of the system is assumed to be zero, because it is of no use. These availability models are called *task based CCA* models in this paper in order to distinguish them from the absolute $CCA$ whose equation was derived earlier. The model is capable of computing both the absolute and task based $CCA$ 's of any multicomputer network.

## 3. SIMULATION TECHNIQUES

In this section we present the simulation techniques for the reliability and the $CCA$ evaluation of various multicomputer networks. We compute the task based reliability as used by Ingle and Seiwiorek [12]. It is defined as follows:

> "If a task needs at least $I$ processors for it's execution, then the system remains operational as long as these minimum resources are available on the system. Otherwise the system goes to the failed state. "

It is to be noted that this technique is a generalization of the previous methods used for reliability computation. For example, when $I=N$ ie. when a task needs all the processors and does not allow any graceful degradation, we get the good old reliability which is the series reliability of all the required components. For $I=2$, the model is similar to the one adopted in [11] and for $I=1$ it is equivalent to Beaudry's model [9].

### Failure and repair assumptions

It is assumed that the failure of the nodes and the links are exponentially distributed over time. A nonexponential assumption will only mean a change to the random selection of failing time and can be easily incorporated into the simulation. We assume homogeneity of all the nodes as well as of all the links to consider identical failure characteristics. Thus we define $\lambda_n$ and $\lambda_l$ as the failure rates of a node and a link respectively. The reliabilities of a node and a link are then given by $R_n(t) = e^{-\lambda_n t}$ and $R_l(t) = e^{-\lambda_l t}$. The node and link failure rates of a system are then given by $X\lambda_n$ and $Y\lambda_l$, where $X$ and $Y$ are the number of active nodes and links taking part in computation/communication at any time $t$. A node is considered active if it is a member of a set of connected nodes and a link is active if it is used for communication between two active nodes.

We consider on-line repair of the nodes and links with exponential distribution of repair times given by $\mu_n^{-1}$ and $\mu_l^{-1}$ respectively. We assume a small repair time of few hours that represents the actual repair duration of a component. However, we may not need such an instant repair facility because of the redundancy provided by the system or due to operating characteristics. So a variation of the above assumption is to stretch the (mean time to repair) MTTR duration. A practical implication of this policy is the unavailability of the repairman to attend the fault. If the unavailability period is very large the actual repair time is negligible and the repair rate is mostly determined by the mean unavailable time of the repairman. The repair is carried out until the system is in the working (up) state so that the system dependability can be computed.

### System representation

The representation of any multicomputer topology is given by an adjacency matrix $A$ using graph theoretic notations. The matrix elements $A[i,j]$ and $A[j,i]$ are '1' if there is a link between node $i$ and node $j$. Otherwise $A[i,j] = A[j,i] = 0$. A nonfailed node $i$, $1 \leq i \leq N$, is represented by making the diagonal element $A[i,i] = 1$. As an example the initial adjacency matrix for a 16 node loop network is given in Fig. 2.

$$\begin{bmatrix}
1&1&0&0&0&0&0&0&0&0&0&0&0&0&0&1\\
1&1&1&0&0&0&0&0&0&0&0&0&0&0&0&0\\
0&1&1&1&0&0&0&0&0&0&0&0&0&0&0&0\\
0&0&1&1&1&0&0&0&0&0&0&0&0&0&0&0\\
0&0&0&1&1&1&0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&1&1&1&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&1&1&1&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&1&1&1&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&1&1&1&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&1&1&1&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&1&1&1&0&0&0&0\\
0&0&0&0&0&C&0&0&0&0&1&1&1&0&0&0\\
0&0&0&0&0&0&0&0&0&0&0&1&1&1&0&0\\
0&0&0&0&0&0&0&0&0&0&0&0&1&1&1&0\\
0&0&0&0&0&0&0&0&0&0&0&0&0&1&1&1\\
1&0&0&0&0&0&0&0&0&0&0&0&0&0&1&1
\end{bmatrix}$$

Fig. 2 Initial Adjacency matrix for a 16 node ring network.

We use a reachability matrix $R$ [3] to show the graph connectivity. The matrix specifies whether or not there exists a path between two nodes which are not necessarily adjacent. The connectivity of any arbitrary graph can be obtained from it's adjacency matrix using any standard algorithm [18]. It is evident that the initial reachability matrix $R$ of any connected network has all it's elements as '1' indicating that there is a path from any node to any other node in the network.

Whenever a node $i$ fails all the entries of the $i$ th row as well as of the $i$ th column of the $A$ matrix are made '0'. Similarly if the random failure of a link destroys the connection between nodes $i$ and $j$, then the $A[i,j]$ and $A[j,i]$ elements of the $A$ matrix are made '0'. So the $A$ matrix is modified depending on the two types of faults. This modification of the $A$ matrix is then reflected in the reachability matrix $R$, which can be divided into various disjoint matrices having all the elements as '1'. For example the $R$ matrix for Fig. 1.b is given in Fig. 3. It can be observed that the failure of node 4 and link 11 has resulted in two disjoint sets. In one of the sets the connected nodes are {1, 2, 3, 12, 13, 14, 15, 16 } and the second connected set is { 5, 6, 7, 8, 9, 10, 11 }. These two sets are obtained from the $R$ matrix of Fig. 3.

$$\begin{bmatrix}
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
0&0&0&0&1&1&1&1&1&1&1&0&0&0&0&0\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1\\
1&1&1&0&0&0&0&0&0&0&0&1&1&1&1&1
\end{bmatrix}$$

Fig. 3 Reachability matrix for Fig. 1.b.

As we will analyze the variation of reliability with time, we divide the selected time frame into uniform intervals. Whenever a node and/or link failure becomes due, the program goes through the following steps:

1) An element is selected at random from the existing active elements.
2) If the fault is covered [19] then go to step 3, else increment the failed count of the system and start a new experiment again from time $t = 0$ with the initial configuration of the system.
3) The number of active elements is decremented by one.
4) The $A$ matrix is modified depending on the type of the fault.
5) The next fail time of the node/link is computed.

With the instant repair policy we use a single repairman service facility. The sequence of the steps for repair are:

1) When ever a component fails its repair duration is computed if the repairman is readily available. Else the component is kept in a *FCFS* repair queue till the service is available.
2) The node/link is returned to the system at the completion of repair and the $A$ matrix is modified.
3) The next failed element from the queue is taken up for repair.

The initial $A$ matrix is thus modified with random number of '0' entries due to the failure/repair of nodes and links with the passage of time. We compute the corresponding $R$ matrix at the specified time intervals. The $R$ matrix gives the connectivity information of each node which is employed to find the system condition.

The $R$ matrix, obtained above, is searched exhaustively to obtain all the available valid submatrices. A submatrix is valid if it has all 1's so that it can represent a set of connected nodes (subgraph). The communication performance of a subgraph is then obtained from $Min\,(N_i, \frac{L_i}{\bar{d}_i})$, where $N_i$ is the number of active nodes in subgraph $i$, $L_i$ is the number of links that are used for communication and $\bar{d}_i$ is the average distance a message has to travel in the $i$ th subgraph. $N_i$ is obtained by counting the number of nodes in subgraph $i$. $L_i$ is obtained by counting all $A[j,k]$ such that $j, k \in$ {subgraph i} and $k \geq j+1$. The average distance for an arbitrary network is defined as:

$$\bar{d} = \frac{\sum_{j=1}^{N_i} \sum_{k=1}^{N_i} d_{jk}}{N_i\,(N_i - 1)}$$

where $d_{jk}$ is the shortest distance from node j to node k. So we use a shortest path algorithm [18] to find $d_{jk}$ from any node to any other node in the subgraph and finally compute $\bar{d}$. The adjacency matrix $A$ is used to find the shortest path between nodes of a subgraph. So the sequence of steps the program goes through to find the $R_s(t)$ and $CCA_s(t)$ at some specified time $t$ are:

1) Compute the $R$ matrix from the $A$ matrix and find the various disjoint groups from the $R$ matrix.
2) Select the number of groups 'x' that satisfy the minimum resource requirements I; if any.
3) If x=0, then the system can not satisfy the resource requirements. Increment the failed count and start the experiment again from the initial configuration of the system. Reset the system time.
4) Otherwise for each subgroup $x_i$, find the $N_i$, $L_i$ and $\bar{d}_i$ from the $A$ matrix as explained earlier.

We use multiple independent repetition technique to determine the $R_s(t)$ and $CCA_s(t)$. The failed count is used to obtain the system reliability and $N_i$, $L_i$, and $\bar{d}_i$ are used to find the $CCA_s(t)$ from equation 1.

## 4. SIMULATION RESULTS

The simulation model, discused in section 3, can be used to analyze any arbitrary network topology. It accepts the initial $A$ matrix and the task requirement $I$ as the input parameters and gives the reliability $R_s(t)$ and computation-communication availability $CCA_s(t)$ variation with time. We present here the fault-tolerant capability of five types of multicomputer networks. They are: Full connection (FC), mesh, Hypercube (HC), binary tree and ring networks. The topologies are shown in Fig. 4. Performance and cost parameters for these networks are reported in [5-7].

We have taken an initial configuration of 16 nodes ($N = 16$) for all the networks. Most of our results are based on a node failure rate $\lambda_n = 100$ in $10^6$ hours and link failure rate $\lambda_l = 20$ in $10^6$ hours. The processor failure rate is taken close to that of an LSI-11 processor [12]. The link failure rate is taken one fifth of the processor failure rate and does include the interfaces at both ends of the link. The effect of varying the node and link failure rates are also discussed. We would like to emphasize that the model accepts these failure rates as inputs and hence is suitable for any other failure rates that can be determined for another implementation based on a component count and technology.

Fig. 5 shows the variation of reliability with time for all the above networks when the task needs a minimum of 12 processors and with no repair facility. The results indicate that the FC has the maximum reliability as expected. The reliability of the HC is very close to that of the FC even if it's number of links are only 32 compared to 120 in the FC. This suggests that with a typical link failure rate of 20 in $10^6$ hours four alternate paths from each node is sufficient to provide reliability close to that of the complete connection.

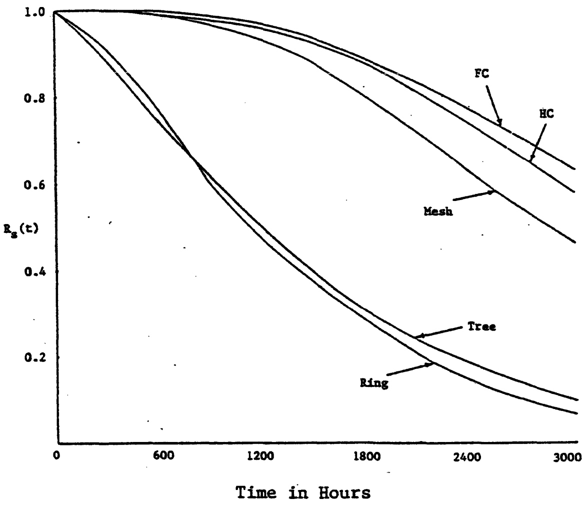

Fig. 5 Reliability variation with time for a task requiring 12 processors and without repair.

$\lambda_n = 0.0001$, $\lambda_l = 0.00002$, coverage = 1.0.

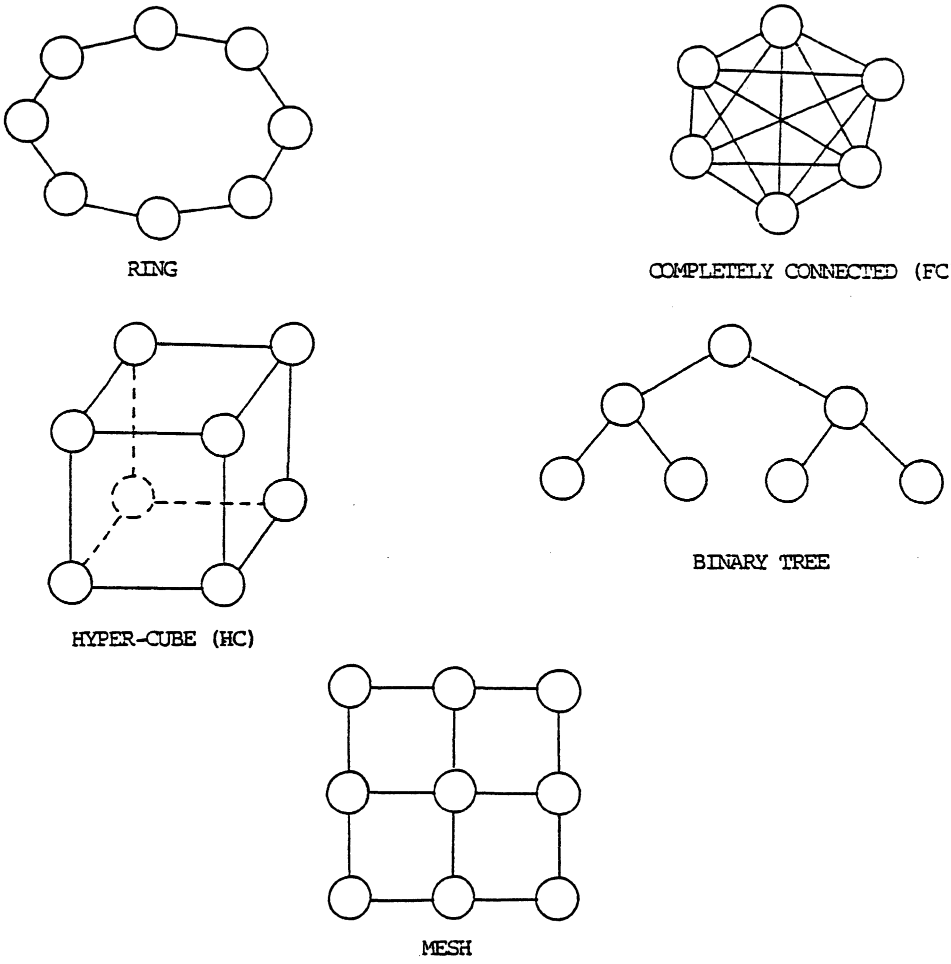

Fig. 4

The ( $N$ -1 ) links from each node in a FC is mostly required for better communication capability and do not increase the reliability linearly. The mesh connection is in the middle range of the reliability bounds. The tree and ring connections have similar poor reliability property. Table I compares the reliability of the five structures for $I=8$, $I=12$ and $I=16$. Naturally as we decrease the value of $I$ ( allow more graceful degradation to the system ) the reliability of the multicomputers increase.

Now, let the system level requirements be that the system has to run for a 1000 hour mission time (unmaintained) and must have $R_s(1000) \geq 0.9$. Fig. 6 shows the effect of node failure rate on the system reliabilities at $t=1000$ hours for $I=8$. It is observed that the FC has the minimum threshold node reliability $R_{nT}$ and is 0.62. The HC and mesh topologies are next in order with individual $R_{nT}(1000)$ being 0.65 and 0.75. So based on the task requirement and operating conditions the above three networks can be designed with less reliable processors. $R_{nT}(1000)=0.92$ for the tree and ring structures. If we increase the task requirement to 12 nodes it is obvious that the threshold $R_n$ for all the networks will also increase. For $I=16$ the system reliability curve for all the networks will lie below the $R_n$ line and $R_{nT}(1000)$ must be $>0.9$ so that the required system reliability is maintained. A practical implication of these observations is that the FC, HC and mesh are considered more costly compared to star and ring topologies. This is based on the assumption that we use the same processors for all types of networks. But if we can design a FC/HC/mesh with less reliable processors and still can assure the system reliability, then why should we spend more by using the same reliable processors as we need for the star or ring architecture?

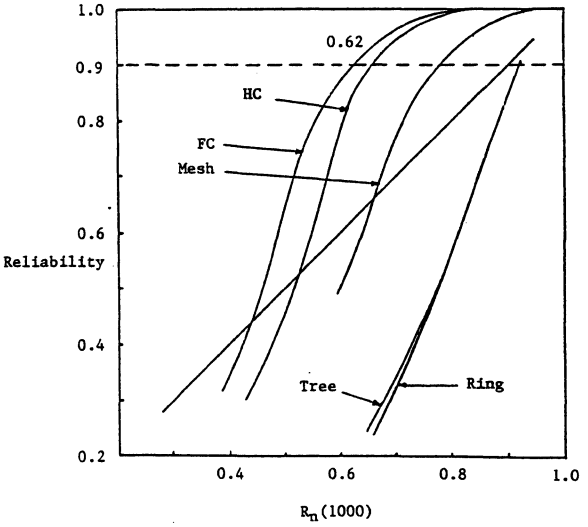

Fig. 6 . Effect of node failure rate on system reliability without repair at t=1000 hours for I=8.

$\lambda_n$ = 0.0001, $\lambda_\ell$ = 0.00002, coverage = 1.0

Fig. 7 shows the variation of $CCA_s(t)$ with time for the five topologies and with no-repair. We use $I=2$ to compute the absolute $CCA$ . It is seen that the FC behaves worst in this case. Even though the FC has the maximum communication performance ( $\bar{d} = 1$ ), its large number of links brings the performance/cost ratio down. The tree and the ring connections lie in the middle of the graph suggesting that they have a fair performance and low cost. They are suitable for applications where communication requirements are not stringent. The HC connection gives the best performance/cost behavior. This is because it has an optimum number of links to provide reliability and $CCA$ close to those of the FC.

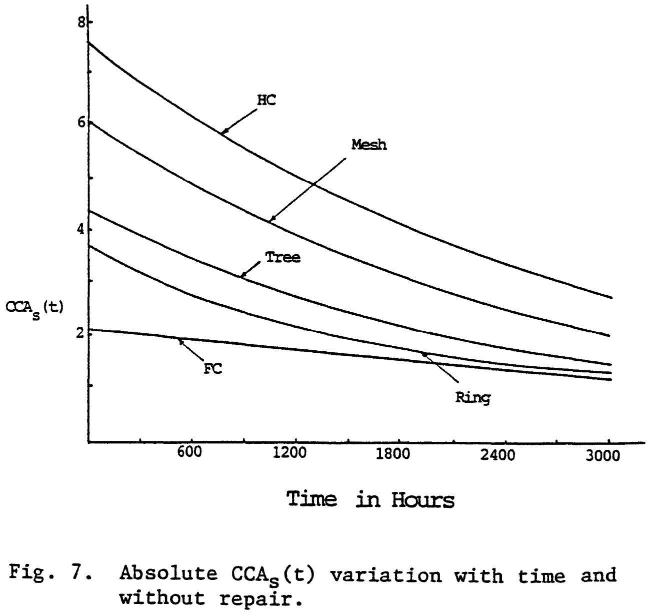

Fig. 7. Absolute $CCA_s(t)$ variation with time and without repair.

$\lambda_n$ = 0.0001, $\lambda_l$ = 0.00002, coverage = 1.0.

Table II shows the task based $CCA$ comparison of the five topologies. It can be observed that the $CCA_s(t)$ of the FC shows the least degradation with time. This is because of very good fault- tolerance and communication attributes. The mesh connection has the second best $CCA$. Comparing the results of Fig. 7 with those of table II for $I=8$, we can observe that $\sum_{i=1}^{x} CCA_i(t)$ of all the subgraphs with minimum two connected nodes gives less $CCA$ degradation with time for all the structures except for the FC. This implies that the FC has very low probability of having a subgraph with less than 8 nodes in 3000 hours. But the $CCA$ of the ring and tree structures increases dramatically for $I=2$.

The task based $R_s(t)$ with repair is given in Fig. 8 for $I=12$, $\mu_n^{-1}=10$ hours and $\mu_l^{-1}=2$ hours. The effect of repair can be observed by comparing the results with those of the tabulated values given in table I. However, the reliability of the tree topology does not increase as of other structures because of it's unsymmetrical nature. Repair has no effect on the reliabilities of the five structures for $I=16$ (results are not shown in the Fig.).

The effect of varying the node repair interval on the normalized $CCA_s(1000)$ is plotted in Fig. 9 for $I=8$. Here we have assumed separate repair facility for the nodes and links. The results show that different topologies can have different repair intervals to maintain a specific system degradation.

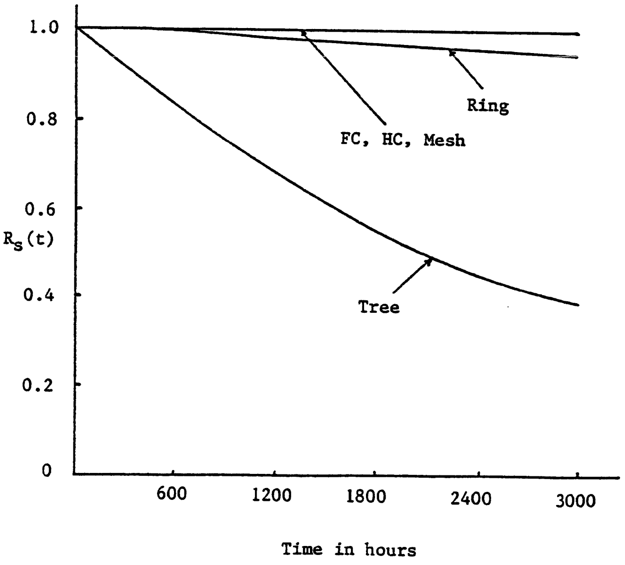

Fig. 8 Reliability variation with time for I=12 and with repair.

$\lambda_n$ = 0.0001, $\lambda_\ell$ = 0.00002,

$\mu_n$ = 0.1, $\mu_\ell$ = 0.5, coverage = 1.0.

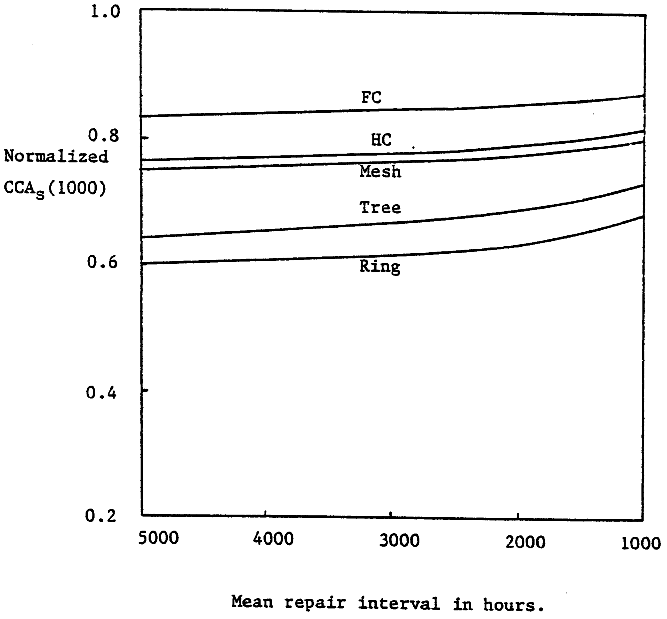

Fig. 9 Normalized $CCA_s(1000)$ against repair interval.

$\lambda_n$ = 0.0001, $\lambda_\ell$ = 0.000005

$\mu_\ell$ = 0.00005, coverage = 1.0.

## 5. CONCLUSIONS

Reliability and computation-communication availability ($CCA$) evaluation of multicomputer networks, with and without repair, are presented in this paper. Simulation is adopted because of the analytical intractability of the problem. The simulation model is quite general and is applicable to all multicomputer graphs. Typical results obtained in section 4, indicate that the hypercube structure performs the best from the reliability and availability stand points. It's cost and performance were earlier shown [5] to be a reasonable balance between loop and completely connected structures.

The effects of node failure rate and repair rate on the system dependability are quite interesting. It is observed that in order to maintain a specified system reliability the node reliability of different networks differs. This is because of the difference in degree of a node of different graphs. Similarly the required frequency of repair varies for various networks to keep the $CCA_s(t)$ within a specified degradable range. These observations lead to another interesting problem: Generally we express the cost of a network in terms of the number of links. This does not take into account the processor reliability at the design phase and the repair cost at the maintenance phase. But we have seen that the threshold node reliability and the node repair rate are lower for structures like FC/HC compared to those of ring/star networks for maintaining a static reliability or availability. Hence, a more appropriate cost model of a network is necessary taking into account node reliability, link cost and repair cost, as is done for software life cycle models. This will allow us to compare the cost of different networks over a specified mission interval.

**Abstract**

This paper describes the maintenance architecture and its LSI implementation of the SIGMA-1, an ultra high speed data-flow computer for numerical computations in scientific and technological applications. The multi-PE version of the SIGMA-1 adopts the semi-custom LSI implementation approach. LSI implementation is closely related to testability and maintenability. In a parallel processing system with a large number of processors, the architecture for resource management, debugging and maintenance is important as the architecture for program execution. The SIGMA-1 uses combined SIMD/MIMD maintenance architecture. Design policy, implementation method, and improved architecture, including maintenance architecture, are discussed.

# 1 Introduction

Data-flow architecture is identified as the most suitable architecture for parallel processing systems. The main reasons are: The hardware construction of a large-scale parallel processing system using data-flow architecture is much easier than von Neumann architecture; and data-flow computing exploits all the parallelism in a program at the architecture level. Much research has been conducted [1-6] and several prototype data-flow processors have already been built [7-10].

The SIGMA-1 is an instruction-level data-flow computer developed at the Electrotechnical Laboratory. The main objective of the SIGMA-1 is to build an ultra-high speed computing environment, to execute numerical computations in scientific and technological applications such as Monte Carlo simulations and particle simulations that cannot be executed efficiently on a conventional vector processor.

The prototype SIGMA-1 processor with a processing element (PE) and a structure element (SE) is in full operation now[11]. The performance of this prototype is approximately equal to the performance of a von Neumann processor constructed using the same technology [12]. The estimated performance of the SIGMA-1 with 200 processing elements exceeds 100 MFLOPS.

This SIGMA-1 prototype has brought out several problems in constructing a data-flow computer system with a large number of processors. The prototype SIGMA-1 processor is constructed by conventional TTL MSI technology. Size, power consumption and hardware reliability will be serious problems if the same implementation technique is used in the construction of the final SIGMA-1 system. Therefore, LSI implementation of the SIGMA-1 is necessary to construct a system with two hundred processing elements.

In a parallel processing system with a very large number of processors, the architecture for resource management, debugging and maintenance (maintenance architecture) is as important as the program execution architecture. LSI implementation of data-flow architecture makes more difficult to perform operations needed in resource management, testing, maintenance, and debugging.

This paper describes LSI implementation and maintenance architecture of the SIGMA-1 and discusses the problems in the constructions of a data-flow computer with large number of processors. Section 2 outlines architecture of the SIGMA-1 and problems in constructing data-flow computing system with a very large number of processor and the way to avoid them in the SIGMA-1. Section 3 discusses the LSI implementation approach for constructing a data-flow processor including interconnection network. Section 4 describes the maintenance architecture of the SIGMA-1 that performs resource management, maintenance, and debugging.

# 2 SIGMA-1 Architecture

## 2.1 Architecture

Figure 1 shows the global architecture of the SIGMA-1. Four processing elements (PEs) and four structure processing elements (SEs) connected by a local network (LNET) form a group. A process or a subroutine is assigned to one of these groups. This group acts as a high-performance processor in the execution of assignment task.

0190-3918/86/0000/0584 $01.00 © 1986 IEEE

Therefore, interconnection within a group must have high speed and high capacity, otherwise the performance of sequential computing segments of programs decreases. The SIGMA-1's local network, 10 by 10 crossbar packet switching network eliminates this problem.

The global network, a two-stage omega network which connects up to 64 local networks is used for communicating processes and accessing structure processing elements. The SIGMA-1 adopts a new load distribution method [14] implemented in an interconnection network. The computer simulation [14] shows that this load distribution by that method is very close to ideal distribution.

Figure 2 shows block diagrams of a PE and an SE. A PE executes all the instructions and data processing operations except structure operations, and an SE executes structure operations such as read, write, allocate and deallocate.

A PE consists of a FIFO buffer (B), an instruction fetch unit (F), a matching unit (M), an execution unit (E) including a floating point arithmetic unit, and a distribution unit (D). Five units in the PE are arranged to operate in a two-stage pipeline. The B unit stores 8K packets, where a packet consists of 89 bits. The M unit stores 64K packets and fires two-input operations. Single bank chained hashing is used for performing matching. The F unit reads the instruction memory according to the address information on the input packet and also reads immediate operands from the instruction memory. The E unit consists of an integer ALU, a floating point ALU, a structure address generator, an input data-type checker and a sequencer. The D unit consists of a PE address generator, a loop count controller, and an output buffer.

An SE consists of a FIFO buffer (SB) and a structure memory unit (S) which includes a structure memory, hierarchical flags, and waiting queue control circuits. Detailed construction is described in [15].

Experience with the single processor SIGMA-1 shows several problems in constructing a data-flow computer system with a large number of processors. The way to avoid the main problems, synchronization and performance on sequential computation of programs, are discussed below.

## 2.2 Synchronization

Synchronization out of concurrent processes and synchronization between processing elements and memory systems are included in the first problem. A data-flow architecture solves the synchronization problems based on data dependency in a parallel processing system since the instruction the arrival of input data triggers the instruction execution. However, in a data-flow architecture it is very difficult to solve synchronization problems which are independent of data dependency since the execution of such instructions is partially decided by the data dependency of the program. This kind of synchronization is necessary for managing activities on processors, detecting program termination, mutual exclusion and sequentializing associated with I/O operation.

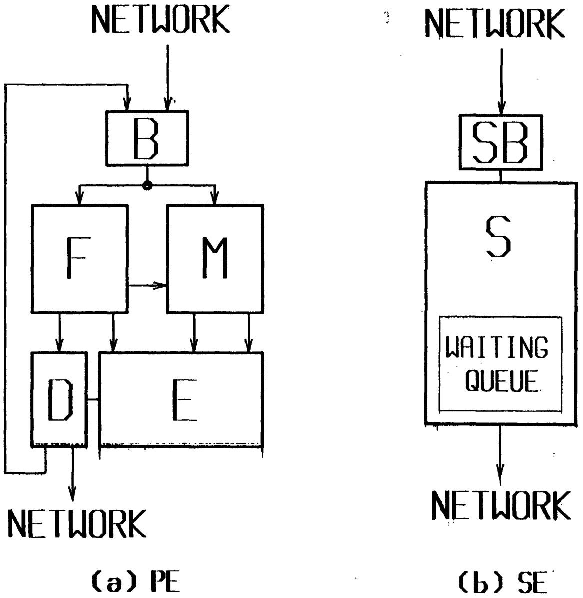

Fig.2 Block Diagrams of Processing Elements

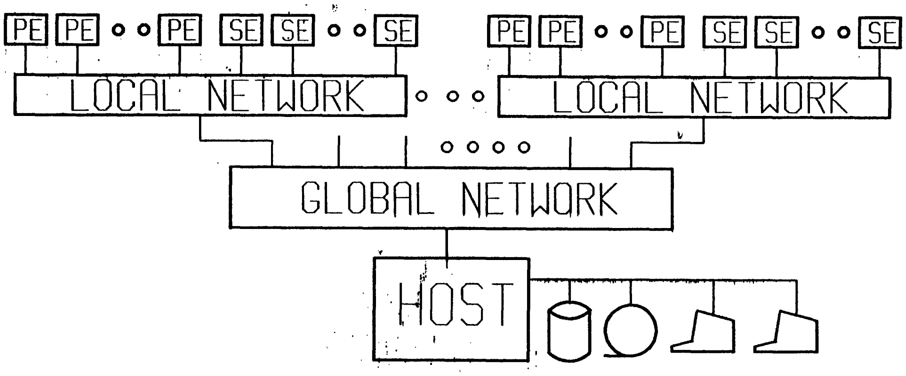

Fig. 1 Global Construction of the SIGMA-1

The SIGMA-1 solves this synchronization problem using operations based on static data-flow model and the maintenance architecture discussed in section 4. In order to realize such operations, the SIGMA-1 utilizes the order preserving property within processing elements and networks and instruction firing and execution without a matching memory. Detailed synchronization based on static operations is discussed in [13].

## 2.3 Performance on Sequential Computing Segments in Programs

Performance of the sequential computations in a program is important in most matrix computations such as linear equations and eigenvalue problems. Figure 3 shows sequential computing segment of matrix computations. Here, the results from operations on all matrix elements (eliminating step or rotation) are accumulated into a scalar variable, then distributed to all elements or all vectors in pivoting in Gaussian elimination and convergence test in iterative programs are performed. In circular pipelined data-flow architecture, all data manipulated by instructions circulate through all processor pipeline stages. However in a von Neumann processor, the data circulates only in the execution stages. This is shown in figure 4. In general, circular pipelined data-flow architecture decreases the performance of the sequential computing segments of a program even in the matrix computations. In order to avoid this problem, the SIGMA-1 uses 2-stage short pipeline control architecture and advanced packet sending mechanism. At the result of this improvement, single input instructions are executed in every 2 clock cycles and two input instructions are executed in every 3 clock cycles in a pure sequential program.

# 3 LSI implementation

The prototype PE constructed consists of eight printed circuit boards with approximately 1900 TTL MSI and MOS memory chips. The number of boards, size, power consumption and reliability prohibit the use of prototype PE's in the construction of the final SIGMA-1 system which has 200 processors. Thus LSI implementation is necessary for constructing the final system.

Data-flow architecture has following characteristics:

1. A data-flow processor does not have registers or history sensitive memories.
2. Pipeline stages in a data-flow processor does not interfere each other except for input and output connection to the neighbouring stages. Independency of each unit enables simple unit design.
3. Communication between processing elements is performed as packet communication. This simplifies interfacing between processing elements.
4. Five memory accesses, two read and two write (insert and delete) accesses to a matching memory, and a read access to an instruction memory are necessary for a two input instruction execution. Figure 5 shows typical memory accesses for an instruction. This is 2.5 times that of a von Neumann processor memory access, where one read access for instruction fetch and one read/write access to data access is performed.
5. Since the concurrency in a program is determined by data dependency, a large buffer that stores excessive parallelism during execution is necessary.

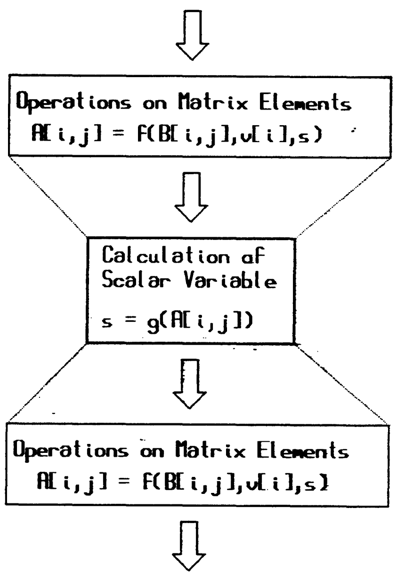
Characteristics (1) to (3) support LSI implementation, while (4) and (5) imply that the data-flow processor requires wider connection between a processing element and memories.

Several approaches in implementing data-flow architecture are considered in the following paragraphs. The first is a single chip approach. Tthere are approximately 60,000 gates in a SIGMA-1 PE. Therefore, it is possible to design a single chip PE by current VLSI technology either adding a sufficient number of pins to the chip or installing buffer memories and matching memories in the chip. However, these conditions cannot be satisfied by the current VLSI technology. Hence, memory interface signals must be multiplexed on a limited number of pins on a chip. Since a data-flow processor requires wider connection between a PE and memories, data-flow architecture is much better than von Neumann architecture if implemented in a VLSI chip.

The second approach is to construct a processing element using ready-made LSIs such as AMD2901 and a microprocessor. Ready made LSIs for fixed-point and floating-point ALUs are most suitable for constructing an experimental processor. However, no ready-made LSIs are available for the most important units, the matching unit, the instruction fetch unit, and the distribution unit in a data-flow processor since they are not common in von Neumann processors. Therefore, the performance of a data-flow processor is reduced if constructed by ready made LSIs.

The single chip approaches are inappropriate for constructing an experimental data-flow processor. We have chosen the third approach, semi-custom LSI approach, for constructing the final SIGMA-1 processing elements. In commercial computers, semi-custom LSI approach has been widely accepted. Design and manufacturing cost for semi-custom design are comparatively high. In addition, modifications to the manufactured LSI is impossible. This is an obstacle for LSI implementation of an experimental processor.

Table 1 shows hardware of the prototype and the final processing element. The final PE consists of semi-custom LSIs, gate arrays and standard-cell LSIs, CMOS memories, and a number of SSIs for drivers and receivers. A PE has eight types of gate arrays, a standard cell LSI,



Operations on Matrix Elements
A[i,j] = F(B[i,j],v[i],s)
Calculation of Scalar Variable
s = g(A[i,j])
Operations on Matrix Elements
A[i,j] = F(B[i,j],v[i],s]

Fig.3 Sequential Computing Segment of Matrix Computation

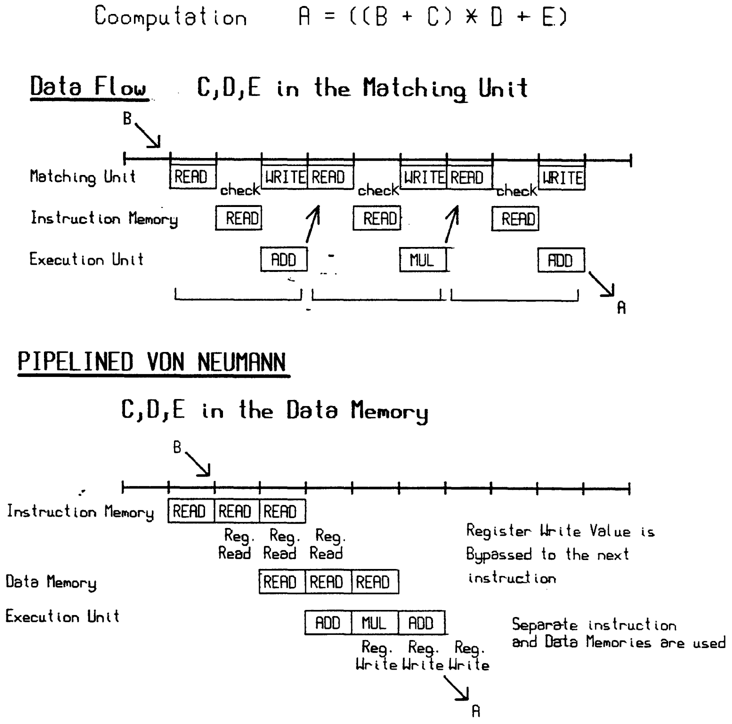


Fig. 4 Execution of a Pure Sequential Program

and contains 28 LSIs. About 42% of ICs in a PE are in the matching unit, (see table 1). This indicates that the matching unit is the most important unit in the SIGMA-1.

These LSIs and memories are assembled on a printed circuit board. The total number of gates in a PE, excluding memories, is approximately 81,000. The total memory capacity in a PE is approximately 1 MB. This includes gates for test and maintenance circuits which will be explained in the next section. The net number of gates, estimated at 54,000, is almost the same as that of a pipelined von Neumann processor employing the same technology. Since the component count is 1570 and there are six printed circuit boards per a PE, both the number of components and the number of printed circuit boards are reduced by one fifth to one sixth of those in a prototype hardware.

# 4 Maintenance Architecture

## 4.1 Maintenance architecture for a dataflow processor

Computer system time for an user includes program execution time, hardware and software initialization, program loading and unloading, execution of an operating system including resource management, program debugging, and hardware testing and maintenance operations. It is necessary to decrease all the computer time to construct a high-speed computing system. So far, resource manage-

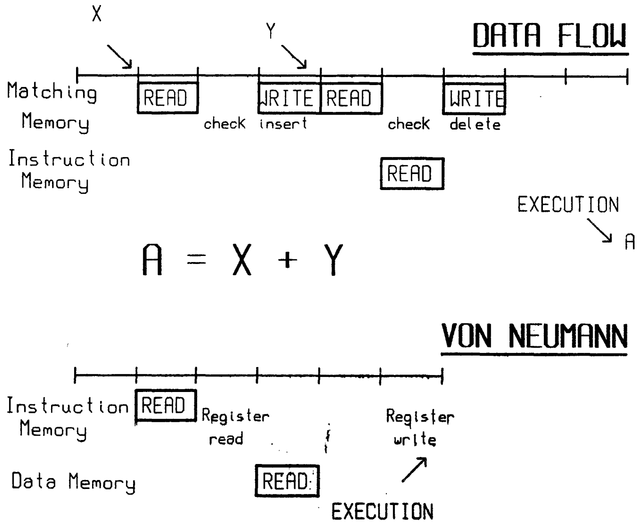

Fig. 5 Memory Accesses for an Instruction

ment, maintenance, and debugging operations on a parallel processor system are performed mutually by many element processors or by a single service processor [16]. If these operations are performed mutually by many processors, it is difficult to control them when overflow or deadlock in hardware resource occurs. If these operations are performed by a single service processor, resource management, maintenance, and debugging can be controlled even if overflow or deadlock occurs. However, the time required for these operations increases linearly with the number of element processors in a system. Hence, the single service processor approach would not be fruitful in a parallel processing system with a very large number of processors. In order to achieve a tolerable time for these operations, a special purpose parallel architecture for resource management, maintenance, and debugging is necessary. This architecture is the "maintenance architecture" of a processor, while the "program architecture" executes the program.

Maintenance architecture is more important in parallel processing environment with a very large number of processors than in a uni-processing environment. The performance of program architecture does not increase linearly with the increasing number of processors in a system. In general, the number of maintenance operations increases slightly more than linearly as the number of processors increases, and interconnection hardware is added to element processors. Consequently, the ratio of program execution time to non program execution system time becomes lower with the increasing number of processors in a system.

When the program architecture is data-flow, non data-flow maintenance architecture is essential because a data-flow architecture alone cannot perform certain kinds of testing and maintenance operations. History sensitive operations or computations utilizing side effects are essentially necessary for resource management, maintenance and debugging. For example, neither the arrival of a data token at a certain node nor data tokens sent to an incorrect position can be detected only by data dependency relationship. Basic hardware tests, such as the connectivity test between components, cannot be performed on data-flow architecture. A von Neumann processor can perform these tests since it can handle history sensitive or side effect operations. Therefore, either von Neumann architecture or non-data-flow architecture is required for maintenance architecture in a data-flow processor. A correct program is successfully executed but the behaviour of incorrect programs or wrong hardware cannot be analyzed by the data-flow architecture itself, since the execution of a data-flow processor is solely determined by data

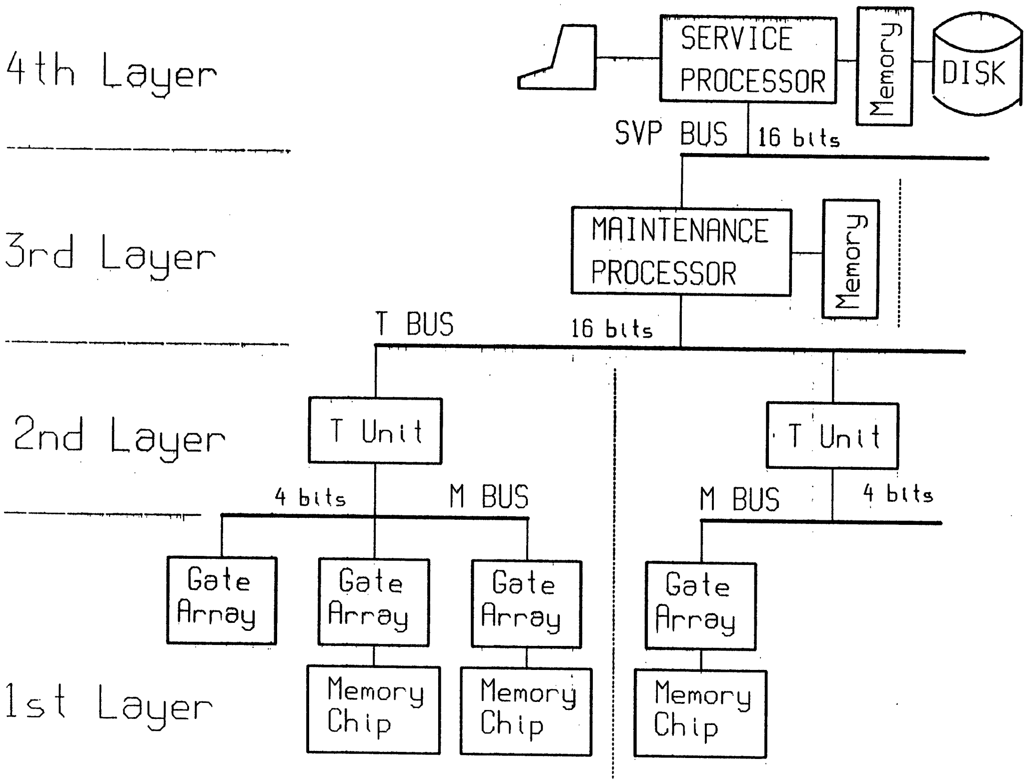

Fig.6 Maintenance Architecture of the SIGMA-1

availability. Hence, a processor solely based on data-flow architecture cannot exist as a standalone computer system, and it is necessary to combine it with non-data-flow maintenance architecture.

## 4.2 SIGMA-1 Maintenance Architecture

The main objective of the SIGMA-1 maintenance architecture is to perform resource management, maintenance, and debugging as fast as a single von Neumann type processor in the 200-PE SIGMA-1 system. For this purpose, the parallelism in the maintenance architecture must be more than that in program architecture because performance of the program architecture does not linearly increase with the increasing number of processors but resource management and maintenance operations increases slightly more than the number of processors in program architecture. Resource management, maintenance and debugging require global control and global data exchanges. Therefore, these operations cannot be executed in independent service processors attached to processor groups in the system.

In order to fulfil these requirements, the SIGMA-1 maintenance architecture adopts a combined SIMD/MIMD parallel architecture. Figure 7 is a block diagram of maintenance architecture in the SIGMA-1. The first and second layers are special purpose SIMD maintenance processors and perform basic operations on hardware components. The third and fourth layers operates as von Neumann MIMD processors and perform high and abstract level resource management, maintenance, and debugging.

The first layer of the SIGMA-1 maintenance architecture consists of maintenance circuits, including conventional scan-in and scan-out circuits in PEs and SEs. This layer accesses all memories, registers and important control signals inside and outside LSIs. All memory cells, registers, and important logic signals are accessed according to M (maintenance) commands sent through the M Bus from T units. All the maintenance items in the first layer are uniquely addressed in the system. Data transfer rate by the first layer is limited, since the data transfer width of the M Bus is limited to four bits and accesses to memories and registers are limited to one bit at a time. However, all the maintenance circuits in the first layer operate concurrently in SIMD fashion. About 33% of logic gates are used in the maintenance circuits. This layer also controls several hardware resources such as the number of packets in a FIFO buffer (B) in a PE, the load factor of a matching unit, execution count of a certain instruction, and deadlock status. This information is passed to higher layers as attention signals and used in the run time control program in the third and fourth layer processors.

The second layer consists of maintenance units (T units) installed one per PE, SE and network board. A T unit is a microprogram controlled special purpose processor that consists of one gate array (2600 gates) and a microprogram ROM. The objective of this layer is to combine bitwise operations in the first layer into wordwise logical operations. The microprogram in the T unit translates the logical maintenance command into a sequence of M commands. These commands are sent to the first layer and gather data from the first layer. The second layer watches for attention signals and controls the system clock signal if necessary. The T unit receives commands and exchanges maintenance data with the maintenance processor through the T Bus.

The third layer consists of maintenance processors, one per group comprising four PEs, four SEs, and a local or global network. A maintenance processor is a commercial microprocessor (8086) with no secondary storage device. This layer checks data from T units, generates maintenance commands to T units, and extracts error or debug information in the data from T units. The fourth layer is a service processor. The service processor, VAX 11/750, is the host processor of the SIGMA-1. This layer is in charge of global human interface control.

The final SIGMA-1 system consists of one service processor, 40 maintenance processors, 360 T units, and over 10,000 maintenance circuits in LSIs.

The maintenance architecture in the SIGMA-1 supports fault tolerant operations. Break down in a processing element breaks down is notified to the service processor immediately. Then the system clock signal to the faulty hardware stops and change configuration registers in networks and processing elements are modified correctly. Thereafter the system operates normally. In this case, maintenance operations can be performed even if the system clock is not applied to processing elements and masks handshake signals in the SIGMA-1 hardware.

# 5 Conclusion

Several problems in constructing a large-scale data-flow computing system with a very large number of processors have been discussed in this paper. Data-flow architecture can solve only some of the problems encountered in a parallel processing system. In the SIGMA-1, most of the other problems are solved by architectural improvements in processing element, network and maintenance architecture.

Semi-custom LSI implementation of the SIGMA-1 indicates that a high-performance data-flow processor with about 1 MB memory can be installed on a printed circuit board. For construct a parallel processing system with a very large number of processors, the data-flow architecture is more suitable than the von Neumann architecture, since the connections to network are much easier in data-flow architecture.

From the hardware point of view, the merit of data-flow architecture is the easy expandability to a large system. Therefore, single chip VLSI implementation is indispensable. However, there are several problems to solve for achieving a single-chip high performance data-flow parallel processor. Some of them are:

1. Design of an efficient, reduced and refined instruction set to reduce the instruction set and the number of instructions executed in a program,
2. Design more efficient matching unit for compact installation of a PE, and
3. Efficient hardware resources management in a PE and an SE.

The preliminary version of the SIGMA-1 PE and SE have been in operation since the latter half of 1984. The final version of the SIGMA-1 was designed and fabricated at the end of 1985. A single group with four PE, four SE and a local network will be in operation at the end of 1986. The final system, consists of 200 processing elements, with a total predicted performance of 100 MFLOPS will be in operation by the end of 1987.

**Abstract:** The problem of array handling is a major issue in the design of data-flow multiprocessor systems. We demonstrate here two solutions (namely the I-structures and the token relabeling approach) and apply them to two well known numerical algorithms. The Fast Fourier Transform and the LU decomposition algorithm have been chosen since they are representative of a large class of algorithms and provide good benchmark for the evaluation of the performance of data-flow systems. We base our research upon the MIT tagged data-flow architecture. The results of a deterministic simulation of Arvind's data-flow machine are presented and show the contrast between the two structure representation methods.

## I. INTRODUCTION

Data-flow systems have been proposed as an alternative to the cumbersome programming methods offered by conventional von Neumann computers. The traditional model of computation implies a central control (the Program Counter) as well as a global state (the memory system represented by the *variables* in the high-level programming language). On the other hand, in a data-flow system, the executability of an instruction is decided by the availability of its operands, thereby implementing a ***distributed control*** very amenable to parallel implementation. For more details, the interested reader may refer to excellent surveys of data-flow principles by Treleaven (1982), Srini (1986) or to a special issue of IEEE Computer magazine (1982).

While these principles describe the interaction of *scalar* elements, careful attention must be given when dealing with larger structures. In this paper, we study in more detail the I-structures (Arvind and Thomas, 1978) and the token relabeling approach (Gaudiot, 1986, and 1985). In section II, we describe these two methods. The two algorithms used for illustration are described in section III and their data-flow graph representations are then explained. The simulated machine and the results from the simulation are shown in section IV. Concluding remarks are made in section V.

## II. ARRAY HANDLING

The basic data-flow principles as described above apply mostly to scalar operations. When large data structures are involved, a different mode of processing must be entered. Indeed, the underlying rule of data-flow systems is the ***single assignment*** principle. It implies that no variable can be assigned a value more than once in the course of the program. A scalar token (a value) cannot be modified but a new token can be created after the appropriate processing. Large data structures can be likewise created after "modification" but the copying operation can impose large overhead if a single element of large element array should be modified. For this reason, several schemes have been developed in the past. We will now describe some of the most representative ones.

### 2.1. Heaps

This scheme has been originally described by Dennis (1974). It involves representing an array as a tree of pointers. When a single array element must be modified, only a sequence of pointer modification steps is involved. For an $n$ element array, the cost of modifying a heap is proportional to $\log n$ which compares favorably with a cost proportional to $n$ when the original array is entirely copied. There are several disadvantages which have been associated with the heaps (Arvind and Gostelow, 1982). These include a sequentialization of some array operations, a centralization of array accesses, storage overhead, etc.

### 2.2. I-structures

The I-structures were introduced by Arvind and Thomas (1980) in order to permit pipelining between the producer and the consumer of structures. In other words, an array element should be readable before the entire array has been produced. This scheme can be implemented by the addition of "presence bits" which can be associated with every cell of storage. When a request is made to a "full" cell, the data can be forwarded to the requestor. When the cell is found to be empty, a tag is left, indicating the forwarding address of the original requestor. When the data is ready, it can be directly forwarded to its intended destination.

This method obviously reduces the latency between the creation of a data element and its consumption and allows a more flexible scheduling of operations. However, it introduces additional overhead at execution time and also requires the design of a complex I-structure handling hardware mechanism.

### 2.3. Token relabeling

This scheme was described by Gaudiot (1985) for a data-flow system which uses the U-interpretation principles. When a producer and a consumer of an array can be readily identified, the notion of structure can be entirely ignored at the low-level. Instead, the *tag* associated with each token under the rules of the U-interpretation is used as

*This material is based upon work supported in part by the National Science Foundation under Grant No. ECS-8404345 and by the USC Faculty Research and Innovation Fund

identification of the index of the array element of the high-level language. In other words, it can be simply said that, when an array A is created, its A(i) element is tagged with "i" (Note that the tag is in fact a more complex structure but this simplified description is sufficient in the context of this paper). This approach can be applied very easily to some operations such as the Fibonnaci numbers (Fig. 1) where R1 and R2 are actors which respectively add 1 and 2 to the input iteration tags in order to allow the result produced by the "add" operator during iteration "i" to be re-used during iteration "i+1" and "i+2".

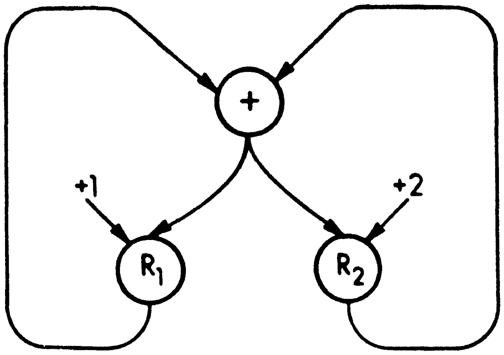

Fig. 1. Token relabeling

More complex program structures are involved in order to apply the scheme to *scatter* and *gather* operations. These constructs, such as the *gather* situation illustrated in Fig. 2, would not be easy to implement (Gaudiot, 1985):

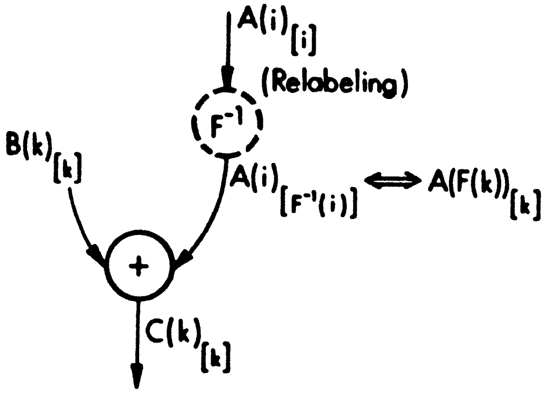

Fig. 2. Gather

```
    DO 1 I=1,100
1   C(i) = B(i) + A(F(i))
```

An inverse function $F^{-1}$ unknown at compile time would be needed to perform the relabeling of data-flow tokens. It has been shown that such a calculation is not necessary. Instead, we introduce in the calling program a sequence generator which produces the F(i)'s, tagged by i (Fig. 3). A relabeling actor (called $\chi$) exchanges the order of the tag and that of the data value. Both the A elements and the i (tagged F(i)) are input to a special actor $\delta$. Without any inverse function, the element A has been matched with the proper F(i); we have found A(F(i)) still attached to its original F(i) iteration label. The special $\delta$ actor is a relabeling actor which takes the A input and relabels it with the content of its other input. In other words, it outputs A(F(i)), with a label i.

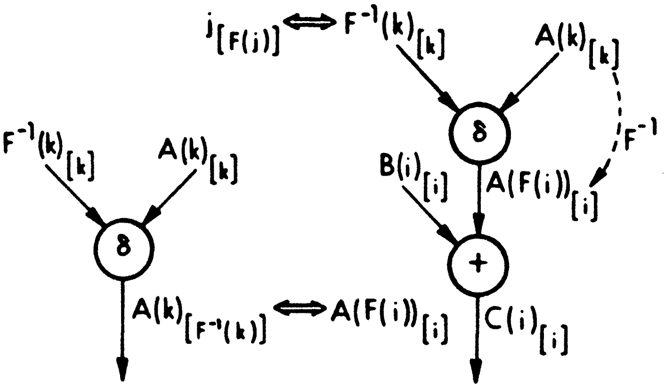

Fig. 3. The $\delta$ actor

This approach has many advantages: better run-time memory management as no intermediary storage is needed, no need for array operations, smaller hardware and execution overhead. However, it requires the complete consumption of a data structure lest some tokens remain orphaned for the rest of the execution of the program.

## III. TWO APPLICATIONS

In this section, we present several data-flow graphs for two parallel algorithms. The crucial consideration in the design of these graphs has been to successfully exploit all the parallelism inherent to the algorithms. Since we are interested in contrasting the performance of the token relabeling scheme with that of the I-structure implementation, we construct two graphs for each algorithm. In each, we apply one of the two different structure handling schemes under study, namely the Token Relabeling approach and the I-structure method. The applications examined in this section have been run on a deterministic simulation program and the results will be shown in the next section.

### 3.1. The FFT application

*3.1.1. The algorithm:* Fig. 4 shows the eight-point decimation-in-frequency FFT computation. In the general case, the FFT computation contains only butterfly constructs with a regular pattern of connections among these butterflies and different multiplicative constants W. The butterfly construct (Fig. 5) obeys the following equations (Oppenheim and Schafer, 1975):

$$x(j+1,p)=x(j,p)+x(j,q) \qquad (1)$$
$$x(j+1,q)=x(j,p)-x(j,q))W_N^r$$

where $x(j,i)$ denotes the data coming into stage $j$, at point $i$. There are $N$ inputs, and $n = \log N$ stages, with the following constraints $0 \le i \le N-1$, and $0 \le j \le \log N-1$. The relation between $p$ and $q$ in a particular stage for a given size of the problem uniquely specifies the connections of butterflies between two successive stages. This means that the routing of data tokens is determined by $p$ and $q$. In addition to the data routing issue, the parameter $r$ is another factor which distinguishes the computations of butterflies located in various place. At a particular stage $j$, the parameters in the equations are derived as follows:

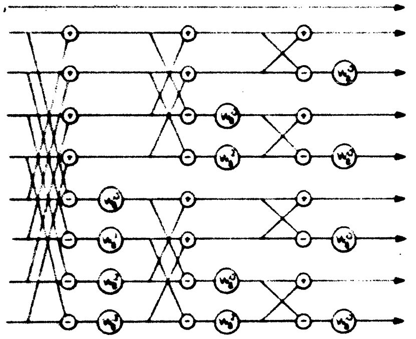

Fig. 4. Eight-point decimation-in-frequency FFT

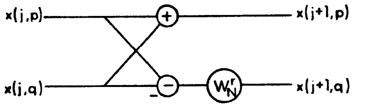

Fig. 5. Butterfly construct

$$
\begin{aligned}
p &= i \ \Lambda\ \overline{2^{n-j-1}} \\
q &= i \ \mathbf{V}\ 2^{n-j-1} \\
r &= (i \mid 2^{n-j-1}) * 2^{j} \\
W_N^r &= e^{-j\pi((i \mid 2^{n-j-1})/2^{n-j-1})}
\end{aligned}
\tag{2}
$$

for all $0 \leq i \leq N$-1, where 'Λ' is a bitwise AND function, 'V' is a bitwise OR function, '|' is an modulo function, and $\overline{k}$ is the one's complement of $k$.

Assuming that $k = 2^{n-j-1}$, then the butterfly becomes:

$$
\begin{aligned}
x(j+1, i\Lambda\overline{k}) &= x(j, i\Lambda\overline{k}) + x(j, iVk) \\
x(j+1, iVk) &= (x(j, i\Lambda\overline{k}) - x(j, iVk))e^{-j\pi(i \mid k)/k}
\end{aligned}
\tag{3}
$$

for all $i$ such that $0 \leq i \leq N$-1.

*3.1.2. The Token Relabeling implementation of FFT:*

As the access pattern of FFT computation is rather regular, the relabeling function is relatively simple. The butterfly construct is implemented by a corresponding data-flow graph which accepts input tokens from two terminals associated with index numbers $j$ and $i$ in the iteration portion of its tag.

In order to express the FFT butterfly of equations (1) and (2) into a data-flow graph, the equations are rewritten as:

$$
\begin{aligned}
x(j+1, i\Lambda\overline{k}) &= x(j, i\Lambda\overline{k}) + x(j, F_1(i\Lambda\overline{k})) \\
x(j+1, iVk) &= (x(j, F_2(iVk)) \\
&\quad - x(j, iVk))e^{-j\pi(i \mid k)/k}
\end{aligned}
\tag{4}
$$

It can be shown that the functions $F_1$ and $F_2$ can be expressed as follows:

$F_2(p) = p \oplus k$
$F_1(q) = q \oplus k$ where $\oplus$ is an exclusive OR

The butterfly is redrawn as shown in Fig. 6 where two index modification blocks $F_1^{-1}$ and $F_2^{-1}$ have been inserted.

The relabeling function $F^{-1}$ is generally not available. This is because it cannot be calculated at compile time. Gaudiot (1985) demonstrated a method which entirely avoids the calculation of $F^{-1}$. This was described in a previous section of this paper. Here, two primitive actors $\delta_r$ and $\delta_w$ are defined for enabling easy operations on the iteration number portion of the tag. The function of the $\delta_r$ actor is to extract the iteration number from the input token while that of the $\delta_w$ actor is to set the iteration field of the tag of one of the input tokens with the data field of another input token (Fig. 7). Note that this $\delta_w$ corresponds to the $\delta$ actor as previously defined by Gaudiot (1985).

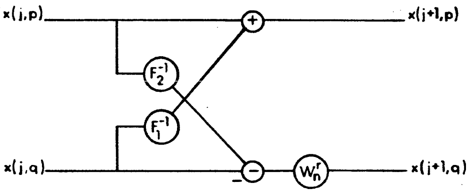

Fig. 6. Modified butterfly construct

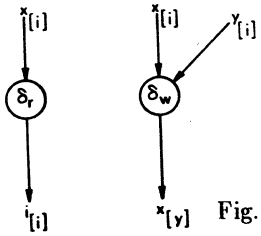

Fig. 7. $\delta$ actors

In general, tag modification can be done by specially designed actors. However, the set of tag modification actors should be kept as small as possible so as not to increase processor complexity. A general solution for the realization of the relabeling function is shown in Fig. 8. In this diagram, the following notation is used: $data_{[i]}$ indicates a data element with an iteration field tag $i$. $\delta_r$ extracts the iteration number from the token $x2_{[i]}$, which $x1_{[F(i)]}$ will be matched to, $i_{[i]}$ is processed by function F. $i_{[i]}$ is then relabeled by $F(i)_{[i]}$ such that $i$ is able to match with $x1$ and relabel $x1$. Finally $x1_{[i]}$ is obtained. The graph containing one $\delta_r$ actor, two $\delta_w$ actors and the function $F$ performs $F^{-1}$ for $x2$. The function $F$ is known from the algorithm and is implemented by the usual arithmetic and logic actors. This general method does not need other specially designed tag modification actors. In the butterfly, $F_1^{-1}$ and $F_2^{-1}$ are realized as shown in Fig. 9.

Fig. 10 is the block diagram of the FFT computation. A stream of one dimension data tokens first passes through the input adaptor which prepares extra context levels and proper iteration numbers for each data to identify the location of data in the FFT graph. The set of input data $x(j,i)$ is separated by the distributor into two groups and which are later forwarded to the two terminals of the butterfly. The butterfly block processes paired tokens and generates one pair of new tokens for the next stage. The loop control block then checks whether the last stage of computation has been reached. If not, the iteration number which stands for the FFT stage is incremented by one and the token is looped back. Otherwise, the token is routed to the output module. A set of constants "$m$" is produced by the constant and $k$-generator and is consumed by the loop control block in order to check for the end of loop. As tokens are produced by the loop, they are postprocessed by the output block. The order is bit-reversed so that a correct set of data could be ready. Both the token relabeling function $F$ and the function $W$ in the butterfly are function of $K$ and of the indices of the token.

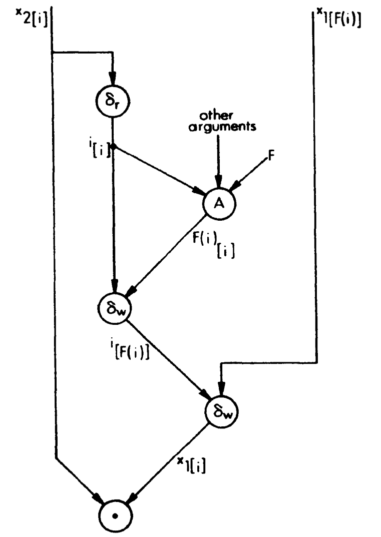

Fig. 8. The relabeling function

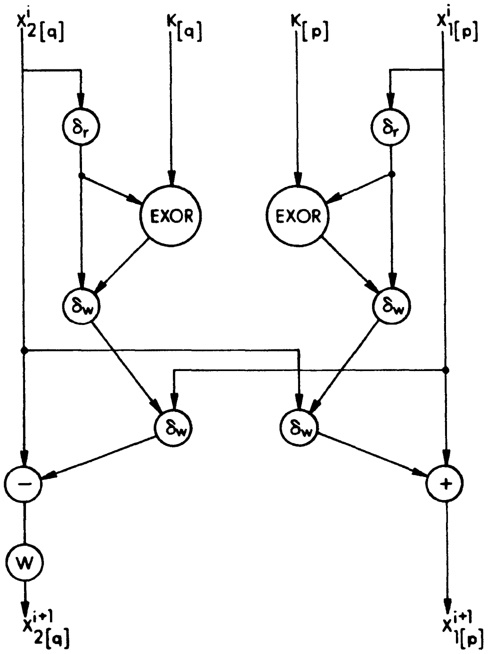

Fig. 9. Realization of $F^{-1}$

*3.1.3. Block diagram of FFT I-Structure graph:* The data-flow graph which corresponds to the "conventional" I-structure organization is represented in a block diagram form in Fig. 11. Instead of entirely unraveling the FFT graph at runtime, an array (using the I-structure representation) is used to buffer the data between stages of the FFT computation. There are four I-structure buffers in the computation of an 8-point FFT since there are 3 stages. Note that since the I-structure definition allows the consumption of an array when it has been partially produced, pipelining is allowed between the stages without waiting for the entire production of the intermediary data. At least on this scheduling point of view, the I-structure representation is similar to the Token Relabeling method. However, as is apparent on the graph of Fig. 11, several additional actors (namely SELECT and APPEND) are required to handle the I-structures. These are not necessary in the Token Relabeling method.

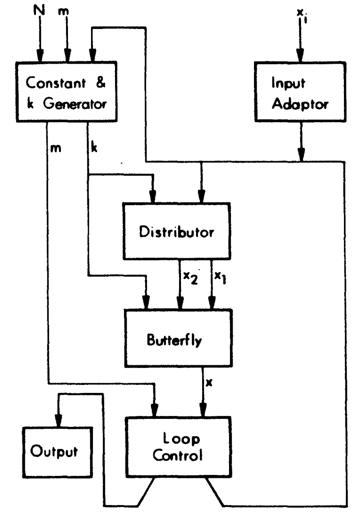

Fig. 10. Block diagram of FFT TR graph

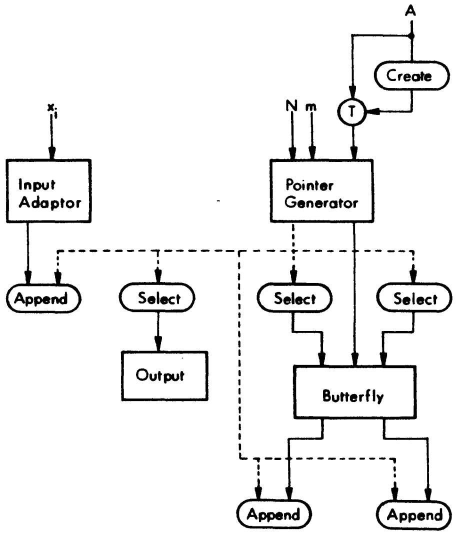

Fig. 11. Block diagram of FFT IS graph

### 3.2. The LU decomposition

The LU decomposition of a matrix is another problem adopted for the evaluation of the behavior of the Token Relabeling and I-structure techniques. There are several reasons in the choice of this algorithm:

- It is a two dimensional problem
- The computation of LU-Decomposition (also referred to simply as LU-D) requires two broadcast operations which can be difficult to efficiently implement in a data-flow environment.

We will only describe the outline of the algorithm to explain the block diagrams of Token Relabeling and I-structure data-flow graphs. Note that the details of this algorithm have been presented by Hwang and Cheng (1982). In Fig. 12, it is shown how the matrix is partitioned into three parts. Part I contains the components of the matrix in first row. Part II contains the components of the matrix in the first column except the one in the first row. The rest of the matrix belongs to part III. The overall outline of the algorithm is presented below:

```
loop size_of_problem > 0
    output I and vertically broadcast I to II and III
    update II
    output II and horizontally broadcast II to III
    update III and set III as new problem
end loop
```

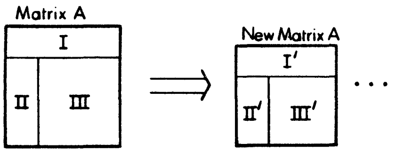

Fig. 12. Matrix partitioning for LU-D algorithm

A new problem with smaller size is created and fed to the next iteration after the current iteration has been completed. Each iteration generates part of the components of the U matrix and of the L matrix.

*3.2.1. LU-D Token Relabeling graph:* Fig. 13 shows the block diagram of the Token Relabeling data-flow graph for LU decomposition. The distributor separates tokens into three streams (I, II, and III). The tokens in stream I are sent out as the partial result of the U matrix. In the mean time, the first broadcast block broadcasts tokens in I to II and III. Receiving tokens from the broadcast block, the second distributor separates tokens into two new streams (II and III). In the new II block, paired tokens in II are processed and a new version of II components is generated. These new II components are sent out as the partial results of L matrix. And, they are also broadcasted to III. The new block III processes three tokens which come from the two broadcast blocks and the distributor and produces a new version of III components. This new version is later sent back as a new smaller problem to be solved. No loop is needed since the size of "new III" will eventually be zero and no more actors will be fired.

Since the token relabeling function is not limited any longer by only the actors $D$ and $D^{-1}$, any function is allowed to modify the tag. As a result, any token in the graph can be arbitrarily chosen and passed to any iteration at will, through the use of the tag detection and tag modification primitives. The broadcast of a token to other iterations of computation is a significant example of the advantages that can be obtained from this method. Systematic mapping of tokens onto the proper iteration is required in order to apply this technique. In this application, the distributor and broadcast blocks indeed realize this mapping.

*3.2.2. LU-D I-structure graph:* As in the FFT algorithm, the difference between the block diagrams of the Token Relabeling and I-structure graphs is in the data accessing modes. The I-structure graph (Fig. 14) uses array accessing actors while the Token Relabeling graph properly labels tokens and uses distributors to route tokens. Both of them share the same major functional blocks and follow the same algorithm. Since the I-structures provide synchronization mechanisms among tokens, the graph is constructed by several functional blocks without interconnections among them. However, pointer generation is complicated by the fact that sets of names and indices of arrays to various iterations for selections and appends of arrays must be generated.

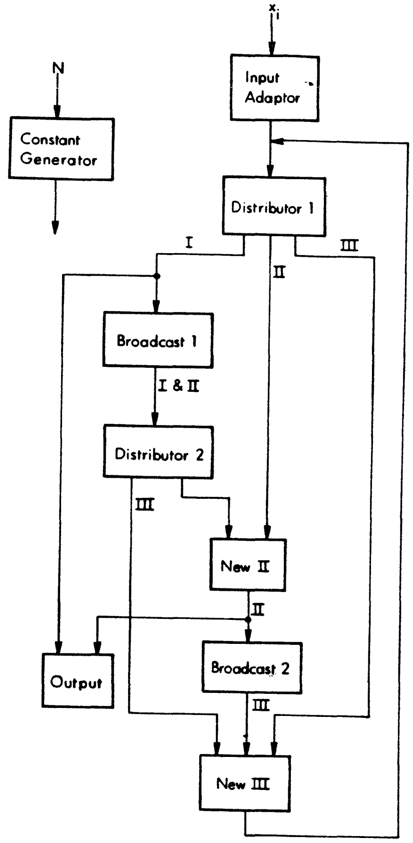

Fig. 13. Block diagram of LU-D TR graph

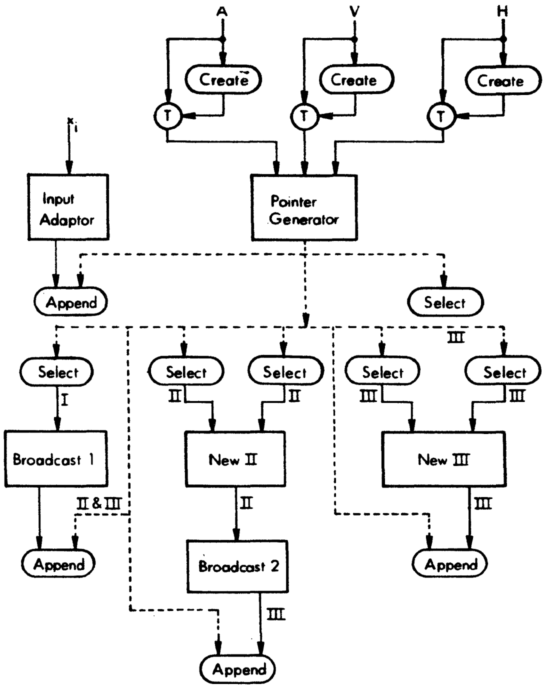

Fig. 14. Block diagram of LU-D IS graph

## IV. SIMULATION AND ANALYSIS

A simulation approach was taken to compare the performance of the Token Relabeling scheme (TR) and of the I-structure scheme (IS). The two applications described in section 3 were simulated under both sets of array representation.

### 4.1. The architecture model

The architecture model of the Arvind/MIT tagged data-flow machine (Arvind, Kathail and Pingali, 1980) was adopted for the machine model of the simulator. It simulates 64 Processing Elements (PEs) interconnected by a packet switching 6-dimension Hypercube network. Each PE can be viewed as three units:

- The *Associative Memory Unit* in which incoming tokens are associatively compared with previously arrived tokens. Matched tokens are then sent, along with the op. code to the next unit.
- The *Processing Unit* receives the ready instruction packets and processes them according to the op. code of the template.
- The *Token Formatting Unit* receives results from the PU and forwards them to the associative memory unit or to another PE through the message passing network.
- The *I-structure controller* where array access operations are handled. Such actors as SELECT or APPEND are executed by this unit.

### 4.2. Simulation results

As in the tagged data-flow architecture, the simulated graphs are executed under the U-interpretation principles. In addition to gathering statistics, this simulator actually computes the results from the simulated data-flow graph and provides correct results. We now describe the results from the simulation. The measures of performance we concentrated on are listed below:

*4.2.1. The graph complexity:* Simply counting the number of actors in the two graphs would not give an accurate measure of the complexity of the graphs. Instead, a dynamic measure must be introduced by counting the number of actors which are actually executed. A convenient method to obtain this figure is to simulate the graphs on a *single processor*. Simulation shows that for the FFT algorithm, the design of the IS graph has higher complexity than that of the TR, while for the LUD algorithm, the TR graph is better.

*4.2.2. Speed up:* Fig. 15 shows the speed-up of two graphs for an FFT computation. The TR graph exhibits a much better speed-up behavior than the IS graph does. All the components of the arrays can be distributed to various processors and processed truly independently. With the communication overhead of structure accessing, the IS graph turns out to have poor speed-up behavior.

*4.2.3. Execution time:* Fig. 16 shows the execution times of FFT-TR and FFT-IS graphs in a multiprocessor environment. For both graphs, tasks are distributed to processors according to the same mapping function.

For a problem with a size smaller than twice the number of processors in the system, the number of processors used for solving the problem is half of the size of problem. Therefore, in Fig. 16, the curve should follow a logarithmic function (log $N$) instead of an $N \cdot \log N$ function in the ideal case (where $N$ is problem size). The TR graph is close to this prediction since its speed-up shown earlier is almost linear. The IS graph appears to follow the $N \cdot \log N$ function because the rate of speed increase becomes slower while the processor number increases. This effect was shown in Fig. 15.

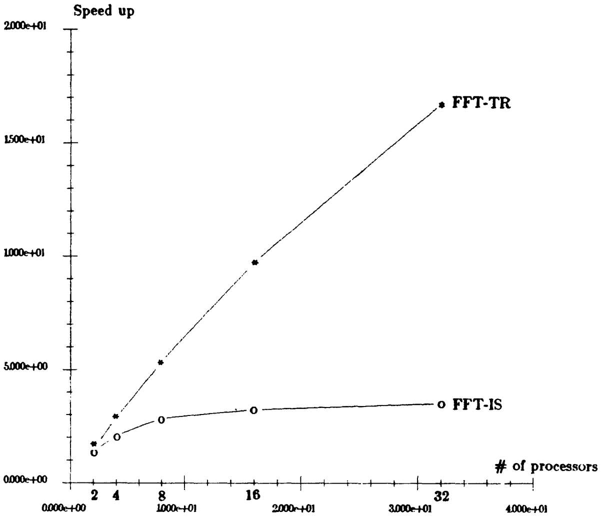

Fig. 15. Speed-up factor

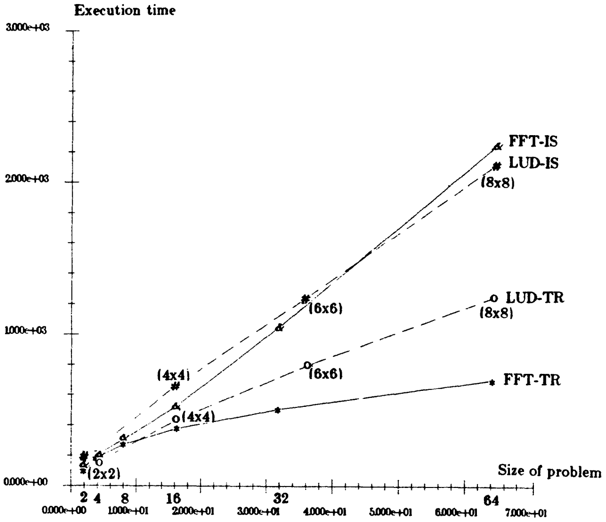

Fig. 16. Execution time

*4.2.4. Number of active tokens:* In Fig. 17, it is shown that the peak number of active tokens in the system for the IS graph is more than twice that for the TR graph in every case. One reason for this is that the requests for structure accessing in the IS computation are always issued before the data are ready. Another reason is that sets of structure names and indices are always generated before the data is computed. Fig. 18 shows that the computation of the IS graph has more than twice the average number of active tokens in the system than the computation of the TR graph has. The reasons can be found in the following:

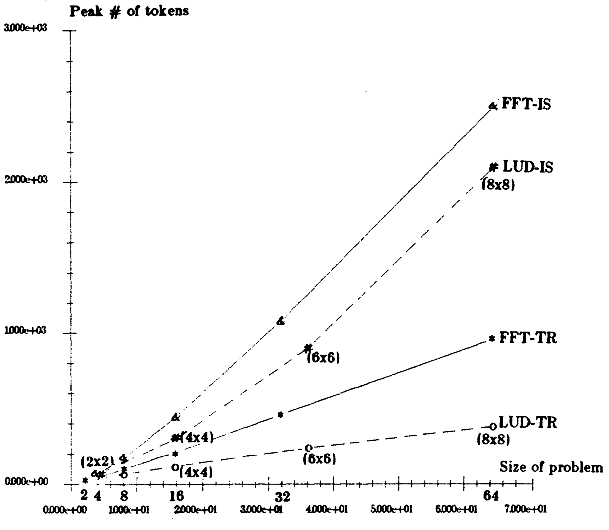

Fig. 17. Peak number of active tokens

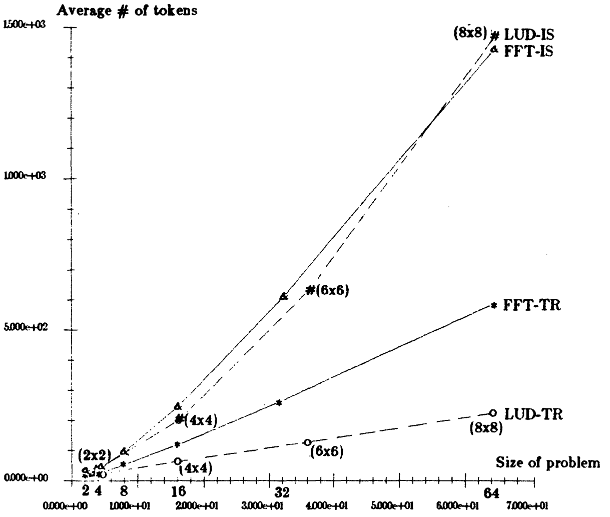

Fig. 18. Average number of active tokens

1) structure names, indices are waiting for data arrival at APPEND actors
2) the requests for data issued by SELECT actors are waiting in the I-structure controller.

*4.2.5. Network load:* Fig. 19 shows that the computation of the IS graph causes much heavier load for the network than the computation of the TR graph does. The higher average number of active tokens in the system introduces more load on the network. Therefore, the figure shows a two to three times increase in network load for IS computation over that for the TR computation.

### 4.3. Analysis

In our performance analysis of the data-flow multiprocessor, many parameters can be observed. We have kept those most closely related to the problems of array handling schemes evaluation.

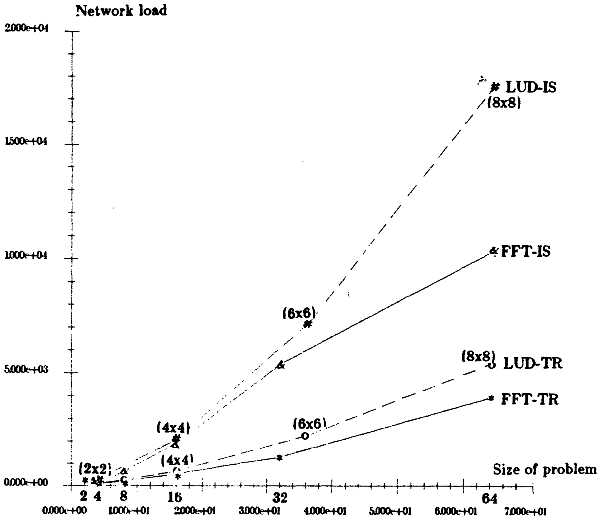

Fig. 19. Network load

*4.3.1. Speed:* Because both the TR scheme and the IS scheme implement graphs based on the same algorithm, the time complexity of the two graphs is similar. The comparison of their execution times eloquently displays the difference in time overhead respectively incurred by the TR and IS schemes. It should be noted that:

1. The execution speed of the TR graph is noticeably higher than that of IS graph. This is because the TR scheme implements the concept of direct data forwarding: A token generated by an actor carries the information about its destination actor and is transmitted without going through any intermediate structure storage. On the other hand, a token in the IS graph format is sent to a designated structure storage and then passed to a destination actor upon request. The overhead is twofold: communication overhead and I-structure handling.

2. The peak number of tokens in the system for the IS graph is larger than that for the TR graph since the request for a data element often exists long before the data is finally computed. Another measure is the average number of token in system. Again the average of tokens of IS graph computation is higher than that of TR graph one. The reason for the higher average number of tokens can be found in the large amount of structure accessing activities.

3. The speed up curve for the TR graph is better than that for the IS graph. The reason is that the I-structure scheme requires requests through complex I-structure controllers.

*4.3.2. Network load:* The IS implementation increases the load on the network more than the TR does because of 1) indirect data movement, and 2) structure names and indices.

*4.3.3. Complexity of the architecture:* For the TR scheme, structured data is converted into scalar elements which are stored in the matching store. This is already supported by the basic data-flow principles. On the other hand, the I-structure scheme requires its own controller.

*4.3.4. Design and generation of data-flow graphs:* A TR graph may be more difficult to design or to generate because the token relabeling function may not be simple and may not be easy to find. The relationship between high level description of an algorithm and the relabeling graph is not always clear which may make the transformation difficult.

However, an IS graph contains concepts close to conventional sequential programming technique. Therefore, the mapping from high level description to graph is simpler. Since the I-structure provides synchronization among dependent stages, loop control is often unnecessary. The body of the graph is simple, but the index generator is complex.

## V. CONCLUSIONS

We have studied in this paper the implementation of two array representation methods. The underlying model of execution was chosen to be the U-interpreter as executed on the MIT tagged data-flow machine. The I-structure method (Arvind and Thomas, 1980) was compared to the token relabeling method (Gaudiot, 1985, and 1986).

Using a deterministic simulation approach, two numerical algorithms were simulated with the two array representation methods. The results of the simulation above pointed to a net speed-up of the Token Relabeling over the I-structure in both cases. Indeed, the TR method presents the following advantages over the I-structure implementation:

- Simplification of the accessing pattern since the tokens need not transit through a special structure controller.
- The data-flow principles of execution can be retained for array handling. This improves schedulability.
- Automatic garbage collection

However, while the token relabeling method can be applied successfully in many cases, there are several drawbacks which often will render the I-structure more applicable:

- The token relabeling assumes a complete consumption of the input stream. Therefore, program constructs which do not completely consume the input stream could require an I-structure implementation.
- Due to the relabeling actors, the graph for the TR implementation is more complex than that of the IS. This implies that for multiple function token relabeling, the overhead might overshadow the advantages.

*ABSTRACT*

Motivated primarily by their potential VLSI implementation, systolic and wavefront arrays have recently attracted significant research interest. A critical research topic is to formalize and systemize the design of such arrays directly from algorithm descriptions. Signal Flow Graphs (SFGs) provide a popular description for recursive parallel algorithms used in digital signal processing. In this paper, a Data Flow Graph (DFG) is used as an abstract model for wavefront array processors. We address first the issue of transforming a SFG into a DFG by an equivalence transformation. Then we discuss the timing analysis for generalized (cyclic or acyclic) DFG networks. Finally, we outline the algorithms to assign minimal number of queues required on all the edges of the DFG and yet achieve the best possible throughput rate. As a side-product of the timing analysis theorem, the deadlock problem associated with the DFG is also resolved naturally.

## 1. Introduction

Systolic arrays[1] and wavefront arrays [2] have recently been introduced as efficient VLSI parallel processors. Since then, numerous researchers have attempted to formalize the design of these arrays.[3] In previous publications,[4, 5] we have proposed methods of mapping algorithmic descriptions onto Signal Flow Graphs (SFGs). These SFGs then serve as a notational tool for a particular space-time parallel implementation. This notation facilitates the understanding of recursive algorithms in terms of the computations required for each recursion and provides a convenient tool for mapping algorithms onto parallel processing arrays. A systolic realization of an algorithm expressed as a SFG is easily derived via a cut-set based systolization procedure. To derive a data-driven wavefront realization of a SFG, we introduced a theorem demonstrating the functional equivalence of each SFG to a particular Data Flow Graph (DFG). A DFG serves as an abstract model of a wavefront architecture, so this equivalence relationship provides a correct wavefront implementation for any SFG. Note also that in our treatment, a DFG is a *cyclic graph* instead of the usual acyclic assumption used by many other authors.

Optimization techniques for synchronous systolic realizations of SFGs have been studied at length.[6, 7] Corresponding techniques for wavefront realizations currently do not exist, due to the additional complexity of analyzing asynchronous parallel behavior. In this paper we address the general issue of transforming a SFG to a DFG, which is correct, deadlock-free, and if desired, optimal in terms of throughput and/or hardware. In the following sections, we first review the SFG model of computation. We then introduce the DFG model as an abstraction of a network of wavefront array processors, and explore some of its properties. The timing analysis of an arbitrary DFG is treated in great detail and constitutes the core of this paper. In addition, several Theorems are presented, and algorithms, which transform SFGs into optimal DFGs, are discussed.

### 1.1. Signal Flow Graphs

A SFG is a directed graph G = (V, E, D(e)), where V is the set of nodes (vertices) and E is the set of edges. Nodes model the computation and edges model the communication in a parallel algorithm. Each edge e has a non-negative integer weight, denoted as D(e), which represents the number of delays (D's) on the edge. Directed loops of edges with zero delays are disallowed. It is assumed that the computations in nodes and communication between nodes take *zero time*. A ***recursion*** is defined as the computation inside a SFG for a single set of input data. So, once a data set is input to a SFG in a recursion, it is assumed to go through the nodes instantly, except where blocked by delays (D's) on edges. If the data is blocked by a delay, it will stay in the delay (D) until the next recursion. Therefore the delays in the SFG have the function of separating two consecutive recursions, and keeping the state of the system. To start, all data in D's are assigned according to the initial conditions of the algorithm. With these observations, it is not difficult to see that the SFG actually displays the activities in one recursion of the algorithm. This simplifies the understanding of the complicated space-time activities associated with parallel processing.

For illustration, an example SFG for matrix multiplication of two matrices, C = A x B is shown in Figure 1(a). In each recursion, a new column of matrix A and a new row of matrix B are sent into the array. Each node will multiply the two data coming from up and left, and add it to the partial sum, which is fed back from itself by a delay edge. The operation of a node is shown in Figure 1(b).

### 1.2. Systolic Arrays

The transformation of such a SFG description to a systolic array can often be accomplished automatically, via e.g. a cut-set retiming procedure.[4, 8] Systolic arrays are very amenable to VLSI implementation and they have the important advantages of modularity, regularity, local interconnection, highly pipelined multiprocessing, and continuous flow of data between the *processing elements (PEs)*. They are especially suitable to certain classes of computation-bound algorithms and have a good number of digital signal processing applications. In fact, they are often derived as a direct mapping of a computational algorithm onto a processor array.[5]

The disadvantages of systolic arrays lie in the fact that the data movements in a systolic array are controlled by global timing-reference "beats". From a hardware perspective, global synchronization incurs problems of *clock skew, fault-tolerance, and peak power.* The burden of having to synchronize the entire computing network will be intolerable for ultra-large-scale arrays. From a software perspective, in order to synchronize the activities in a systolic array, an exact number of additional delays are required. A simple solution to these problems is to take advantage of the control-flow locality, as well as the data-flow locality, inherent in most DSP algorithms. This permits a data-driven, self-timed approach to array processing. Conceptually, this approach replaces the requirement of correct "timing" by correct "sequencing". This concept can be realized in dataflow computers and wavefront arrays.

### 1.3. Wavefront Arrays

Interconnection and memory conflict problems remain very expensive in a general-purpose dataflow multiprocessor. Such problems can be greatly alleviated if *modularity* and *locality* are incorporated into dataflow multiprocessors. This motivates the concept of Wavefront Array Processors (WAPs).[2] Moreover, there are many one- or two- dimensional digital filters and parallel matrix algorithms which are generally expressed in a SFG form. Therefore, it is desirable to explore the relationship between the SFG forms and the corresponding wavefront arrays.

Conventionally, the approach to deriving wavefront arrays is to trace the computational wavefronts and pipeline the fronts on the processor array. In this paper, however, we introduce a new approach based on converting a SFG array into a Data Flow Graph (DFG) array. The DFG is then converted into a wavefront array by properly imposing several key elements in data flow computing. To achieve this, we introduce a general methodology for the timing analysis of DFGs, and use it to optimize the conversions in terms of throughput and queue requirements.

### 1.4. Data Flow Graphs

Data Flow Graphs (DFGs) are used extensively in the area of computer architecture, perhaps most commonly in data flow research.[9] Our purpose is to use a DFG as a formal abstraction of a network of wavefront array PEs. To suit our needs, we use the following definition of a DFG.

A basic DFG is a directed graph G = (V, E, D(e), Q(e)), in which nodes in V model computation, and directed edges in E model asynchronous communication. Each edge e has a queue capacity, represented by an positive integer weight Q(e). Each edge e is also associated with a non-negative integer weight D(e), representing the number of initial data tokens on the edge (initial state). The state of a DFG is represented by the distribution of tokens on its edges. Each edge may contain a nonnegative number of tokens that is less than or equal to its queue capacity. These token may be thought of as filling in a part of the edge queue. This leaves the remainder of the queue empty. Each empty queue slot is called a "space". Therefore, each edge e is also associated with a non-negative integer weight S(e), representing the number of initial spaces on the edge. Obviously, the total edge queue capacity Q(e) is equal to D(e) + S(e), the sum of the initial tokens and spaces on an edge. Hence, the state of a DFG may also be represented by either the distribution of tokens or spaces on its edges.

A node is enabled when all input edges contain a positive number of tokens and all output edges contain a positive number of spaces. The state of a DFG is altered by the firing of enabled nodes. The new state is determined by subtracting one token (and adding one space) from each input edge of the fired node, and adding one token (and subtracting one space) from each output edge.

DFGs have the following properties†:

(1) *Persistence* - Once a node is enabled, it remains enabled until it is fired.

(2) *Conservation* - In any nondirected loop, the sum of the total number of tokens on edges in one direction and the total number of spaces on edges in the opposite direction is unchanged by state transition. A special case of this is the directed loop, in which the total number of tokens (and the total number of spaces) remains constant.

## 2. Equivalence Transformation Theorem

### 2.1. The Equivalence Relation between SFG and DFG

**Theorem 1 :** (Equivalence Transformation between SFG's and DFGs) Barring deadlock situations, the computation of any SFG can be equivalently executed by a self-timed, data-driven machine with a topologically identical DFG. The number of initial tokens assigned on each DFG edge is equal to the number of delays in the corresponding SFG edge. []

*Proof:* What needs to be verified is that the global timing in the SFG can be (comfortably) replaced by the corresponding sequencing of the data tokens in the DFG. Note that the transfer of the data tokens is now "timed" by the processing node. This ensures that the relative "time" between data tokens received at the node is the same as it was in the SFG, as far as that individual node is concerned. By induction, this can be extended to show the correctness of the sequencing in the entire network.‡ []

*Remark:* In the above transformation, any queue capacities greater than or equal to the numbers of initial tokens on the edges are acceptable, from the point of view of functional correctness. The discussion on throughput of any DFG equivalent of a SFG is presented in the next section.

For convenience, we shall term this transformation the **SFG/DFG Equivalence Transformation**. The SFG/DFG equivalence transformation helps establish a theoretical footing for the wavefront array as well as provide insight towards programming techniques. The transformation implies that all regular SFG's can be easily converted into wavefront arrays, making modularly designed wavefront processing elements very attractive to use. Based on the equivalence relationship, the correctness of the DFG is assured.

The D's in the SFG locate the proper setting of the initial conditions in the corresponding wavefront array. We stress that the initial data token distribution plays a very important role in assuring the correct sequencing in a data-driven computing network. The initial state assignment is straightforward: for each delay in the SFG there is an initial data token (regarded as an initial value) assigned to the corresponding DFG edge. We also note that an arbitrary length queue may be inserted on any edge without affecting the validity of the equivalence transformation. It may however, affect the deadlock situation, and may significantly influence the throughput rate, as discussed in Sections 3-5.

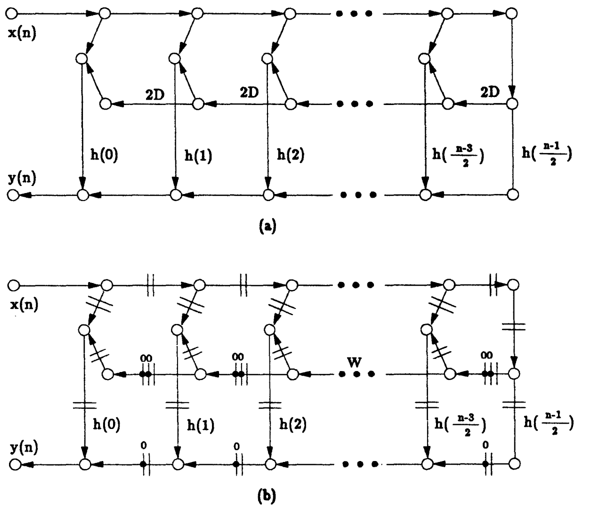
### 2.2. Example: Linear Phase Filter Design

To illustrate the role of the initial states and the correctness of data sequencing, as guaranteed by the equivalence relationship, let us discuss the SFG/DFG equivalence transformation via a linear phase filter example. Linear phase filters have two key features: they have a symmetrical impulse response function, i.e., h(n) = h(N-1-n), and they do not add phase distortion to the signal. Figure 2(a) shows a SFG which takes advantage of the symmetry property, and reduces the amount of multiplier hardware by one half. By the SFG/DFG equivalence transformation, the dataflow graph is derived as in Figure 2(b). In order to ensure the correct sequencing of data, the W data should propagate twice as slowly as the Y data does. Note that the queues play the role of ensuring such a correct sequencing.

Let us now explain the initial conditions shown in Figure 2(b). Note that one initial zero-valued token is placed on each Y-data edge; and two initial zero-valued tokens are placed on each W-data edge.

† These can be easily demonstrated by examining a simple Petri Net [10] model of a DFG.

The first zero-valued token of the Y-data edge, when requested by the Y-summing node, will be passed to meet the V-data token arriving from the upper node. When the operation is done, the way is cleared for sending the next Y-data token from the right-hand PE. The situation is similar for the W summing node, but only one zero-valued token is "used" and the W-data is still one token away from meeting an X-data in the summing node. It will have to wait until the Y-data and the second "0" meet in the lower summing node. This explains why the propagation of W is slower than Y. (This is just what is needed to ensure a correct sequencing of data transfers.)



*Notation for the DFG:*
*An empty buffer is denoted as a bar on an edge, and a full buffer, a bar with a dot on it.*

**Figure 2(a):** *Linear Phase Filter SFG*
**(b):** *Linear Phase Filter DFG*

## 3. Throughput Considerations and Examples

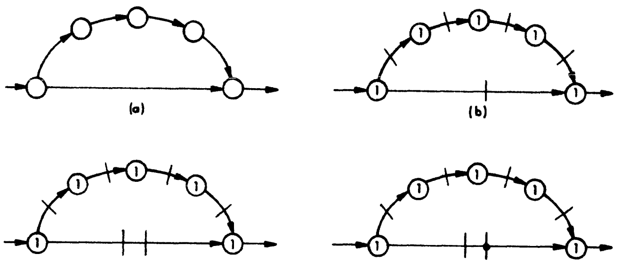
Once the correctness of the DFG is assured, the questions of pipelining speed (i.e. throughput rate) should be explored. To facilitate these analyses, we shall incorporate the notion of time into our DFG model:

*Each node is assigned a deterministic computation time (positive number) and the node fires after it has been enabled for its computation time.* Now a complete specification of a DFG consists of a 5-tuple, G = (V, E, D(e), Q(e), T(v)), where each node v is assigned a positive number T(v), representing the computation time of the node. The persistence property of DFG results in a deterministic behavior of state transitions over time.

### 3.1. An Example Showing the Effect of Queues on Throughput

Figure 3(a) shows a SFG which has two directed paths departing at one end and merging at the other. On the other hand, two corresponding DFGs are shown in Figure 3(b) and 3(c). The operation times of the nodes are indicated by the numbers inside the nodes. With only one space on the lower branch in Figure 3(b), the DFG can accept input tokens at times 1, 6, 11, ... . However, in Figure 3(c), an equivalent DFG with two spaces on the lower path can accept input tokens at times 1, 2, 6, 7, 11, 12, ... . In Figure 3(d), we show a similar DFG (not corresponding to the SFG in Figure 3(a)), in which there is one space and one token on the lower path. And this DFG can accept input only at times 1, 6, 11, ... .

It is clear from this example that the queue capacities and token distribution on the edges play an important role in determining the pipelining period of the DFG.



*Notation for the DFG:*
*The number in a node is the operation time for that node.*

**Figure 3(a):** *A SFG* **(b):** *First DFG corresponding to (a)*
**(c):** *Second DFG corresponding to (a)* **(d):** *Another DFG*

## 4. Timing Analysis for General DFG Networks

The previous example has demonstrated that the pipelining period depends heavily on the queue capacities of the DFG edges. In this section, we shall provide a complete timing analysis for general (i.e. acyclic and cyclic) DFG networks. Our objectives can be stated as twofold: (1) Given a DFG, with defined initial tokens and spaces on the edges, "is it deadlock free?" and "what is the average pipelining period?" (2) Given a desired pipelining period, "how to assign minimal queues on the edges of a DFG to achieve the maximal speed?" Both the questions may be answered by a unified approach based on a duality concept of "token" and "space".

### 4.1. Duality of Token and Space

Figure 4 (a) shows a directed loop with many spaces, but only one token. Since the number of tokens in a directed loop is conserved, there will always be only one token in this loop. The token can traverse the loop repeatedly by a series of firing of the nodes in the loop, and each trip around the loop takes $T_L$ time, which is the sum of all node operation times in the loop. The pipelining period is $T_L$ . However, if we put one more token in the loop, then by the time one token traverses around the loop, the other one also finishes its own trip around the loop. So, the period is only half, $T_L/2$.

Suppose we keep putting more tokens into the loop. We can observe that the period decreases for a while, and then it increases. Let us look at a contrasting case in Figure 4(b). Here, we have many tokens, but only one space. Since the firing of a node requires at least one space on all output edges, we see that only one node can fire at any time. So, effectively, this space will traverse (in reverse direction) around the loop in $T_L$ time also. The pipelining period of this loop is again $T_L$ . By the same analogy, if we put in one more space in the loop, the period will become $T_L/2$. Recall that the number of spaces in a directed loop is conserved.

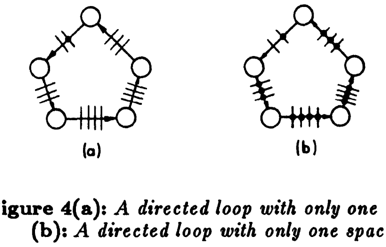


**Figure 4(a):** *A directed loop with only one token.*
**(b):** *A directed loop with only one space*

From this example we see clearly that tokens and spaces play a very similar role in firing nodes. They are both the "resources" to be used by the nodes in order to fire. They display a duality relationship which is quite analogous to the duality of "electrons" and "holes" in semi-conductors. More precisely, a space in one direction plays the same role as a token in the reverse direction. There have been some observations on the roles of tokens and spaces in a DFG,[12, 13] but not to the extent treated here.

‡ The conclusion that the correctness of the computation is independent of the node computation times also follows from results derived by Karp and Miller.[11]

### 4.2. Augmented Flow Graph (AFG)

Based on this key observation, we can simplify our discussion by adopting an augmented graph of the original DFG, which is termed the *Augmented Flow Graph (AFG)*. The augmented graph is constructed by starting with the DFG and adding a reverse edge e' for every existing edge e. We leave the number of tokens on e unchanged. To e', we assign a number of tokens equal to the number of spaces on e. This conversion is shown in Figure 5(a). In effect, we treat spaces as tokens in the AFG.

Recall that, in a DFG, a node can fire only when there is at least one token on all the input edges and one space on all output edges. However, in an AFG, spaces are represented by dual tokens. Therefore, the firing rule of a node in an AFG is also modified to: ***a node is enabled when and only when there exists at least one token on every input edge.*** (It then fires after it has been enabled for its computation time.) It can then be shown that the operation of this AFG is the same as the original DFG. In particular, the throughput analysis will remain the same.†

The DFG properties can be restated in terms of the AFG:

(1) *Persistence* - Once a node is enabled, it remains enabled until it is fired.

(2) *Conservation* - The number of tokens in a directed loop remains constant.

As an example of this conversion, we show in Figure 5(b) a DFG, which is a directed loop, and in 5(c), its AFG. Note that because of augmenting all edges in the original loop, we obtain two directed loops. The inner loop contains only tokens and the outer loop contains only spaces. We also show in Figure 5(d) a DFG, which is an undirected loop, and in (e), the AFG of (d). Notice that in this case the two directed loops in (e) contain both spaces and tokens. The tokens and spaces here play exactly the same role in the timing analysis, which will be explained in the following theorem.

### 4.3. Pipelining Period

**Theorem 2 :** Given a DFG with preassigned initial data tokens and spaces, the pipelining period $\alpha$ of the DFG is:

$$\alpha = Max \left\{ T_V,\, T_P,\, \frac{T_L}{(\, D_{LC} + S_{LCC}\,)},\, \frac{T_L}{(D_{LCC} + S_{LC}\,)} \right\} \quad (1a)$$

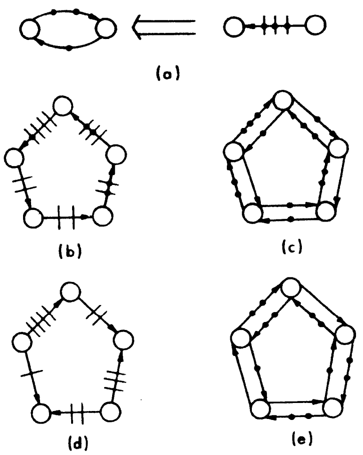
Where L is any ***undirected*** loop in the DFG, $T_L$ is the sum of all node operation times in loop L, $D_{LC}$ is the total number of tokens on edges in the clockwise direction in L, and $S_{LC}$ is the total number of spaces on edges in the clockwise direction in L. $D_{LCC}$ and $S_{LCC}$ are similarly defined for the counter clockwise direction in L. $T_V$ is the maximum of the operation times of all nodes in the DFG. Lastly, $T_P$ is the maximum of any sum of the operation times of a pair of nodes, which are connected by an edge with only one queue on it. []

The above theorem has an equivalent but somewhat simpler statement in terms of the more convenient AFG notation.

**Theorem 2 (Rephrased Version):** Given an AFG derived from a DFG with preassigned initial data tokens and spaces, the pipelining period $\alpha$ of the AFG (or DFG) is:

$$\alpha = Max \left\{ T_V\, ,\, \frac{T_{DL}}{K_{DL}} \right\} \quad (1b)$$

where DL is any ***directed*** loop in the AFG, $T_{DL}$ is the sum of all node operation time in loop L, $K_{DL}$ is the total number of tokens (including dual tokens) in L, and $T_V$ is the maximum of the operation times of all nodes in the AFG.‡ []



*Notation for the AFG:*
*Tokens in the AFG are denoted as dots on the edges.*

**Figure 5(a):** *Rule for converting a DFG to an AFG*
**(b):** *a directed loop DFG* **(c):** *its AFG*
**(d):** *an undirected loop DFG* **(e):** *its AFG*

Note that if DL is a clockwise directed loop in the AFG generated by the undirected DFG loop L, then $K_{DL} = D_{LC} + S_{LCC}$. Likewise, for counterclockwise DL, $K_{DL} = S_{LC} + D_{LCC}$. Therefore, the above two statements are the same in content and differ only in notation. For convenience, our proof will be given only in terms of the AFG notation. For this, let us first establish several useful lemmas.

**Lemma 1:** The pipelining period of an AFG (or DFG) must be greater than or equal to every node operation time. []

*Proof:* This is obvious, since no internal pipelining is assumed inside a node. []

**Lemma 2:** Consider a directed loop L in the AFG. The pipelining period $\alpha_{DL}$ of this loop, when it is operating independently of the remaining part of the AFG, is:

$$\alpha_{DL} = \frac{T_{DL}}{K_{DL}}\,. \quad (2)$$

*Proof:* To show this, first recall that, from the conservation property of an AFG, the number of data tokens in a directed loop DL is constant. If we mark one token which begins its trip around the loop at one particular node, it is clear that there will be $K_{DL}$ tokens fired at that particular node during the period when this marked token completes its loop trip. This marked token will need $T_{DL}$ in time to return to the starting node and this firing pattern will repeat at a period $T_{DL}$, assuming that this loop operates independently of the rest of the AFG. So, we obtain the average period for that loop DL, which is $T_{DL}/K_{DL}$. Note also that ***all nodes in this loop must operate at the same pipelining period.*** []

**Lemma 3:** All nodes in the AFG operate at a uniform period in the steady state. []

*Proof:* While all the nodes in the DFG are in general ***weakly*** connected only, the nodes in the AFG are always ***strongly*** connected, i.e. there exist directed paths in both directions between any pair of nodes in the graph. Consequently, all nodes in the AFG have to operate at a uniform period in the steady state. Were this is not the case, some edges of the AFG will eventually have an unbounded number of tokens. Recall that there are only finite initial tokens in the AFG, and all tokens are contained in some directed loops. By the conservation of tokens in the directed loops, the number of tokens in the AFG remains finite. []

*Proof of Theorem 2:* The proof of Theorem 2 has two parts: "necessity" and "sufficiency".

**Necessity:** To prove the necessity part, we need to show that the DFG can not operate with a pipelining period less than the $\alpha$ in Eq. (1). Since the AFG is strongly connected, according to Lemma 3, all the loops will operate at the same period. Obviously, the slowest

† With this definition, AFGs form a subclass of marked Petri Net Graphs, augmented with node times.

‡ Similar results have been reported by Reiter[14] in the scheduling context and by Ramamoorthy and Ho[15] for petri nets. Ramamoorthy and Ho's analysis, dealing with a class of petri nets that they define as "decision-free, consistent, extended timed petri nets", is the closest to our own. However their treatment neglects the case where

$$Max \left\{ T_V \right\} > Max \left\{ \frac{T_{DL}}{K_{DL}} \right\}.$$

In addition, their proof, while formally presented, utilizes some non-rigorous techniques in the manipulation of infinite terms.

loop will prevail; therefore, the pipelining period for the total system will be at least the maximum of all periods associated with the individual directed loops. Thus, the necessity part is proved.

**Sufficiency:** Here we want to prove that the DFG can operate at the period of $\alpha$ in Eq. (1).

Consider two directed loops A and B. Assume that $\alpha_A = \alpha_B$, and loops A and B are coupled at some nodes. Then the pipelining period of both loops A and B together will be $\alpha_A$, except for some "phase difference" between A and B when both loops start computing. After some finite amount of time, both A and B will be synchronized at the period of $\alpha_A$.

Now assume that $\alpha_A > \alpha_B$. We first modify the loop B into B' by adding extra operation time into nodes in loop B that are not also in loop A, such that the new period for loop B' becomes $\alpha_A$. This is always possible, since the number of tokens in a directed loop is constant, and we can increase the period by prolonging the total node time around a loop. By step (2), now the two loops A and B' can operate at the period of $\alpha_A$.

Comparing loops B and B', it is clear that any node time in B' should be greater than or equal to the corresponding node time in B. It is not hard to envision that the loop B can always operate at the speed of loop B', since the nodes of B are as fast or faster than their B' counterparts. Since loop B' can operate at the period of $\alpha_A$, it is straightforward to see that loop B can operate at this speed also. So, the resulting loops A and B can operate together at the period of $\alpha_A$.

By induction, the above argument can be extended to any number of directed loops in the AFG. Namely, if the slowest period of all directed loops in the AFG is $\alpha$, all nodes in the AFG will eventually operate at a period of $\alpha$, and the time needed for the synchronization of all loops will be finite, since there are only finite loops in the AFG. Thus, the sufficiency part is proved. Q.E.D. []

A special case of this formula concerns the effect of putting only one queue on an edge in a DFG. In Figure 6(a), we show a simple DFG with two nodes, and only one queue on the edge between the two nodes. In Figure 6(b), the corresponding AFG is shown. It is clear that an edge between two nodes in a DFG induces a small loop in its AFG counterpart. This results in a special effect for the case when there is only one queue on the edge. According to Eq. (1b), the pipelining period must be greater than or equal to T(1) + T(2). This implies that these two nodes can only operate sequentially, i.e., only one can operate at any instant. This is the reason that the term $T_P$ appears in Eq. (1a).

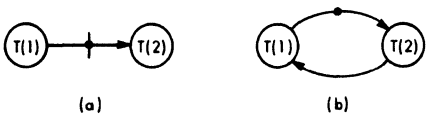


**Figure 6(a):** *a DFG with one buffer on the edge*
**(b):** *the equivalent AFG of (a)*

Another observation is that while there are many directed loops in the AFG, only some of them are ***simple directed loops***, i.e. loops which visit nodes only once, except for the node where the loop "begins" and "ends". In Figure 7, there are two simple directed loops, denoted as $(n_1\, e_1\, n_2\, e_3\, n_1)$, $(n_2\, e_2\, n_3\, e_4\, n_2)$. An example of non-simple directed loop is $(n_1\, e_1\, n_2\, e_2\, n_3\, e_4\, n_2\, e_3\, n_1)$. Fortunately, we need to consider *only the simple directed loops* for the pipelining period computation. This claim is proved in the following lemma:

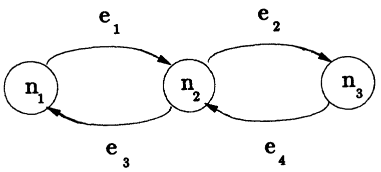

**Figure 7:** *AFG Example*

**Lemma 4:** The pipelining period of a non-simple directed loop DL in an AFG is less than or equal to the maximum of the periods of all simple directed loops contained in DL. []

*Proof:* Without loss of generality, we can use Figure 7 as the AFG. We want to show that

$$\text{For} \left[ \begin{array}{ll} T_1 = T(n_1) + T(n_2) & K_1 = K(e_1) + K(e_3) \\ T_2 = T(n_2) + T(n_3) & K_2 = K(e_2) + K(e_4) \end{array} \right.$$

$$Max \left\{ \frac{T_1}{K_1}, \frac{T_2}{K_2} \right\} \geq \frac{(T_1 + T_2)}{(K_1 + K_2)}$$

$$\textit{Assuming that:} \frac{T_1}{K_1} \geq \frac{T_2}{K_{2,}} \textit{ it is easy see that:}$$

$$\frac{T_1}{K_1} \geq \frac{(T_1 + T_2)}{(K_1 + K_2)}$$

Other cases can be proved similarly. []

It can be deduced from this lemma that we can consider *only the simple directed loops* for the pipelining period computation. So, in Eq. (1b), we can assume that DL is a simple directed loop.

### 4.4. Deadlock Analysis

The issue of deadlock can be regarded as a special application of the above Theorem. The result is stated in the following Corollary:

**Corollary:** The DFG is deadlock free if and only if there exists a finite solution $\alpha$ for Eq. (1). A finite solution for $\alpha$ exists if and only if the AFG contains no empty directed loops. []

*Proof:* It follows directly from Theorem 2. []

An example of deadlock is shown in Figure 8.

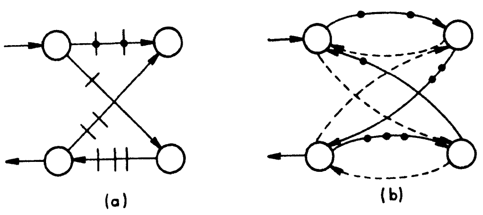

**Figure 8(a):** *A deadlocked DFG* **(b):** *Its corresponding AFG*
*Note that there are no tokens in the loop indicated by dashed edges. According to Eq. (1b), there exists no finite solution for $\alpha$.*

### 5. Optimization of Throughput

Theorem 2 gives the pipelining period of a DFG when the initial token assignments and number of queues on edges are given. The dual problem of determining the assignment of minimum queue capacities on the edges in a DFG to achieve the minimum (or optimal) pipelining period $\alpha^*$ is treated in the following theorem:

**Theorem 3 :** Given a DFG with initial token assignment, (i) the minimum (or optimal) pipelining period and (ii) the minimum queue capacities on the edges to achieve that pipelining rate can be determined as follows:

(i) The minimum pipelining period $\alpha^*$ is

$$\alpha^* = Max \left\{ T_V \text{ , } all \ \frac{T_{DL}}{D_{DL}} \right\} \tag{3}$$

where DL is a ***simple directed loop*** in the DFG, $T_{DL}$ is the total node time in DL, and $D_{DL}$ is the total number of tokens in DL. $T_V$ is the maximum of the operation times of all nodes in the DFG.

(ii) The assignment of the minimum queue capacities on the edges of the DFG requires that the queue capacities must be the minimum numbers satisfying the condition in Eq. (1a) in Theorem 2:

$$S_{LC} \geq \frac{T_L}{\alpha^*} - D_{LCC} \tag{4a}$$

$$S_{LCC} \geq \frac{T_L}{\alpha^*} - D_{LC} \tag{4b}$$

*for any simple undirected loop* L in the DFG. and,

$$Q(e) \geq \left\lceil \frac{T(source) + T(sink)}{\alpha^*} \right\rceil \quad (4c)$$

$$Q(e) \geq D(e) \quad (4d)$$

for any edge e in the DFG. []

Note that $\alpha^*$, $T_L$, and $D_{LC}$, $D_{LCC}$, $S_{LC}$, and $S_{LCC}$, are defined in Theorem 2. And Q(e) is the queue capacity of an edge e, T(source) and T(sink) are the operation times of the source and sink nodes of the edge e.

*Proof:* Note that the optimal pipelining period may be obtained by putting $\infty$ spaces on all edges in the DFG. Theoretically, it is clearly the best one can do in order to maximize the pipelining rate. In this case, for all DFG undirected loops with both clockwise and counterclockwise edges (all but the directed loops), $S_{LC} = S_{LCC} = \infty$. As a result their individual pipelining periods will be 0 (according to Eq. (2)), which can never adversely affect the overall pipelining period. Thus, such undirected loops may be excluded for the purpose of applying Eq. (1) for determining $\alpha^*$. Therefore, only those directed loops in the DFG remain to be considered. In this case, Eq. (1) becomes Eq. (3) and the Step (i) is thus verified. The validity of Step (ii) follows directly from Theorem 2 and Eq. (1). (Eq. (4d) is needed to insure spaces for the initial tokens.) []

In fact, the formula Eq.(4) in the step (ii) of this theorem is also valid for any given desired pipelining period which is greater than or equal to $\alpha^*$. In general, there are non-unique solutions to this assignment. Among several possible approaches to deriving a feasible solution, we propose in the next subsection a simple cut-set procedure [4, 8] to tackle this assignment problem.

## 6. Linear Queue Assignment Algorithms

### 6.1. Comparison with Retiming for Synchronous Systems

In this section, we will present a cut-set retiming scheme to analyze the timing of an asynchronous system, i.e. a DFG. This cut-set procedure basically extends the earlier timing analysis research on synchronous circuits.[6, 7] In order to deal with generalized asynchronous data flow arrays, the DFG modeling is required to abstract an asynchronous circuit with initial conditions. Note that initial conditions affect the optimal pipelining period $\alpha^*$.

Moreover, compared with the systolic array, the wavefront array represents an effective means to deal with multi-rate processing elements. In systolic arrays, a common procedure is to adopt a uniform clock unit based on the slowest node, which is not a good scheme in terms of pipelining speed. It is also noted that, the DFG modeling, with queues accommodating initial tokens, has an important advantage. It allows us to avoid the tedious (and sometimes impossible) procedure of initial tokens reassignment as required in systolic design.

### 6.2. Cut-Set Procedure for Asynchronous Systems

A direct approach to compute the optimal queue assignment would involve tracing all the simple loops - a very time consuming task. To avoid this, we propose a cut-set retiming procedure (to be detailed in the Appendix), to assign queues on the edges in the DFG. In short, a cut-set retiming procedure consists of two basic transformations of a computing network which preserve the functional correctness of the network. One transformation is time scaling, i.e. slowing down the clock rate. The other is the transferring of time delays along a cut-set of the computing network. The objective of cut-set retiming is to transform from the SFG in which nodes have zero-delays, to a *retimed* DFG in which the operation time of the node is assigned to its output edges. With these two basic operations, ***The cut-set procedure determines the optimal pipelining period of the DFG, $\alpha^*$, and also assigns to each edge e of the DFG an appropriate time delay, denoted as t(e), needed to achieve this optimal period.*** This procedure is stated in the following theorem:

**Theorem 4 :** After the cut-set procedure, the queue capacity Q(e), needed for the edge e in a DFG for optimal pipelining period $\alpha^*$, can be computed as:

$$Q(e) = Max \left\{ D(e), \left\lceil \frac{(t(e) + T(sink))}{\alpha^*} \right\rceil \right\} \quad (5)$$

where the "ceiling function" $\lceil x \rceil$ denotes the smallest integer greater than or equal to x. Also, t(e) and $\alpha^*$ are defined as above (and derived in the Appendix). D(e) is the number of initial tokens on edge e, T(sink) is the operation time of the sink node corresponding to the edge e. []

*Proof:* We want to show that the queue capacities obtained from Eq.(5) satisfy Eq.(4). According to the rule used in the cut-set retiming procedure, t(e) should be greater than or equal to the operation time of its source node. (Note that in our retimed graph the node operation time has to be absorbed by its output edges.) Now, consider any undirected loop L in the retimed DFG. For the purpose of illustration, an undirected loop and its retimed DFG are shown in Figure 9.

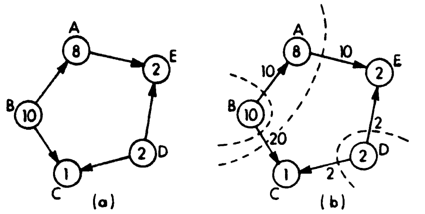

**Figure 9(a):** *An undirected loop in the DFG.*
**(b):** *The retimed DFG.*

Let us first assume that there are no tokens in this loop. We want to assign queue capacities to the counter-clockwise (CC) edges first. From the cut-set procedure, the total time assigned to the counter-clockwise (CC) edges is the same as the total time assigned to the clockwise (C) edges. Note that the total time assigned to the C edges (or the CC edges) is greater than or equal to the sum of node times of nodes A, B, D, since they are the source nodes of the C edges. Therefore; if we add the total time of the CC edges and the total operation times of the sink nodes (in this case, they are nodes C and E) of the CC edges together, as implied by Eq.(5), the sum is greater than or equal to the loop time $T_L$. So, the queue assignment of the CC edges satisfies Eq.(4b), i.e.

$$S_{LCC} \geq \frac{T_L}{\alpha^*} - D_{LC}$$

We can show that the queue assignment for the clockwise C edges satisfies Eq.(4a), follows basically the same argument except exchanging the roles of C edges and CC edges.

Now let us consider the case when there are $D_{LC}$ tokens on some C edges in the undirected loop L. By the cut-set retiming procedure, for each token on a C edge a time-delay $\alpha^*$ is assigned on that edge initially. As a result, after the cut-set retiming, the total time of the CC edges is greater than or equal to (total source node times of the C edges) - $\alpha^* D_{LC}$. If we sum up this total time and all the sink nodes time of the CC edges, the sum is greater than or equal to $T_L - \alpha^* D_{LC}$. Therefore, Eq.(4b) is again satisfied. Of course, the counter-clockwise case can be proved similarly. Moreover, if the loop under consideration happens to be a directed loop, it can be simply regarded as a special case, and there is no need of any different treatment.

Next, we want to show that Eq. (4c) is also satisfied for all edges. This is true since t(e) is always greater than or equal to its source node time, T(source), and therefore t(e) + T(sink) is greater than or equal to T(source) + T(sink) of node e. It is then clear that Eq.(4c) is satisfied for all edges in the retimed DFG. Eq.(4d) is also satisfied because D(e) is included in the maximum operator in Eq.(5).

Finally, we note that since the queue capacities have to be integers, this quotient is rounded up by the ceiling operation. It is obvious that the queue capacity Q(e) must be greater than or equal to D(e) in order to accommodate all the initial data tokens on edge e. Therefore, the maximum of the above two integers is taken for the queue assignment. Q.E.D. []

### 6.3. Linear Programming Formulation

The cut-set queue assignment above is not minimal, in large part because the retiming is not unique. In general, there are many SFG retimings that will meet the constraint that each edge delay is greater than or equal to its source node computation time. To minimize the queues, we would like the "minimal retiming", or the retiming that minimizes the overall sum of the edge delays.

To specify a particular retiming, we can use notation similar the notation introduced for the synchronous retiming case.[6] This notation is equivalent to describing a complete retiming in terms of cut-sets around each individual node. A retiming is specified by a mapping R from graph nodes to numbers. The number assigned to each node corresponds to the delay added to the outgoing edges and subtracted from the incoming edges. The delay transferred to an edge by a retiming is R(source) - R(sink). Using this notation, we can reformulate the retiming as a linear programming problem as follows:

The cost function is the sum of the edge delays after retiming. With initial edge delay of $\alpha^* D(e)$, the retimed edge delay is $\alpha^* D(e) + R(source) - R(sink)$. Since $\alpha^* D(e)$ is a constant, we need to minimize:

$$\sum_{edges} \left\{ R(source) - R(sink) \right\} \qquad (6a)$$

under the constraint:

$$\textit{For all edges}:$$

$$R(source) - R(sink) \geq T(source) - \alpha^* D(e) \qquad (6b)$$

Once the minimal retiming is derived, then queues are assigned by equation (5).

## 7. Integer Programming Algorithms

Since queues must have integer lengths, the "linearized" methods of the previous section do not necessarily yield the absolute minimal queue assignment. To eliminate this small quantization error, we can deal directly with the integer quantities, expressing the problem in an integer programming formulation.

### 7.1. Simple Minimal Queue Assignment

The assignment of the minimum queue capacities on the edges of the DFG requires that the queue capacities must be the minimum numbers satisfying the conditions in Eq. (7a,b,c,d), i.e.

minimize $\sum_{e:\,edges} Q(e)$, under the linear constraints:

$$S_{LC} \geq \frac{T_L}{\alpha^*} - D_{LCC} \qquad (7a)$$

$$S_{LCC} \geq \frac{T_L}{\alpha^*} - D_{LC} \qquad (7b)$$

for any simple undirected loop L in the DFG. And,

$$S(e) \geq \left\lceil \frac{(T(source) + T(sink))}{\alpha^*} \right\rceil - D(e) \qquad (7c)$$

$$Q(e) \geq D(e) \qquad (7d)$$

for any edge e in the DFG.

The validity of this formulation simply follows Theorem 3. Note that here the variables are all integers, thus giving a integer linear programming formulation.

### 7.2. Minimal Queue Assignment with Initial Token Redistribution

In some instances we find that part of the queue capacity of an edge, needed to accommodate initial tokens, is never used in the rest of the computation after the initialization stage. In these cases a smaller edge queue capacity can support the computation after initialization. Use of this smaller capacity necessitates the redistribution of initial tokens so that all can fit into the reduced edge capacities. It turns out that this redistribution can be formulated along the same lines as we proposed for the integer programming formulation and can be integrated into a larger size integer programming problem to solve the real minimal queue assignment problem. Space limitations preclude us from including the details.

## 8. Applications of the Timing Analysis

### 8.1. Improving Processor Utilization

It is clear from our timing analysis that any node in the DFG can at best operate at the optimal period, i.e. once in $\alpha^*$ time. If $\alpha^*$ is large compared to the node computation times, the utilization of nodes is quite low. There are two ways to improve this situation. One way is to use the technique of *processor sharing*,[4] i.e. we use one real PE to simulate several nodes, so as to improve the utilization of PE's. For example, if the average node utilization in a DFG is only 1/3, i.e. all nodes compute for only one third of time in average, it is possible that we can group 3 nodes into one real PE to obtain full utilization of PE's. It is not trivial to partition the nodes in an arbitrary DFG and assign them to real PE's to achieve maximal PE utilization.

Another way to get around this problem of low node utilization is to change $\alpha^*$ by changing the node operation times in a DFG. Note that the operation of a node can be changed by using different hardware realizations. Then it is possible to reassign the node times of a DFG to obtain better $\alpha^*$, and thus better utilization.

### 8.2. A Lattice Filter Example

The SFG of a Lattice Filter is shown in Figure 10(a), and one equivalent DFG of the SFG is shown in Figure 10(b). The initial data tokens, queue capacities, and node operation times are also displayed.

We first apply the main theorem to determine the pipelining period of the DFG in Figure 10(b). The augmented flow graph, AFG, is shown in Figure 10(c). And the loop which has the maximum period $\alpha$ is also shown in Figure 10(d). From this loop, we obtain $\alpha$ = 11.

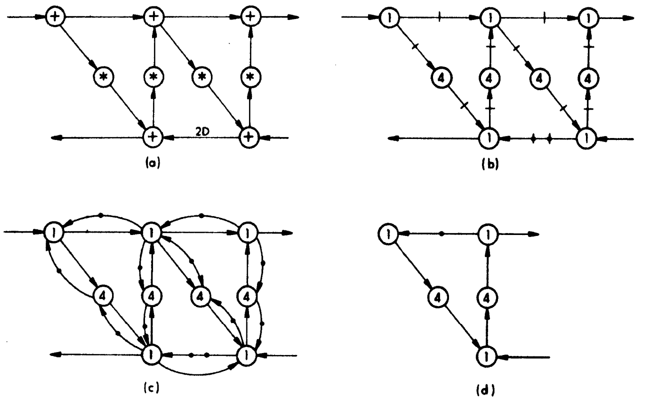

**Figure 10(a):** *a Lattice Filter SFG* **(b):** *one equivalent DFG of (a)* **(c):** *the AFG of (b)* **(d):** *the slowest loop in the AFG*

To assign minimum queues on the edges in order to achieve the optimal pipelining period, we first derive the retimed DFG of the Lattice Filter by the cut-set procedure. The retimed DFG of the Lattice Filter is shown in Figure 11(a). The optimal pipelining period $\alpha^*$ obtained by the cut-set procedure is 5.5. Applying Eq.(5) to all edges in the DFG, the assignment of minimum queues is shown in Figure 11(b).

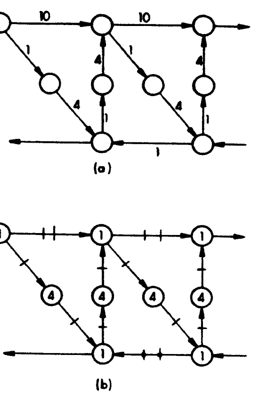

**Figure 11(a):** *the retimed DFG*
**(b):** *queue assignment for optimal period*

## 9. Conclusion

We have presented a systematic approach of converting a parallel algorithm described by a Signal Flow Graph to a functionally equivalent Data Flow Graph, which sets the stage toward its wavefront array implementation. Based on the notion of token and space (and their intriguing duality property), pipeline timing analysis and optimal queue design of generalized dataflow arrays are investigated. Of the four algorithms we proposed for the optimal queue assignment, the cut-set procedure is computationally easiest; however, it does not give an optimal or minimal assignment. The linear programming formulation gives closer approximation of the minimal solution at the expense of more computation. Finally, both integer programming formulations with or without initial token redistribution yield true minimal assignments at the cost of even more computation. It is expected that dataflow, wavefront, and fault-tolerant architectures will play a central role in the future VLSI or wafer-scale computing systems. It is our belief that, for these applications, the theorems and the timing analyses proposed in this paper will prove to be very useful.

## Appendix : Transforming a SFG to a Retimed DFG

Let us for the time being assume that each node in the SFG actually takes some known amount of time (though each node may take different times). To analyze the queue assignment, we first introduce a *retimed* DFG, in which the operation time of the node is assigned to its output edges. This is illustrated in Figure 12.

**Figure 12 :** *Assignment of node times to output edges in the retimed DFG.*

In order to synchronize the operations among nodes in the retimed DFG, edges will also be assigned extra time delays to serve the synchronization purpose. This assignment is based on the cut-set retiming procedure.[4]

### A Cut-set Retiming Procedure

We first define a cut-set for a SFG as: A ***cut-set*** in a SFG is a minimal set of edges which partitions the SFG into two parts. The retiming procedure is based on two simple rules:

(i) **Time-Rescaling:** All delays D may be scaled, i.e., $D \rightarrow \alpha$ , by a single positive number $\alpha$. Correspondingly, the input and output rates also have to be scaled down by a factor $\alpha$. The time-rescaling factor (or, equivalently, the slow-down factor) $\alpha$ is determined by the slowest loop in the SFG array.

(ii) **Delay-Transfer:** Given any cut-set of the SFG, we can group the edges of the cut-set into ***in-bound edges*** and ***out-bound edges***, depending upon the directions assigned to the edges. The Rule (ii) allows advancing k time-units on all the out-bound edges and delaying k time-units on the in-bound edges, and vice versa. It is clear that, for a (time-invariant) SFG, the general system behavior is not affected because the effects of lags and advances cancel each other in the overall timing. Note that the input-input and input-output timing relationships will also remain exactly the same only if they are located on the same side. Otherwise, they should be adjusted by a lag of +k time-units or an advance of -k time-units.

The optimal $\alpha^*$ for the retimed DFG is decided by the slowest loop in the SFG. In other words, $\alpha^*$ should be the minimum number such that after time scaling, there are enough delays to be distributed for all loops. Note that when there are no directed loops in the SFG, the optimal time interval between two input data, namely, $\alpha^*$ is the maximum of all node operation times. This is required because a pipelined system can not operate faster than the time needed for the slowest section in the pipeline.

### Procedure for Transforming a SFG to a Retimed DFG Array

A retimed DFG array is derived from the original SFG by the following procedure:

(1) Set initial $\alpha$ as the maximum of all node operation times. Scale all delays.

(2) For each target edge (edge that does not have more or equal amount of delays as required by the node it incidents from), find a cut-set containing the target edge and such that after suitable delay-transfer along the cut-set, the target edge will have the exact amount delay it needs, and at the same time, no new target edges are generated by this delay-transfer.

(3) If such a cut-set can not be found, a directed loop L which contains the target edge will be found. Rescale the $\alpha$, i.e. $\alpha = T_L / D_L$.

(4) Repeat the above step until there are no more target edges. The final $\alpha$ is the optimal pipelining period $\alpha^*$. []

The detailed algorithm for this has been previously published.[8] Only the important ideas have been outlined here.

Abstract -- This paper presents preliminary work on the analysis of dataflow algorithms. The focus is on developing techniques for modeling dataflow computation to obtain both theoretical and architecture-dependent performance estimates. Operator nets provide the basic model of a computation. The dataflow language used is Lucid. An example from the field of digital signal processing is used to demonstrate a theoretical data dependency analysis, analysis on an operator net and Lucid program, and performance figures derivable in terms of dataflow architecture models.

## Introduction

Dataflow is emerging as one of the important models of parallel processing, providing the potential to exploit the maximum concurrency inherent in an algorithm without requiring explicit statement of the parallelism. However, because the execution sequence is not expressed explicitly in the dataflow program, conventional algorithm analysis techniques for predicting the performance of an algorithm are not immediately applicable. In this paper, we use examples of analyses on a digital signal processing algorithm to demonstrate some analysis methods that provide both theoretical and architecture-dependent performance estimates.

## Algorithm, Language, and Architecture Models

Our model of a computation will be an *operator net* [2], which is a directed graph whose nodes represent operations or functions to be performed on the data items (datons) which arrive at the node via the incoming edges. An operator net is built up from subgraphs which specify subcomputations. The dataflow language used is Lucid [7], which allows a direct linear representation of operator nets. Lucid is a functional, definitional language in which the values of variables are infinite time-varying sequences. The structure of Lucid programs resembles the mathematical statement of a function definition. The model of a Lucid program is a filter which processes a time-varying infinite input stream, with the output of the program being the output stream which results from application of the filter to the input. Lucid programs therefore have a "built-in" time index. The model is in many ways well matched with operations in digital signal processing.

We will consider dynamic or tagged dataflow models [1, 7], in which each daton is associated with a tag, and the datons which are to be used together as the arguments of an operator or function are identified by matching their tags. The basic model of execution in such architectures is a ring. Data-driven architectures (e.g., the Manchester Dataflow Computer [3, 7]) are modeled by a single ring; demand-driven machines (e.g., the Eduction Engine [4]) are modeled by two intersecting rings, one for handling demands and one for applying operators to the results of demands; the hybrid Eazyflow Architecture [5] is modeled by intersecting data, demand, and application rings. The Eduction Engine and Eazyflow Architecture have been designed to perform direct execution of operator nets, expressed in linear form as Lucid programs.

## Analyses

Three types of analyses are demonstrated. A data dependency analysis based on the theoretical statement of the computation exposes the available parallelism. Analysis of the operator net and/or Lucid code provides a means of determining the parallelism that can be extracted from the program. From these analyses, requirements on the architecture can be derived.

The digital filtering computation

$$y_n = \sum_{k=0}^{p} a_k x_{n-k} + \sum_{k=1}^{q} b_k y_{n-k} \quad \text{for } n \geqslant 0 \qquad (1)$$

will be used to illustrate the analyses. We assume that the data arrival rate is $S$ (in signal processing terms, a sampling rate of $S$), the sample period is $\delta$, and that the data output rate matches the data input rate. (A faster data output rate is not possible; a slower rate implies eventual infinite buffering of inputs.) Except where specified otherwise, we will take the multiply-accumulate, denoted *mac*, ($sum = sum + w*v$, where $sum$, $w$, and $v$ are scalars) as the basic operation performed. In (1), $x_n = y_n = 0$ for $n < 0$.

### Inhłrent Parallelism

Conventional analysis of the data dependencies in the computation defines the maximum degree of parallelism attainable. Graphically, this can be represented by structures such as Petri nets. In many cases, this analysis can be performed directly on the mathematical statement of the problem. For example, in the digital filtering case, expansion of Eqn. (1) shows that each $x_i$ will be used in $P = p + 1$ terms and that each $y_i$ will be used in $Q = q$ terms. In any time interval $\delta$, then, it will be possible to initiate $P + Q$ *mac* operations. Because of the associativity of addition the *mac*'s can be performed in any order, so the only constraint on the computation is that imposed by the availability of the $x_i$'s and $y_i$'s. The maximum degree of parallelism (the number of *mac*'s that can be in progress simultaneously) will therefore be $\alpha(P+Q)$, where $\alpha = \lceil t_{mac} / \delta \rceil$ and $t_{mac}$ is the total time to perform one multiply-

This work was supported by NSF Grant Number DCR-84 13727, by funds from the DARPA Strategic Computing Program, monitored by the Office of Naval Research under ONR Contract Number N00014-85-C-0775, and by SRI International.

accumulate. Depending on the architecture, $t_{mac}$ may represent only the actual time for the arithmetic operation or it may, in fact, include the complete cycle of instruction-fetch/decode/execute or token-match/instruction-fetch/execute.

### Operator Net and Lucid Parallelism

The operator net and Lucid program provide equivalent representations of the computation. In addition to representing the data dependencies, these forms also incorporate temporal dependencies introduced by the language constructs used. In particular, the effect of the program strategy and data structures used can be derived from the operator-net/Lucid representation. Since Lucid programs implicitly operate on time-varying sequences, the notion of "Lucid-time" is contained in operators such as **first** (which accesses the first element of the sequence), **next** (which yields the remainder of the sequence), **is current** (which temporarily freezes time with respect to a specified variable), **asa** (which selects a value *as soon as* a condition is met), and **fby** (which allows the construction of the time-varying sequences): and by built-in variables such as **index** (which is automatically incremented by one for each tick of Lucid-time). The operator net reveals the temporal relation between portions of the computation. Incorporation of timing constraints introduced by the use of Lucid-time constructs allows analysis of individual code blocks. Combining these analyses with information about data input arrival rates allows derivation of the potential parallelism in the Lucid program.

Fig. 1 shows two different Lucid code segments to compute the steady-state output of Eqn. (1). Given the notion of data streams (and lacking the notion of stored, randomly accessible vectors) and the capabilities of Lucid, it is easier to access "future" data items in the input or output streams than to access "past" items, so the computation has been reformulated as

$$y_{n+q} = \sum_{k=0}^{p} c_k\, x_{n+q-p+k} + \sum_{k=0}^{q-1} d_k\, y_{n+k} \text{ for } n \geqslant -q \quad (2)$$

where $c_i = a_{p-i}$ for $0 \leqslant i \leqslant p$ and $d_i = b_{q-i}$ for $0 \leqslant i < q$. Zero-padding of $x$ and $y$ ensures correct alignment of the two sums (see Fig. 1).

**Implementation Using Recursive Function Calls**

```
//input = x; zpad_x = x with P-1 zeros prepended
//output = y; zpad_y = y with Q zeros prepended

y where y = xsum(c,zpad_x,P) + ysum(d,zpad_y,Q)
   where
     xsum(coeff,z,P) =
       f(coeff,z,first P) fby xsum(coeff,next z,first P);
     ysum(coeff,z,Q) =
       f(coeff,z,first Q) fby ysum(coeff,next z,first Q);
     f(w,v,N) = sum asa index eq N
       where sum = 0 fby sum + w * v; end;
   end;
 end
```

**Non-Recursive Implementation**

```
//A from I is <A_I ,A_I+1,A_I+2, · · · >

y where
   y = g(c*X,P) + g(d*Y,Q)
     where
       I is current index;
       X = zpad_x from I;
       Y = zpad_y from I;
     end;
   g(s,N) = sum asa index eq N
     where sum = 0 fby sum + s; end;
 end
```

Fig. 1. Portions of two digital filter algorithms.

Fig. 2 shows the operator net for the *xsum* and *ysum* functions from the recursive version, where *f* can be specified by a subgraph representing the operator net for the function *f*. The operator net reveals the temporal relation between the two major portions of the computation. In terms of the dataflow model, the computation of *f* can begin immediately. After a delay of one time unit $\delta$ (corresponding to advancing one time unit in the $x$ or $y$ data stream) the *xsum* (or *ysum*) function will be enabled, allowing another *f* computation to begin. The operation of *f* is constrained by the sequential character of the input and by the **fby** construct to proceed linearly. (Thus, although the associative addition allowed accumulating the terms in any order in the theoretical analysis, the Lucid model imposes a linear order on the computation.) In general, then, $t_f = (N-1)\delta + t_{mac}$. Except for the case of $N$ small and $t_{mac} \gg \delta$, $t_f = \lambda N \delta$ for some $\lambda$. Combining the analysis of *f* with the enabling pattern of the *xsum* or *ysum* functions yields Fig. 3, where the length of the rectangles is $\lambda N \delta$. Once steady state has been achieved, taking a horizontal cross section across the graph shows the number of instances of *xsum* (or *ysum*) that can proceed simultaneously. Including the addition that combines *xsum* and *ysum* gives an approximate steady state potential parallelism of $\lambda(P+Q)+1$.

In the non-recursive implementation, the fact that the filter moves across the signal is contained completely in the implicit advancing of Lucid-time. At each time step $I$, time is frozen and an output $y$ value is computed using $X = zpad\_x_I, zpad\_x_{I+1}, \cdots$ and $Y = zpad\_y_I, zpad\_y_{I+1}, \cdots$. As in the recursive implementation, a new computation can begin upon arrival of a new $x$ value or completion of a new $y$ value, i.e., at each interval $\delta$. In function $g$, the **fby**

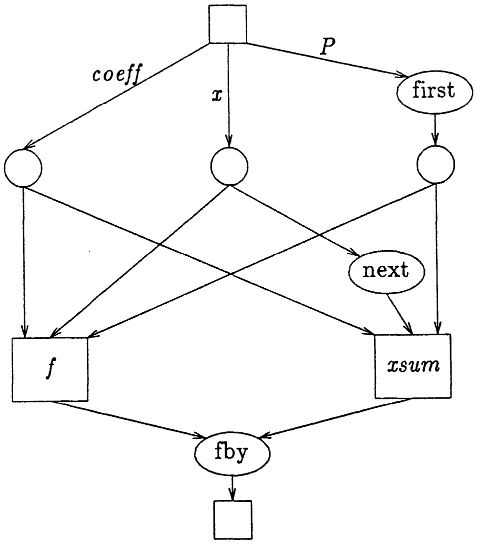

Fig. 2. Operator net for function *xsum*.

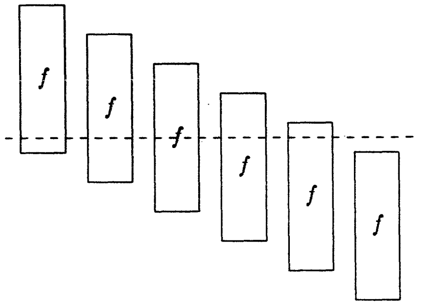

Fig. 3. Time sequence of *xsum* computations, shown for $\lambda N = 5$, in time units of $\delta$.

forces linear operation, with execution time proportional to $P$ (for $g(c^*X, P)$) or $Q$ (for $g(d^*Y, Q)$). The analysis is similar to that for $f$ above. Combining the implicit advancing of the computations with the analysis of $g$ yields the same execution characteristics as shown in Fig. 3 for the implementation using recursive function calls. In the non-recursive case, the basic operations are additions and multiplications rather than multiply-accumulates. The asymptotic behavior will be the same for the two cases; specific differences will depend on factors such as how the recursion and how the tagging requirements arising from the **is current** construct are implemented.

### Architecture Analysis

We consider analyses relating the dataflow architecture to the Lucid algorithm. The characteristics of the algorithm are used to derive requirements on the architecture in order to achieve the desired performance. This entails combining the constraints imposed by the input arrival rate, desired output rate, and the computational complexity characteristics obtained via the analysis of the Lucid program. The resulting model of the progression of the algorithm's execution can be combined with the architecture model to derive the processing rates required at each component of the architecture. For simplicity, we use a data-driven model, shown in Fig. 4. The computation can proceed essentially as outlined above. Assuming equal data arrival and output rates of $S$ samples per second, the minimum required processing rates shown in Table 1 can be derived. The "$S(P+Q+1)$" terms are due to the computation steps; the "$S$" terms account for the input. The fundamental operation is taken to be a 3-operand multiply-accumulate. If more basic arithmetic operations and 2-operand matches are used, the entries due to computation approximately double.

Table 1. Processing Rates for Dataflow Ring (sec$^{-1}$)

| | |
|---|---|
| Switch | S(P+Q+1)+S tokens |
| Token Queue | S(P+Q+1)+S tokens |
| Matching Store | S(P+Q+1)+S matches |
| Instruction Store | S(P+Q+1) accesses |
| Processors | S(P+Q+1) operations |

The operations count in the processors implies that in time $\delta$, $P+Q+1$ operations must be performed. The parallelism analysis has shown that this may be done in as many as $P+Q+1$ processors. Depending on $\delta$ and $t_{mac}$, fewer processors may suffice. The more stringent requirement is on the operation of the matching store. If $P$, $Q$, and $S$ are such that the matching store cannot function at the required rate, multiple submachines, such as those proposed for the Eazyflow Architecture [5] and the next generation Manchester system [3], could provide the needed capability.

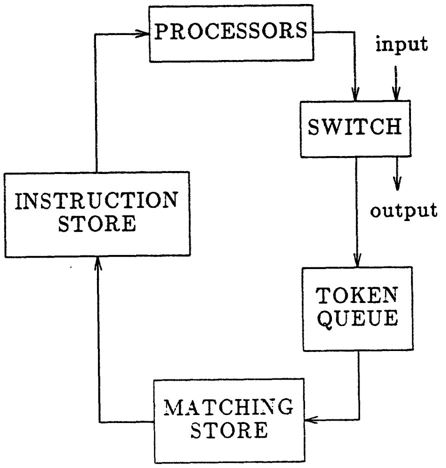

Fig. 4. Ring of a data-driven architecture [7].

### Summary

This paper addresses the problem of analyzing signal processing algorithms for dataflow architectures. The dataflow language Lucid differs significantly from traditional computer languages, just as the dataflow model of computation differs significantly from the von Neumann serial computer. Development of efficient signal processing algorithms for Lucid/dataflow execution therefore requires new algorithm approaches, programming strategies, and analysis techniques. We present some analysis tools which allow us to obtain design parameters for dataflow architectures targeted for signal processing applications.

# A MODEL OF QUANTITATIVE ANALYSIS FOR PERFORMANCE EVALUATION OF STATIC DATA FLOW COMPUTERS

Liu Gui-zhong and Ci Yun-gui
Department of Computer Science
Changsha Institute of Technology
Changsha, Hunan, P.R. China

Abstract — First, a model of static data flow computer and a model of data flow graph are proposed, then a model of system is presented for calculating practical parallelism degree with overhead of instruction execution on data flow computers as its parameter. From the computation, we can conclude that the maximum practical parallelism degree of a program running on a static data flow computer is determined with MP/OH (MP is the mean parallelism degree of a program, Oh is the overhead of instruction execution on the computer ). Therefore the overhead has great influence on the performance of a data flow computer.

## Introduction

The main purpose of research on data flow computers is exploiting parallelism in programs and speeding up their running. Instructions on data flow computers are driven by data, therefore data flow computers have great potential power in exploiting parallelism. However, progress in studying data flow computers is not great. In recent years, some people have criticized the approach of data flow. They point out that one of its problems is the great overhead, such as communication overhead in packet switched networks, extra accessions of memory, etc. While other people don't think the overhead is a problem. They consider a data flow computer as an asynchronous pipelined structure, and believe that if there are enough instructions available, each part of the computer can run efficiently even though the overhead is great.

In this paper, an approach is presented for studying the overhead. First, a model is given for a class of static data flow computers, then the relationship between the overhead of instruction execution and the parallelism degree on such a computer is established using the theory of stochastic process. The computed results show that for an user program, the practical maximum parallelism degree is only limited by the overhead of instruction execution.

## 1. MODEL OF STATIC DATA FLOW COMPUTERS AND MODEL OF DATA FLOW GRAPH

A typical structure of static data flow computers is shown in fig. 1. This is in fact a macro pipeline consisting of several units performing different operations. In such a system, many auxiliary operations are introduced, such as fetching instructions, sending them to processors through switched network, constructing result packets, sending packets back through network, storing packets into memory, and arbitrating whether instructions can be fired, etc. The so called EFFECTIVE OPERATION means the operation which directly do what the opcode of an instruction indicates. For example, the effective operations of arithmetic instructions are to perform arithmetic operations. The OVERHEAD of an instruction execution is all of its auxiliary operations. In this paper, we suppose the effective operation of each instruction takes one unit of time. The overhead of instruction execution is measured in units of time. In general, the overhead of instruction execution depends on what the instruction is and what environment the instruction is executed in. Here, the overhead practically refers to the average value of overheads of all instructions. In the following, the overhead of instruction execution is briefly called overhead, denoted by OH.

The model of pipelined structure for studying overhead is shown in fig.2. The N processors in the model, which represent N processors in a system, execute only effective operations of instructions in one unit of time. The n pipelines correspond to delays of auxiliary operations. The number of stages in each pipeline represents the corresponding value of overhead. Suppose the delay of one stage is one unit of time, then the number of stages of a pipeline is OH, $OH \in \{1,2,3,\ldots\}$. The memory in fig.2 is an idealized unit with unlimited size and accessing time 0. Its delay is considered as some of the stages of the pipelines.

A data flow graph is a directed cyclic graph. In fig.3, a data flow graph for computing N! is depicted. In order to describe the dynamic behaviour of a program, the data flow graph of the program should be unfolded to become an acyclic graph. That is, each function call should be replaced by its data flow graph and each loop should be unfolded. Therefore, no cycle exists in the graph obtained (the graph is an infinite one, if its program running will not stop). In such a graph, each node represents an instruction.

A pseudo-node, which is named start node and denoted by sn, and which emits all arcs to nodes that input tokens from outside of the graph, can be added to an unfolded graph, as shown in fig.5. Such a graph is called an extended data flow graph. In the flowing, we will only discuss this kind of graphs and call them data flow graphs(DFG) in brief. Suppose the length of each arc in such graphs is one.

DEF.1.1 Level of a node. The level of the start node is zero, the level of any other node is the length of the longest path to it from the start node.

DEF.1.2 Parallelism degree of level j of a program (j is a positive integer) $PD_j$ is the number of nodes at level j in its extended data flow graph. Parallelism degree of a program, PP is

$$PP \triangleq \begin{cases} \sum_{j=1}^{m} PD_j / m & \text{m is the maximum level of the graph} \\ \lim_{m \to +\infty} \sum_{j=1}^{m} PD_j / m & \text{if the graph is infinite} \end{cases}$$

DEF.1.3 Balanced data flow graph. If there are two or more paths from the start node sn to a node in a data flow graph, then their lengths

0190-3918/86/0000/0611 $01.00 © 1986 IEEE

are the same. Such a graph is a balanced data flow graph, otherwise it is an unbalanced one.

When a balanced data flow graph is used to process a set of data in a pipelined way, high efficiency can be achieved. Unfortunately, most data flow graphs are unbalanced ones. In order to transform them into balanced ones, some identity instructions (I), which only delay tokens by one unit of time, should be inserted in some short paths, thus increasing their lengths. An unbalanced DFG is shown in fig.5. We insert an identity instruction into it, so that it becomes a balanced one, as shown in fig.6.

On balanced DFG, the nodes at level i receive data tokens only from level i-1. In other words, instructions at level i are only driven by tokens from level i-1. So, we propose an assumption.

ASSUMPTION ON DRIVING LEVEL BY LEVEL. On extended DFG, instructions at level i are only driven by tokens from level i-1.

For any unbalanced DFG, it is possible that an instruction at level i receives tokens not only from level i-1, but also from other levels. Because the tokens from level i-1 goes through the longest way from the start node sn to the instruction, it is mostly possible that the instruction is fired by this token. Therefore, this assumption is reasonable in general.

Let Object_No$_{j-1}$ denote the total number of result packets generated by all instructions at level j-1, and Operand_No$_j$ the total number of operands required by all instructions at level j. According to the previous assumption, we have

$$\text{Object\_No}_{j-1} = \text{Operand\_No}_j \quad j \in \{2,3,4,\dots,m\}$$

A stochastic process PD$_j$, $j \in \{1,2,3,\dots\}$ is used for describing the dynamic behaviour of parallelism degree of a program. Suppose that all PD s are independent, identically distributed random variables with distribution $N(MP, \sigma^2)$, where MP and $\sigma^2$ are the mean and the variance of PD$_j$ respectively, PD$_j$ is the parallelism degree of level j.

## 2. MODEL OF SYSTEM FOR COMPUTING PARALLELISM DEGREE

First, we make some assumptions on this system.

Assumption 2.1. The system has n processors. In other words, the maximum parallelism degree of the system is n. Let $\mathcal{N} = \{0,1,2,\dots,n\}$, is a set of all possible practical parallelism degree of the system.

Assumption 2.2. The maximum parallelism degree of a program is $P_{max}$. $P_{max} = MAX(P_1, P_2, \dots, P_m)$, $P_j$ is the parallelism degree of level j, m is the maximum level. Let $\mathcal{P} = \{1,2,3,\dots, P_{max}\}$, is a set of all possible parallelism degrees of the levels.

Assumption 2.3. The numbers of result packets produced by instructions at each level are independent, identically distributed variables with revised Poisson distribution.

Suppose the mean number of result packets produce by an instruction at level j is $\lambda_j$, the revised Poisson distribution $P^+(\lambda_j)$ is

$$P^+(\lambda_j) = \frac{\lambda_j^{x-1}}{(x-1)!} e^{-\lambda_j} \quad \begin{array}{l} x = 1,2,3,\dots \\ \lambda_j \in \{1,2,3,\dots,\lambda_{max}\} \\ \quad = MAX(\lambda_1, \lambda_2, \cdots, \lambda_m) \end{array}$$

Assumption 2.4. Any result packet is transmitted to each instruction at next level with identical probability.

Assumption 2.5. The numbers of operands needed by instructions at each level of a program are independent, identically distributed variables with revised Poisson distribution $P^+(\beta_j)$, where $\beta_j$ is the mean number of operands required by an instruction at level j.

DEF.2.1. A description vector of level i of a program is a k-tuple sequence $M_j$, $M_j = (a_{j1}, a_{j2}, \dots, a_{jk})$, $a_{ji} \in \mathcal{P}$, $1 \leq i \leq k$, $k = \lambda_{max} * MP$. $a_{ji}$ is the number of instructions requiring i operands. At beginning, $PD_j = \sum_{i=1}^{k} a_{ji}$.

According to assumption 2.5.

$$\text{Let} \quad a_{ji} = \frac{\beta^{(i-1)}}{(i-1)!} e^{-\beta_j}$$

$$M_j \in \underbrace{\mathcal{P} * \mathcal{P} * \cdots * \mathcal{P}}_{k} = \mathcal{P}^k$$

Let $\mathcal{M} = \mathcal{P}^k$, called a set of description vectors.

When a result packet is produced and passed to the next level, the Probability with which the result is sent to a set of instructions requiring i operands is $a_{ji} / \sum_{i=1}^{k} a_{ji}$ according to assumption 2.4. After that, the number of instructions requiring i operands decrements, whereas the number of instructions requiring (i-1) operands increments. The description vector $M_j$ is transformed to $M_j'$.

$$M_j' = \begin{cases} (a_{j1}, a_{j2}, \dots, a_{ji-1}+1, a_{ji}-1, \dots, a_{jk}) & i>1 \\ (a_{j1}-1, a_{j2}, a_{j3}, \dots, a_{jk}) & i = 1 \end{cases}$$

When the result packet is transmitted to a set of instructions requiring only one operand (i=1).one instructions in the set can be fired. The number of instructions $a_{j1}$ decrements $(a_{j1}-1)$,the total number of instructions at level j also decrements, and the number of instructions in the buffer increments. In other cases, the instructions at level j does not decrease. Obviously, when $\sum_{i=1}^{k} i * a_{ji}$ result packets are received at level j, all instructions at this level can be fired.

From the assumption on driving level by level, $PD_{j-1} * \lambda_{j-1} = PD_j * \beta_j$ then $\beta_j = \lambda_{j-1} * PD_{j-1} / PD_j$

DEF.2.2. The state of processors is an integer PR, $0 \leq PR \leq n$, n is the number of processors in the system.

DEF.2.3. The state of the pipeline is a vector PI with OH elements, $PI = (n_1, n_2, \dots, n_{OH})$, $n_i \in \mathcal{N}$, $1 \leq i \leq OH$. $PI \in \underbrace{\mathcal{N} * \mathcal{N} * \cdots * \mathcal{N}}_{OH} \triangleq \mathcal{N}^{OH}$

DEF.2.4. The state of the buffer is an integer BU, $BU \in \{0,1,2,\dots, m*P_{max}\}$

DEF. 2.5. A descriptor of a program with m levels is a m-tuple sequence $PG_m$, $PG_m = (M_1, M_2, \dots, M_m)$, $M_j \in \mathcal{M}$, $1 \leq j \leq m$, $PG_m \in \mathcal{M} * \mathcal{M} * \cdots * \mathcal{M} \triangleq \mathcal{M}^m$.

The model of system for computing parallelism degree is shown in fig.7, in which PR is the state of processors, PI the state of pipeline, BU the state of the buffer. The value of BU represents the number of instructions, which can be fired. but are waiting for free processors. The memory of the system is composed of two parts. One is a half infinite linear storage with locations 1,2,3, .... Each location can store a description vector, and location 1 stores $M_1$, location 2 stores $M_2$,... location m stores $M_m$, that is, m description vectors are stored in order from location 1 to m. The second part of the memory is a pointer Point.which points to a location that can be read or written currently. Point can stay at the original place or move one location to the right. Its initial is at the first location. Except the m locations storing $PG_m$, the locations in the memory all store blank vectors B, B = (b,b,b,...,b), b is a blank character.

DEF.2.6. The state of the system s for computing parallelism degree is a triplet (PR, PI, BU), in which PR, PI, and PU are the state of processors, the state of the pipeline, and the state of the buffer respectively (as def. 2.2,2.3,2.4).

Let $\mathcal{PS}$ be a set of system states,

$\mathcal{PS} = N*N^{OH} * \{0,1,2,\ldots,m*P_{max}\}$, $s \in \mathcal{PS}$.

DEF.2.7. The model of system for computing parallelism degree is a 5-tuple ($\mathcal{PS}$, $s_o$, $\mathcal{M}$, B, $\delta$), in which $\mathcal{PS}$ is the set of system states, $s_o$ is the initial system state, $s_o = (0, (0,\ldots,0), 0)$, $\mathcal{M}$ is the set of description vectors of a program, B is the blank vector, and $\delta$ is a map

$$\delta : \mathcal{PS} * \mathcal{M} \longrightarrow \mathcal{PS} * \mathcal{M} * \{L, A\}$$

L means that the Point does not move

A means that the Point advances one location to the right

$\delta$ is called the transform rule of the system state. We shall describe it with the algorithm TRANS as follows.

Supposition 1. $Poisson^+(\lambda)$ is a random number generator with revised Poisson distribution. $\lambda$ is the mean of the random numbers.

Supposition 2. $U(M_j)$ is also a random number generator, which give a positive integer i, $1 \leq i \leq k$, according to assumption 2.4.

```
Algorithm TRANS
if $M_j$ = B then stop else
  if $M_j = (0,0,\ldots,0)$ then j:=j+1 else
    begin
    RN:=PR; PR:=PI ;
    for i :=2 to OH-1 do $PI_i := PI_{i+1}$ ;
    if BU >= n then [$PI_{OH}$:= n; BU:=BU - n]
     else [$PI_{OH}$:=BU; BU:=0];
    Packet := 0;
    while RN>0 do (Packet:=Packet + $Poisson^+$
      ($\lambda_{j-1}$); RN:=RN-1] ;
    While (Packet>0 and $M_j \neq (0,0,\ldots,0)$) do
      begin
      i:=U($M_j$); $a_{ji} := a_{ji} - 1$;
      if i>1 then $a_{ji-1} := a_{ji-1} + 1$ else
        BU:=BU+1
      end
    end;
```

Suppose the system is executing instructions at level (j-1) in a data flow graph. After a unit of time, instructions in n processors of the system are all finished, each of which produces some result packets randomly. The total number of these result packets are stored into a variable Packet. At the same time instructions at the first stage of the pipeline PI is sent into the processor PR, and some instructions are fecthed into the last stage of the pipeline PI from the buffer BU. The result packets in Packet are passed to the instructions at level j with identical probability. The random number generator $U(M_j)$ produces a number i, then one result packet is transmitted into one of the instructions at level j, which needs i operands. If i >1, then the description vector $M_j = (a_1, a_2, \ldots, a_{i-1} + 1, a_i - 1, \ldots, a_K)$; If i=1, then one of instructions can be fired, and is passed to the buffer BU. After all the result packets (in Packet) are passed to the memory one by one, $M_j$ is changed to $M_j'$, BU to BU', and system goes into a new state.

When the model is running, the values of PR and the number of steps of the system proceeded are accumulated, and then the practical parallel degree can be calculated as $\sum$PR/steps.

Before running the model, the mean of parallelism degree of a program, its varience, and the overhead of instruction execution are set as parameters. When the system finishs, the relation among the overhead, parallelism degree, and the number of processors can be determined.

## 3. RESULTS COMPUTED AND DISCUSSION

According to the model, some results computed for various parameters have been obtained. And two sets of curves are depicted in fig.8,9.

In fig.8, we suppose the communication overhead is in proportion to log N, so OH = $C_1 + C_2 \log N$, where $C_1, C_2$ are integers ($C_1, C_2 > 0$). Since packets pass through the networks two times, $C_2$ equals to two.

Each curve in fig.8 has a maximum value. After the maximum value is reached, the practical parallelism degree falls, the efficiency of processors decreases, although the number of processors N in system increases.

The table 1. shows the relationship between the maximum practical parallelism degree and other variables.

In fig.9, a set of curves of relations between practical parallelism degrees and parallelism degrees of systems with OH as parameter are shown. where on each curve there is also a maximum value of practical parallelism degrees.

From the model of the system, we can see that in order to obtain high efficiency, the pipeline representing overhead must be filled up with OH*N enabled instructions. If MP<OH*N, all instructions at one level are not enough for filling the pipeline. As a result, the practical parallelism degree decreases.

When MP of a program and OH of a system are given, the maximum practical parallelism degree is equal to or less than MP/OH. In the following, we give the explanation on this.

(1) Suppose MP<OH*N.

Since MP instructions are executed during OH steps, practical parallelism degree is MP/OH;

(2) Suppose MP$\geq$OH*N

Obviously, the practical parallelism degree is the possible maximum parallelism degree of a system, N. Since MP>=OH*N, then N<=(MP/OH).

Therefore, the practical parallelism degree is not greater thanMP/OH. Consequently, when parallelism degree of a program is a constant, its practical maximum parallelism degree is only determined by the average overhead of instruction execution on a system and have nothing to with the number of processors in the system. If we hope to speed up the running of a program on a system, only by means of increasing the number of processors, even at the cost of increasing the overhead, then the result may be countrary to our hope. The increasing of the overhead may cause the practical parallelism to be decreased, and the running time of programs increased.

The practical parallelism degrees computed from the above model is much less than MP/OH, because the execution of instructions enabled on data flow computers is in random order, which is not suitable for pipelines.

From the above computation, we can see that overhead has great influence on the performance of a data flow computer. If we want to increase the parallelism degree of data flow computers, we must be sure that the overhead does not increase quickly.

Obviously, although the conclution is obtained from static data flow computers, it is also useful for other types of multi-processor systems.

Abstract -- We address the problem of improving the efficiency of the parallel evaluation of functional programs. We assume that those programs are evaluated by a set of concurrent agents which communicate with each other and cooperate together while the computation progresses. Communications among agents improve the performance, because properties or facts about the functions to be computed are exploited. In particular we show that those communications may avoid redundant computations of intermediate results.

## 1.Introduction

Functional languages have been advocated as a formalism for expressing algorithms which allow to overcome the limitations imposed by the von Neumann computer architecture [1]. Applicative expressions in fact, can be evaluated in a parallel way by a set of concurrent computing agents, because there is a unique value associated with any subexpression, independently from the context in which it occurs (by the referential transparency property). That context independence property allows us to compute the various subexpressions in a parallel way by assigning each of them to an individual computing agent.

In order to fix our ideas and to introduce our Hope-like notations [3], let us consider the following simple program for computing binomial coefficients:

$$\text{BO:}\quad \begin{cases} \text{bin}(n,0)=1 \\ \text{bin}(n,n)=1 \\ \text{bin}(n,m)=0 \quad \underline{\text{if}}\ n<m \\ \text{bin}(n+1,m+1) = \text{bin}(n,m)+\text{bin}(n,m+1) \\ \qquad\qquad\qquad\qquad\qquad\qquad \underline{\text{if}}\ n> m \end{cases}$$

The computation of the function bin(n,m) can be informally described as a rewriting of sets of agents.(The formal definition of a generic computation will be given later). For the time being,an agent can be thought of as a pair consisting of a string, i.e.,the name of the agent, and an expression, i.e.,the expression which the agent has to evaluate.

We may assume that initially there is the agent ε::bin(n,m), which can be rewritten into the set of agents:

{ε:: .0+.1, 0::bin(n-1,m-1), 1::bin(n-1,m)}
where n>m≥1.

In the rewriting we see that:i) new agents are generated by the recursive calls of the program equations, ii) the left and right sons of the initial agent ε have names 0 and 1 respectively, and iii) .k denotes in any given expression the result of the computation of the agent whose name is k for k=0 or 1.

We assume that the convention for giving names to the agents is the following: the initial agent has name ε, and if the agent x has k+1 sons, i.e., it uses for the rewriting a recursive equation with k+1 recursive calls, the names of its sons are x0, x1, ..., xk, respectively, according to the left-to-right order of those recursive calls.

For our binomial function, in the second step of the computation the agents 0 and 1 generated by the agent ε, can be rewritten independently from each other, so that the computation of bin(n,m) can be more precisely viewed as a nondeterministic and parallel rewriting of sets of agents into new sets of agents (see figure 1). The nondeterminism consists in choosing one (or more) agents to be rewritten, and parallelism consists in rewriting all agents which have been chosen, according to the recursive equations of the program.

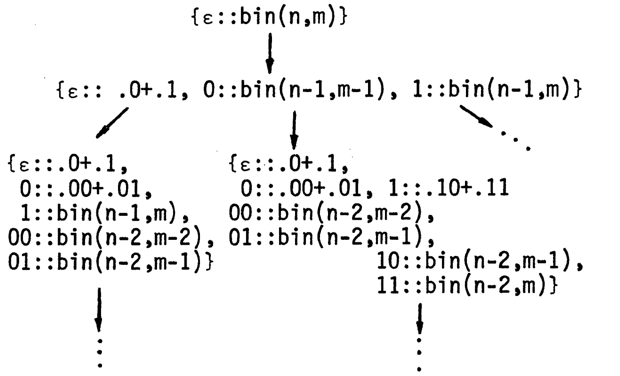

figure 1. Possible rewritings of the parallel computation of bin(n,m) when n>m≥2.

Notice that, according to the naming convention, each set of agents can be viewed as a tree-structured set, and therefore we may say that the computation progresses as a nondeterministic and parallel rewritings of trees of agents.

In this paper we will be concerned with the problem of improving performance of the trees of agents for the parallel evaluation of functional programs.

We will propose a method based on the discovery or knowledge of some "facts" concerning the functions to be evaluated. Those facts will be implemented as suitable communications among computing agents and the occurrence of those communications will realize the expected efficiency improvements.

Suppose, for instance, that we know the following fact about the binomial coefficients function: if n>m≥2 then the left son of the right son of bin(n,m) is equal to the right son of the left son of bin(n,m). In the language of facts which we will formally introduce later, we write:

bin(n,m)]01 = bin(n,m)]10

(see figure 2).

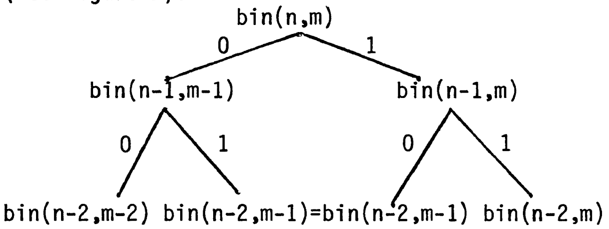

figure 2. A fact for the binomial coefficients function: bin(n,m)]01=bin(n,m)]10 where n>m≥2.

In the rewriting of the tree-structured set of agents we may then avoid the expansion of the agent 10 and allow the expansion of the agent 01 only. Once the value of bin(n-2,m-1) has been obtained, the agent 01 may send it to the agent 10, and save its computation. We will see in the sequel how that communication takes place and how it can be implemented by associating a local memory with each agent.

Avoiding the expansion of the agent 10 reduces the number of agents we need for performing the required computation of bin(n,m) and in most cases that saving is crucial,because in practice the number of available computing agents cannot be considered as unbounded.

There is another reason why the knowledge of relevant facts about recursive functions may drastically improve the efficiency. Suppose that during the computation of a given function we have used all the agents at our disposal. At that point we have to backtrack by deallocating the tasks from some agents which are leaves of the current tree of agents. The deallocation will make some agents available for the rewriting of other leaf agents and then more computation steps can be performed. It is desirable that backtracking steps are done in the most effective way, so to avoid,if it is possible, subsequent backtracking steps and at the same time, allow the maximum utilization of the agents at our disposal. Unfortunately the deallocation-allocation procedure in general cannot be optimized, if we do not know enough properties about the dynamical expansion of the trees of agents during the computation of the particular function we have to evaluate. In the binomial coefficients case, for instance, when computing bin(n,m) it may be better to expand the tree of agents so that we activate as soon as possible bin(m,m) or bin(n-m,0) because no extra agents are needed when computing those function calls.

In the Section 2 we will present a method for implementing facts about recursive functions and we will see how they can be translated into communications among agents.

In the subsequent Sections we will give a more formal presentation of the ideas introduced in Sections 1 and 2, and we will study some properties of the communications among agents.

## 2. The general scenario and a preliminary example

We consider the functional programs written as a set of recursive equations in a language L0 (to be defined later), and we assume that the programmer discovers or knows some useful facts about the functions to be computed. Those facts, written in the language of facts LF, are first submitted to a calculus which may or may not accept them. The role of the calculus is twofold: i) it makes sure that the facts are correct with respect to the given programs, and ii) it validates the efficiency improvements they determine, once implemented as communications among agents. Those two aspects of the calculus are very important, because otherwise we may derive, as we will see, erroneous or inefficient programs.

Facts which are accepted by the calculus are then translated by a translation algorithm, which produces a new set of recursive equations, written in a language L1, where it is possible to denote communications among function calls.

The general scenario of our approach is the one depicted in figure 3.

"Parallel Programs" (Rewriting Rules for Communicating Agents)

figure 3. The general scenario for improving the parallel execution of functional programs.

The scenario we presented can be considered as an extension of the ideas of the transformation system of Burstall and Darlington [2]. However in our approach the knowledge the programmer has about the functions to be computed, is expressed in a language LF of facts (not as "eureka steps" [2]). Moreover, the presence of the calculus which deals with the facts and ensures their correctness and their usefulness for improving efficiency, avoids the problems inherent to the Burstall-Darlington approach, where it may be that during the transformation process correctness is not preserved [8] and efficiency is not improved.

Notice that we explicitly deal with functional programs executed in a parallel way, so that the facts discovered by the programmer may refer to the behaviour of the associated sets of computing agents, but we allow only facts which can be written in a high level language LF. In this language it is possible to describe properties of sequences of expressions generated by the standard rewriting technique, so that the programmer is not involved in all the peculiarities connected with the computing agents behaviour. The system can accept facts if they are "true" facts and "efficiency improving" facts. Accepted facts about functional programs are used for increasing the efficiency of their parallel execution.

The semantics Sem0 and Sem1 are identified as 2 translations. Given a program P in L0 (or L1) Sem0 (or Sem1) produces a corresponding parallel program P'. Indeed, Sem0(or Sem1) defines a set of agents for evaluating the functions defined in P, and a set of rewriting rules which specify the concurrent behaviour of those agents.

The meaning of P' is given by a transition relation which defines for any given finite set of computing agents, i.e., a configuration, all possible future configurations. That transition relation is able to capture the nondeterministic and parallel execution of the program P' by constructing a tree of configurations as indicated in figure 1.

We will show that the translation Sem0 from a program P to P' (or the translation Sem1∘tr from P with some additional facts to P') can be done automatically for some classes of programs and facts.

The system is able to improve efficiency by automatically introducing suitable communications among computing agents. Those communications are derived on the basis of the given facts only.

It will be shown that the introduction of the intermediate language L1 in which functional programs with communications are written, allows us to have a simple calculus for checking the correctness of the communications among computing agents.

The language of parallel programs should be considered as a lower level language, which is understood by the system which realizes the parallel execution of functional programs via a set of computing agents.

The following example (given at schema level and taken from [4]) will clarify the main ideas we have presented so far.

Let us consider the program schema P:

$$\text{P:}\begin{cases}\text{f(x) = a(x)} & \underline{\text{if}}\ \text{p(x)=true}\\ \text{f(x) = b(x,f(c(x)),f(d(x)))} & \underline{\text{otherwise}}\end{cases}$$

Let us suppose that we discovered that for any x s.t. p(x)=false we have f(x)]01 = f(x)]10. That fact can be expressed as

f(c(d(x)))=f(d(c(x)))

and it means that the left-son call of the right-son call of f(x) is equal to the right-son call of the left-son call of f(x). That fact is then submitted to the calculus (whose definition will be given later). If it is accepted as a "true" fact and an "efficiency improving fact", it will be incorporated into the program P by the translation algorithm which produces the following program P1:

$$\text{P1:}\begin{cases}\text{f(x)=a(x)} & \underline{\text{if}}\ \text{p(x)=true}\\ \text{f(x)=b(x,f(c(x))(1}\ \underline{\text{comm}}\ \text{l),} & \\ \qquad\text{f(d(x))(0}\ \underline{\text{comm}}\ \text{l))}\underline{\text{decl}}\ \text{l} & \underline{\text{otherwise}}\end{cases}$$

The informal meaning of the expression "e decl l" is that a temporary memory location l, is kept during the evaluation of the expression e. That location is discarded when the evaluation of e is completed (see figure 4).

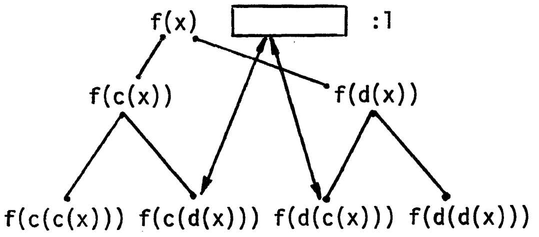

figure 4. The program for f(x) with communications via the location l.

The informal meaning of f(c(x))(1 comm l) (and analogously for f(d(x))(0 comm l)) is that the value of the right son of f(c(x)), i.e., f(c(d(x))) is stored in the location l. To be more precise, f(c(x))(1 comm l) means that i) during the evaluation of f(x), the agent which has to compute f(c(d(x))) may look at the content of the location l to get the result of its computation, and ii) at the end of the computation of f(c(d(x))), that value is stored in l. If a computing agent looks at the content of a location l and there is no value stored in it, its computation continues by activation of recursive calls.

From the informal description we have given, it is clear that efficiency improvements may take place, because before the end of the computation of f(d(c(x))), the corresponding agent may look at the location l and get the value it has to compute.

In particular, that agent may simply wait for the result of its computation to be written in l by the companion agent, which has to compute f(c(d(x))). If it does so, the generation of redundant agents is avoided, but we have to make sure that the agents do not wait for each other and no deadlock occurs.

Notice that the identification of a descendant call of a function f(x) is done via a string in $\{0,1,\ldots,k\}^*$. f(x)]ε denotes the function call f(x) itself, and f(x)]s.j recursively denotes the j-th son call of f(x)]s, for $s\in\{0,1,\ldots,k\}^*$ and $0\leq j\leq k$.

The calculus used in our approach is based on the symbolic evaluation of functions and it makes sure that for the given functions c and d, we have indeed: f(c(d(x)) = f(d(c(x))). The efficiency improvements due to the realization of the facts, are guaranted by the property that when a communication occurs, it is like making many rewritings of trees of agents in one step only.

The following new fact, called periodic redundancy in [4], can be discovered about the function f(x):

$$f(x)]0^{n+1} = f(x)]1^{m+1} \quad \text{for some m and } n\geq 0,$$

where $j^n$ denotes the string of n j's.

The above fact can be implemented as new additional communications between computing agents, and we get the following program P2:

```
    ┌ f(x)=a(x)                          if p(x)=true
    │
P2: ┤ f(x)=b(x,f(c(x))(1 comm l1)(0^n comm l2),
    │
    │          f(d(x))(0 comm l1)(1^m comm l2)))
    └                  decl l1,l2   otherwise
```

Notice that the programmer, when he discovers new facts, has only to suggest them to the system, and their translation into new recursive equations with communications is done automatically by the translation algorithm (at least for the facts we considered here, i.e., the ones which can be expressed as equality of functions calls). Indeed it is not difficult to see that one can derive the communication expressions of the form:

s comm l and decl l

starting from the strings denoting function calls in the language of facts.

The goal of our project is to build a system for recognizing different classes of facts concerning functional programs, and exploiting those facts for improving efficiency.

## 3. Parallel programs

In this section we introduce the notion of parallel programs [8-10].

AExp, MExp, Exp are sets of terms constructed in the standard way from constants, variables and function symbols.(The sets of constants, variables and function symbols are fixed in our considerations.) The elements of the sets AExp, MExp, Exp are called agent-name expressions, message expressions and expressions, respectively. If T is a set of terms then by CT we denote the subset of T s.t. t∈CT iff t is a term without variables.

An agent expression is a triple

< agn,msg >:: e

where agn∈AExp, msg∈MExp, e∈Exp.

A computing agent (or simply an agent) is an agent expression without variables.

Configurations are finite sets of agents. By CON we denote the set of all configurations.

A rule (or recursive equation) is an expression of the form:

lh <= rh if cond

where lh,rh are finite sets of agent expressions and cond is a boolean expression.

By r(x1,...,xk) we denote the rule r in which x1,...,xk are the only variable occurrences. If a1,...,ak are constants (of suitable types) then by r(a1,...,ak) (or r or lh <= rh if cond) we denote a concrete instance of r which we derive by substituting a1,...,ak for x1,...,xk in r.

A parallel program is any non-empty finite set of rules.

Let c,c'∈CON and let r be a concrete instance of the rule r and let us assume that:

$c \xrightarrow{r} c'$ holds iff cond is true and lh ⊆ c and c'=(c-lh)∪ rh .

$\xrightarrow{r}$ is called the transition relation of r.

The transition relation corresponding to a given sequence s= r1,...,rk of instances of rules is defined as the composition of the transition relations:

$\xrightarrow{r1}$ ,..., $\xrightarrow{rk}$ and it is denoted by $\xrightarrow{s}$.

The transition relation of a program P (denoted by $\xrightarrow{P}$) is defined as follows:

$c \xrightarrow{P} c'$ holds iff there is a non-empty finite sequence s of instances of rules in P (derived by the same substitution)s.t. for an arbitrary permutation s' of s we have:

$$c \xrightarrow{s'} c'.$$

As an example, let us consider the parallel program BO' for computing the binomial coefficients.BO' is a set of rewriting rules which implements BO.

```
     ┌{<x,E>::bin(n+1,m+1)}<={<x,E>::.x0+.x1,
     │                         <x0,E>::bin(n,m),
     │                         <x1,E>::bin(n,m+1)}
     │                                if n>m
     │{<x,E>::.x0+e, <x0,E>::n}<={<x,E>::n+e}
BO': ┤{<x,E>::e+.x1, <x1,E>::n}<={<x,E>::e+n}
     │{<x,E>::bin(n,0)}<={<x,E>::1}
     │{<x,E>::bin(n,n)}<={<x,E>::1}
     │{<x,E>::bin(n,m)}<={<x,E>::0} if n<m
     │{<x,E>::n+m}<={<x,E>::k} where k=n+m
     └{<x,E>::n-m}<={<x,E>::k} where k=n-m
```

where E is the empty message.The messages will play significant role in others examples, here they do not.

We see the above rules in action in the following computation of bin(3,2), where we write x::exp instead of <x,E>::exp and by ——> we denote the transition relation of BO'.

```
{ε::bin(3,2)}——> {ε::.0+.1,0::bin(2,1),
                          1::bin(2,2)}——>
{ε::.0+.1,0::.00+.01,00::bin(1,0),01::bin(1,1),
                                  1::1}——>
{ε::.0+.1,0::.00+.01,00::1,01::1}——>
{ε::.0+1,0::1+1}——>{ε::.0+1,0::2}——>
{ε::2+1}——>{ε::3}.
```

## 4. The translation functions Sem0 and Sem1.

This section is a technical section where we formally define the language L0 in which preliminary program versions are written, the language LF in which facts as equality of terms are written, and the language L1 in which recursive programs and facts are translated. We also present methods for translating programs in L0 (or L1) into parallel programs.

We will define a <calculus,fact-translation> pair for which facts accepted by the calculus can be correctly translated into communications among recursive calls. A correct fact-translation tr is the one which makes the diagram of fig.3 commute.

We will give an explanation of the various notions by discussing the problem of computing the binomial coefficients.

The language L0 in which the functional program for computing binomial coefficients is written is a Hope-like language [3]. An expression e of L0 is defined by

```
    e::= n|x|g(e,...)|f(e,...)
```

where n∊Constants, x∊Variables, g∊Basic_Functions and f∊Recursive_Functions.

A program P in L0 is a set of recursive equations each of which is of the form:

```
    f(e,...)=n (base case)
or
    f(e,...)=e' with f occuring in e' (recursive
                                        case).
```

For L0 expressions we assume a parallel and distributed evaluation using computing agents [9]. The translation Sem0 of functional programs in L0 into parallel programs is defined by the following list of rules:

1. Generation of sons.

```
   f(e0,...,ek)=g(...,f(e,...),...,f(e',...),...)
produces:          0            p
{<x,E>::f(e0,...,ek)}<={<x,E>::g(...,.x0,...,.xp,...),
                        <x0,E>::f(e,...),...,
                        <xp,E>::f(e',...)}
```

2. Base configurations.

```
   f(e0,...,ek)=n produces:
{<x,E>::f(e0,...,ek)}<={<x,E>::n}
```

3. Values to fathers.

```
{<x,E>::g(...,.xj,...),<xj,E>::n}<=
                       {<x,E> ::g(...,n,...)}
```

4. Basic functions evaluation.

```
{<x,E>::g(n1,...)}<={<x,E>::m} if m=g(n1,...)
```

Initial agent.For computing f(n1,...) the initial configuration {<ε,E>::f(n1,...)} is generated.

E is the empty message. It will play a significant role in Sem1, here it does not.

One can check that our parallel program B0' is the result of the above translation applied to B0.

In order to produce an improved version of the program B0 we may use our system by supplying it with "facts", i.e., properties of the computation of bin. We will restrict our attention to facts which can be expressed as equalities of agent expressions. They can be discovered by symbolic evaluation.

The syntax of the language LF of facts is as follows:

```
          e::=...(as in L0)| e]s  with s∊{0,1,...,k}*
          fact::=f(e,...)]s1=f(e,...)]s2.
```

A fact is checked by a Calculus and, once accepted, a Translation algorithm produces from it an improved version of the given program.

The Calculus for checking facts is given by the rewriting rules, which we will present for any program P0 in L1 with one recursive case only. Let P0 be :

```
 {f(e,...)=n1,...,f(e',...)=nk  (base cases)
 {f(e,...)=e' (recursive case).
```

The rules for the Calculus are:

```
 1. e]ε⊢—>e
 2. n]s⊢—>error  if s≠ε
 3. x]s⊢—>error  if s≠ε
 4. g(e0,...,ek)]js⊢—> if 0≤j≤k then ej]s
                                else error
 5. f(e0,...,ek)]s⊢—>if f(e0,...,ek)=e is an
                     instance of the recursive
                     case then e]s else error.
```

We write:

```
             e]s = e']s'
```

iff it is possible to reduce e]s and e']s' to the same expression (different from error) after applying to them a finite number of times the rules 1-5 and the rules of the Basic_Functions algebra.

For instance, in the program B0 we have for n≥2 and m≥2:

```
bin(n,m)]01⊢—>bin(n-1,m-1)]1⊢—>bin(n-2,m-1)
bin(n,m)]10⊢—>bin(n-1,m)]0⊢—>bin(n-2,m-1),and
   bin(n,m)]01=bin(n,m)]10.
```

The program produced by the translation is written in the following language L1. The syntax of L1 is like that of L0, with the following additions:

```
       e::=...|e(s comm l) with s∊{0,1,...,k}*,
                                l∊Locations.
```

The r.h.s. of an equation can be of the form: e or e decl l.

The parallel programs which we will get after the translation of programs in L1 have a special form of messages.

Messages are either E, i.e.the empty message or em≈L, where:

i) em is the empty elementary message ϕ or a constant elementary message n∊Constants,

ii) L is a set of names of son agents which may read or write the associated elementary message. L is represented as the list [s1,..., sn],where each si∊{0,1,...,k}*.

For instance, if the left son of an agent has to read/write the message of its father, that message will initially be: ϕ≈[0].

Now we are ready to define the translation of the set of programs in L1 into the set of parallel programs.

A program P in L1 is translated as a program in L0 (i.e.,rules 2,4 and the initial agent rule for Sem1 are like those for Sem0) with the following additions and changes:

1'. Generation of sons with communications.

```
f(e0,...,ek)=g(...,f(e,...),...,
                   0
                   f(e',...)(s comm l),...)decl l
produces:          j
{<x,E>::f(e0,...,ek)}<=
    {<x,ϕ≈L>::g(...,.x0,...,.xj,...),
     <x0,E>::f(e,...),...,<xj,E>::f(e',...),...}
where L={js| s comm l occurring in the j-th
                recursive call}.
```

3. Values to fathers.

```
{<x,m>::g(...,.xj,...), <xj,m'>::n}<=
{<x,m>::g(...,n,...),<xj,m'>::n}.
```

Notice that contrary to the previous case,after reporting to its father a son agent remains present. It may need to communicate its value to a message location.

5.Writing a message location.

```
{<x,ϕ≃L>::e,<xs,m>::n}<={<x,n≃L-{s}>::e,<xs,m>::n}
                                             if s∊L
```

Notice that after writing a location a son agent remains present because afterwards it may have to return its value to its father.

6. Reading a message location ("reading communications")

```
{<x,n≃L>::e,<xs,m>::e1}<=
      {<x,n≃L-{s}>::e,<xs,m>::n}  if s∊L.
```

The Calculus and the Translation algorithm enjoy the necessary properties with respect to correctness and efficiency of the derived programs, as the following results show.

Let *P0* be the class of all programs in L0 with 1 recursive definition only and let *P1* be the class of all programs in L1. We consider the class TR of translations from *P0* into *P1* such that if tr∊TR then tr adds s comm 1 and decl 1 annotations only.

Correctness Theorem for Communications. If for every program P0∊*P0* and s comm 1, s'comm 1 occurring in tr(P0) in the recursive call at position j and j' respectively, we have in our Calculus:

f(...)]js = f(...)]j's'

then tr is correct, i.e. for every P0∊*P0* the parallel programs Sem0(P0) and Sem1(tr(P0)) compute the same function. □

Remark. Sem1(tr(P0)) is more efficient than Sem0(P0) if some reading communications take place.

Let us consider the following program B1 in L1:

```
    ⎧bin(n,0)=1
    ⎪bin(n,n)=1
    ⎪bin(n,m)=0   if n<m
B1: ⎨bin(n+1,m+1)=bin(n,m)(1 comm 1) +
    ⎪             +bin(n,m+1)(0 comm 1)decl 1
    ⎪                          if n>m≥1
    ⎩bin(n,1)=n   if n>1
```

The program B1 is equivalent to B0, i.e., the parallel programs Sem0(B0) and Sem1(B1) compute the same function bin.This follows from the Theorem above and from the fact:

bin(n,m)]01 = bin(n,m)]10

accepted by the Calculus when n>m≥2.

The following parallel program Sem1(B1) is the result of translating B1:

```
{<x,E>::bin(n+1,m+1)}<={<x,ϕ≃[01,10]>::.x0+.x1,
                        <x0,E>::bin(n,m),
                        <x1,E>::bin(n,m+1)}
                                   if n>m≥1
{<x,mes>::bin(n,0)}<={<x,E>::1}
{<x,mes>::bin(n,n)}<={<x,E>::1}
{<x,mes>::bin(n,1)}<={<x,E>::n}  if n>1
{<x,mes>::bin(n,m)}<={<x,E>::0}  if n<m
{<x,mes>::n±m}<={<x,E>::k}       if k=n±m
{<x,mes>::e+.x1,<x1,mes1>::n}<=
                 {<x,mes>::e+n,<x1,mes1>::n}
{<x,mes>::.x0+e,<x0,mes1>::n}<=
                 {<x,mes>::n+e,<x0,mes1>::n}
{<x,ϕ≃[01,10]>::e,  <x01,mes>::n}<=
           {<x,n≃[10]>::e,<x01,mes>::n}
{<x,ϕ≃[01,10]>::e,  <x10,mes>::n}<=
           {<x,n≃[01]>::e,<x10,mes>::n}
{<x,n≃[01]>::e, <x01,mes>::e1}<=
           {<x,n≃[]>::e,<x01,mes>::n}
{<x,n≃[10]>::e, <x10,mes>::e1}<=
           {<x,n≃[]>::e,<x10,mes>::n}.
```

Let us consider an example of computation of the program Sem1(B1) with the initial configuration {<ε,E>::bin(5,3)}:

```
{<ε,E>::bin(5,3)}——>

{<ε,ϕ≃[01,10]::.0+.1,

 <0,E>::bin(4,2),     <1,E>::bin(4,3)}——> ...——>

          {<ε,ϕ≃[01,10]>::.0+.1

<0,ϕ≃[01,10]>::3+.01           <1,ϕ≃[01,10]>::.10+1

              <01,ϕ≃[01,10]>::3   <10,E>::bin(3,2)}
 A
——>       {<ε,3≃[10]>::.0+.1

<0,ϕ≃[01,10]>::3+.01           <1,ϕ≃[01,10]>::.10+1

              <01,ϕ≃[01,10]>::3   <10,E>::bin(3,2)}
 B
——>
          { <ε,3≃[]>::.0+.1

<0,ϕ≃[01,10]>::3+3             <1,ϕ≃[01,10]>::.10+1

                                  <10,E>::3 }
...
```

In the transition *A* the value computed by the agent 01 is communicated to the agent ε and in *B* this value is communicated to the agent 10 (by the agent ε). That communication avoids the computation of bin(3,2) by the agent 10.

Let us consider now a program FIB in L0:

```
     ⎧fib(0)=1
FIB: ⎨fib(1)=1
     ⎩fib(n+2)=fib(n+1)+fib(n)
```

and a program FIB1 derived from FIB and the fact

fib(n)]01 = fib(n)]10  (n>1)

```
      ⎧fib(0)=1
FIB1: ⎨fib(1)=1
      ⎪fib(n+2)= (fib(n+1)(0 comm 1)+
      ⎩               fib(n)W(ε comm 1))decl 1
```

where we use the annotation *W* to tell the system that the newly generated computing agent with the task fib(n) is forced to wait until the corresponding value appears in the location 1.

The reader can easily modify our language L1 and the fact-translation algorithm for coping with the new kind of annotations.

Fact. Let FIB1' be the result of application of that new translation algorithm to FIB1.The parallel program FIB1' uses a linear number of computing agents (with respect to n) in the computation with the initial configuration

{<ε,E>::fib(n)}.

The length of this computation is a linear function of n. □

In the <calculus,fact-translation> pair we use, it is possible to express facts as equality of terms, so that repeated evaluations of common subexpressions are avoided. The calculus is based on the unfolding rule [2] and the symbolic evaluation technique. The associated translation realizes communications among concurrent agents and improves the efficiency of their computations.

## 5. Another class of facts.

In this Section we will consider a new class of facts which turn out to be very useful for deriving efficient versions of parallel programs. As an example we will derive a program for finding the connected components of undirected graphs.

Some facts can be viewed as making "jumps into the future". They improve efficiency by identifying several subexpressions which can be evaluated in a parallel way, and by allowing us to know in advance the results of some concurrent computations.

Other facts have more sophisticated structure, but all of them can be discovered by analysing the behaviour of the given functional programs, maybe using a little induction.

We think that by developing more techniques similar to those presented in this paper it will be possible to construct advanced systems which (semi)automatically derive parallel programs with high performances (at least for some specific classes of problems).

In this Section we will not give all the technical details. We leave them to the reader.

We will suggest the construction of another <calculus,fact-translation> pair for the facts of the form "jumps into the future".The calculus is based on symbolic evaluation and induction, while the translation algorithm in most cases reduces to a straightforward inclusion of the discovered facts as new rewriting rules for the computing agents (see for instance, the following facts F1 and F2).

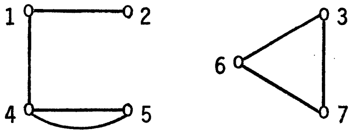
Let us derive the program for computing the connected components of a given graph.We are given the following functions:

```
dec succ: nodes ——> set nodes
    succ(n) computes {n}∪s, where s is the set of
    nodes adjacent to n.
dec f: set nodes——> set nodes
    f is the extension of succ to a set of nodes.
    f(nilset)=nilset
    f({n}∪̇s)=succ(n)∪f(s)  where ∪̇ denotes disjoint
                                      union.
```

Given a graph G, that is, a particular function succ, we may use the following function F to compute the connected components of G, by taking as input for F the set of singletons of the nodes in G.

```
dec F: set set nodes ——> set set nodes
    F(nilset)=nilset
    F({a}∪̇X)=F({f(a)}∪X)  if f(a)≠a
    F({a}∪̇X)={a}∪F(X)     if f(a)=a
    F({a,b}∪̇X)=F({a∪b}∪X) if a∩b≠nilset.
```

For instance, given the graph:



where the nodes are denoted by natural numbers, we get:

```
F({{1},...,{7}})=...
=F({{1,2,4},{2,1},{3,6,7},{4,5,1},{5,4},{6,7,3},
   {7,6,3}})=...
={{1,2,4,5},{3,6,7}}.
```

The reader can observe that if he translates the functional program defining F into a parallel program by applying the algorithm Sem0, he will not get an efficient implementation.
It is easy to see that the following fact holds:

(F1) F({a,b}∪̇X) = F({fa∪fb}∪X)  if fa∩fb≠nilset.

By using that fact we can simplify the rewriting of the expression:

F({{1},...,{7}}).

The system can implement that fact as a special rule of the form:

```
{x::a1...a...ak, y::b1...b...bm}<=
        {x::a1...fa∪fb...ak, y::b1...b̸...bm}
                                  if  fa∩fb≠ nilset
```

where we omitted some set brackets and b̸ denotes the erasing of b.

The computing agents with names x and y can communicate if fa∩fb≠nilset, and if this communication takes place, the result can be computed much faster. Also the following fact F2 holds:
(F2) F({a1,...ak}) = F({f̄a1,..,f̄ak})

where f̄ is equal to f or it is the identity.

The translation of that fact can improve the efficiency, because it allows the computations of the f̄ai's in a parallel way. However, in order to avoid the repeated evaluations of common subexpressions it is advisable to activate as often as possible the communications which derive from the fact F1. In a sense a good implementation of the program for F should balance the requirements from facts F1 and F2.

That objective can be achieved by implementing the following fact F3 [13].

Let us define first the following operation:

$$g(X,Y) = \{a \cup b \mid fa \cap fb \neq \text{nilset and } a \in X, b \in Y\}$$

$$\cup \{a \in X \mid fa \cap fb = \text{nilset for all } b \in Y\}$$

$$\cup \{b \in Y \mid fa \cap fb = \text{nilset for all } a \in X\}$$

where X,Y are families of finite sets of nodes.
We define also the operation C on finite sequences of families of finite sets:

$$C(X1,X2,X3,X4,\ldots)=[g(X1,X2),g(X3,X4),\ldots].$$

Finally we can formulate the following fact F3:

$$\text{(F3)} \quad F(\{\{n1\},\ldots,\{nk\}\}) = C^{p}(\{\{n1\}\},\ldots,\{\{nk\}\})$$

where $p=\lceil \log_2 k \rceil$.

Now we are ready to present the parallel program in which facts F1, F2 and F3 are implemented. As usual we will write it as a set of rewriting rules for computing agents.

Connected Components Program

```
1. {x0 :: a1...a...ak, x1 :: b1...b...bm}<=

   {x0 :: a1...fa∪fb...ak, x1 :: b1...b̸...bm}

                                     if fa∩fb ≠ nilset

2. {x :: a1...a...b...ak}<=

        {x :: a1...a∪b...b̸...ak}

                                     if a∩b≠nilset

3. {x0 :: a1...ak, x1 :: b1...bm, x:: .x0∪.x1}<=

        {x :: a1...ak b1...bm}

                  if rules 1. and 2. cannot be applied

4. {x :: F({a1,...,ak})}<={x :: .x0∪.x1,

                          x0 :: F({a1,...,a⌈k/2⌉}),

                          x1 :: F({a⌈k/2⌉+1,...,ak})}

5. {x :: F({a})}<={x ::{a}}
```

where instead of <x,m>:: we write only x:: because messages are not used. a,b,a1,...,ak,b1,...,bm are finite sets of numbers (i.e.,nodes of graphs).

## 6. Conclusions

Through some examples we presented various kinds of facts for improving the efficiency of the parallel evaluation of functional programs. We also presented the structure of a system which is essentially a <Calculus,Fact-translation> pair for making those improvements in an automatic way.Facts are to be accepted by the Calculus and then they are used by the translation algorithm to produce efficient parallel implementations of the functional programs to which they refer. We think that more work should be done in the direction we indicated here. In particular it would be important to develop a theory for the automatic improvements of functional programs and their implementations.

In a sense we follow the program derivation technique à la Burstall-Darlington, and we provide a framework for overcoming some difficulties encountered by those authors.In particular we propose an intermediate "language of facts",used by the programmer for writing some properties or facts of the program to be improved. Facts accepted by the calculus are indeed bound to increase the efficiency, and in this way we can make sure, contrary to the original Burstall-Darlington approach, that efficiency is improved when new versions are derived. Moreover the language of facts gives to the programmer freedom for expressing intuitions or discoveries, while the "eureka steps" à la Burstall-Darlington need to be expressed into the recursive equation language used for programs. Similarly, in our approach, the language of the new versions of the program may be be different from the language of the old versions. Therefore, efficiency improvements may also derive from better compilers one can construct for the language of the new versions. Our approach allows also for the incremental discovery of the facts to be incorporated into old program versions. Most of those facts can be interpreted as establishing some communications among computing agents, so that they work in a cooperative way while the computation progresses.

Abstract--Spatial redundancy denotes computation characterized by simultaneous execution of redundant program elements on separate computing channels. This paper presents a mechanism called molecular activity for the support of spatially redundant distributed computation. It is shown that molecular activities extend the domain of existing software fault-tolerance techniques to include applications constructed as sets of communicating processes and involving access to global data. Molecular activities also allow exploitation of high-level parallelism in a large class of applications, particularly in the area of artificial intelligence.

## I. Introduction

Spatial redundancy is a term used to describe computation characterized by the simultaneous (or concurrent) execution of redundant program elements on separate computing channels. Some mechanism for reaching agreement among the redundant elements is employed to facilitate decisions regarding the results produced by the computation.

The concept of spatial redundancy has been employed to achieve tolerance of software failures through a notion known as a design diversity and a technique called n-version programming [1]. In a broader sense, spatial redundancy could also be used to exploit parallelism in the solution of certain important types of problems. Many computationally difficult problems are characterized by the existence of alternative algorithms or heuristics for obtaining a desired solution. Examples include certain planning problems in the field of artificial intelligence, as well as various VLSI design problems involving heuristic search of a large solution space. Although it is known that one algorithm or heuristic may perform significantly better than another for a particular instance of the problem (in terms of execution time or solution optimality), there is typically no way to determine a priori which one will perform best. Spatial redundancy could potentially be employed to carry out alternative strategies in parallel, with some mechanism being used to select the desired result (and perhaps preempt other still-executing alternatives).

In a distributed system environment, spatially redundant computation should ideally allow a redundant program element to be structured as a set of communicating processes residing at various nodes of the system. This would allow for exploitation of concurrency and parallelism within the individual program elements.

Thus, the implementation of spatial redundancy could lead to the existence of multiple distinct sets of communicating processes, each set representing one of the redundant elements. If it is allowed that several different distributed computations (each employing spatial redundancy) might exist simultaneously in a distributed computing system, the situation may become quite complex. Clearly, some technique for structuring the interactions between these computations is necessary.

In this paper we discuss mechanisms for structuring spatially redundant distributed computations. It will be shown that the conventional mechanism for enforcing data consistency among concurrent computations, the atomic action, is insufficient for supporting general spatially redundant distributed computation. New mechanisms known as atomic activities and molecular activities are proposed for this purpose. It is argued that these new mechanisms are necessary in order to extend the usefulness of existing techniques for structuring redundant computations, such as n-version programming, to cover a wide range of distributed applications.

## II. The Need for a New Structuring Mechanism

Distributed computation is characterized by programmed actions on data objects that may be located at various nodes of a distributed system. Data objects accessed by a distributed computation can be classified into two categories:

1. Local Data Objects--These are objects declared in, and local to, the program that specifies the computation. Their lifetime coincides with that of the computation.

0190-3918/86/0000/0624 $01.00 © 1986 IEEE

2. External (global) Data Objects--The lifetime of these objects supercedes that of the computation. They may represent permanent or semi-permanent information that exists independently of the various computations which access and manipulate them. The collection of data objects in a distributed database provides an example of external data objects.

One of the fundamental differences between internal and external data objects lies in the ability to statically determine which objects will be accessed and/or modified by a computation. Since local objects are declared within, and belong to, a computation, it is possible to enumerate all of the local objects that will be accessed by computation at the time when the program specifying the computation is written. However, the external data objects to be accessed, and the nature of that access, may be determined, at least in part, during the execution of the computation.

For instance, consider an application concerned with routing certain connections during the design of a VLSI circuit. This application must access a large database representing the layout of the circuit. However, the specific portions of the layout data to be traversed during an instantiation of the routing application, and the portions to be modified, can be determined only during the execution of the router.

The basic mechanism for maintaining the consistency of external data objects operated upon by concurrent computations is the atomic action [2]. An atomic action is some program-specified computation that reads or modifies the state of one or more data objects and appears as an indivisible operation from the point of view of computations outside the atomic action.

Built-in atomic actions greatly simplify a programmer's task in coping with unplanned concurrency and failures. The programmer of an atomic action can write his software without bothering about other computations and failures that may affect the data that his program manipulates. In recent years, a number of distributed systems supporting atomic actions have been implemented. However, the intoduction of spatial redundancy into distributed computation introduces new problems in consistency maintenance that cannot be addressed by the simple use of atomic actions.

Consider an example of two distinct computations, C1 and C2, in a distributed system that may access and modify common external data objects. Let us suppose that those two computations are entirely logically independent and that they may reach execution concurrently (perhaps on different nodes of the system). For example, in the VLSI design example mentioned earlier, they might represent different design operations being carried out upon the database representing a partially completed circuit. Structuring each of these computations as an atomic action would allow them to execute in a correct and serializable fashion. However, suppose that design diversity--for instance, in the form of n-version programming--was used to implement each of the computations in order to enhance software reliability.

Now, consider the atomic action representing the spatially redundant computation C1. Note that the external data objects used by each of the n-versions must be copied into a local data space for that version, before execution and modifications are made to the local copy. This is done because the versions must execute in isolation, and hence must not independently modify the actual external environment. At the conclusion of the execution of the n-versions, a vote is taken on the modifications to (copies of) external objects, and based upon the outcome, the actual modifications are made to external data objects.

There are a number of problematic aspects to this scheme, including:

1. It may not be possible to determine a priori which external objects will be accessed by a version of the computation. Even if it is possible, the number may be too large to effectively or efficiently copy into n different local data spaces. For example, duplicating the huge state space of a large artificial intelligence problem might not be practical. (Note that other schemes, such as the use of logging in each of the versions in lieu of copying external state space into local states, are possible, but these suffer from similar problems.)

2. Since the n versions may be executed concurrently on distinct processing nodes, and since external data objects may also be distributed among nodes, a run-time structure must be constructed to coordinate and synchronize the copying of external objects to the local data spaces, the final voting upon results, and the copying of results back to the external data space of the global atomic action for $C_1$. This structure is over and above that required for the support of atomic actions.

## III. Atomic and Molecular Activities

In this section we propose a new structuring mechanism, called a molecular activity, intended to deal with problems of the type illustrated in the above example. This mechanism provides a general way of structuring spatially redundant distributed computations that access external data objects. As such, it is applicable not only to n-version programming problems of the sort described above, but also to supporting other constructs for design diversity, such as the parallel execution of recovery blocks or conversations [3-5]. It is also appropriate for supporting the parallel execution of alternative strategies in order to speed up the solution of computationally difficult problems. The mechanism automatically manages the consistency of external objects accessed by spatially redundant computations without requiring that the objects be identified in advance. In addition, the mechanism provides the support for committing final results of the spatially redundant computation.

We define an atomic activity as a program-specified computation whose computational steps are executed such that the intermediate state of data objects manipulated by an atomic activity are not visible to any computation outside the atomic activity. An atomic activity that constitutes a molecular activity may be specified by a sequential or concurrent program, and hence, the computation of an atomic activity may be represented by either a single sequential process or a set of interacting processes.

A molecular activity is defined as a collection of one or more atomic activities that may execute concurrently such that, from the point of view of computations outside a molecular activity, it appears as an indivisible operation whose effect on the state of the data objects in the system reflects the actions of at most one of its component atomic activities. The indivisibility of molecular activities implies that the concurrent execution of any two molecular activities is equivalent to the sequential execution of the two molecular activities in some order. Thus, during the execution of a molecular activity, objects whose values are read by steps in the atomic activities constituting a molecular activity cannot be modified by any computation outside the molecular activity. Also, intermediate states of data objects that arise during the execution of a molecular activity will never be observed by computations outside the molecular activity. In fact, even for the computations within the molecular activity, modifications made to the data objects by one atomic activity will not be visible to other atomic activities constituting the molecular activity.

Let $S_M$ denote the set of data objects accessed by the computations in the molecular activity M. Let A = $A_1$, $A_2$,..., $A_n$ denote the set of atomic activities defining the molecular activity M. The initial state I of M is defined by the values of the data objects in $S_M$ before they were modified by any computation within M. The final state F of M is defined by the values of the elements in $S_M$ after the completion of the molecular activity M.

From the definition above, it is clear that the final state F of M is determined by the transformation on I performed by the computation of at most one of the atomic activities in A. Now, the criterion for determining which, if any, of the atomic in A is to be chosen to reflect the execution of the molecular activity M is application dependent. It is specified by a set of user-defined procedures encapsulated within a construct called a decision module, which is associated with each atomic activity of the molecular activity M.

The informal definition of a molecular activity given above provides only an abstract description in terms of the effect of its execution on the state of the system and ignores details of the internal structure of a molecular activity. A more formal model of atomic activities and molecular activities is presented in [6].

## IV. Molecular Activities--Implementation Issues

The implementation of a system supporting molecular activities must satisfy the following requirements.

R1: Let $M_I$ denote the initial state of a molecular activity M that is composed of atomic activities $A_1$, $A_2$, ..., $A_n$. Then, the concurrent execution of $A_1$, $A_2$, ..., $A_n$ should be such that each atomic activity $A_i$ in M is oblivious to the transformations on $M_I$ made by any other atomic activity of M. We call this the isolation requirement.

R2: After the completion of the molecular activity M, the final state $M_F$ of M should reflect the transformations on $M_I$ made by at most one of the atomic activities of M. We call this the global data consistency requirement.

R3: The transformation from the initial state, $M_I$, to the final state, $M_F$, of the molecular activity M appears as an indivisible and primitive step to all computations outside M. Requirement R3 can be refined as follows:

R3a: During the execution of the molecular activity M, the intermediate states of objects accessed by computations in M should not be visible to computations outside M.

R3b: If $A_1$, $A_2$, ..., $A_n$ represent atomic activities belonging to different molecular activities, the concurrent execution of $A_1$, $A_2$, ..., $A_n$ must be equivalent to the sequential execution of $A_1$, $A_2$, ..., $A_n$ taken in some permutation.

To satisfy requirements R1 and R3 we need a mechanism that controls access to data objects in the system. We call this mechanism the synchronization mechanism. To ensure requirement R2 we need another mechanism, which we call the committment mechanism. The implementation of these mechanisms in a distributed system is presented in [6].

## V. Concluding Remarks

In this work we have described a mechanism, called a molecular activity, for the support of spatially redundant distributed computation. This mechanism allows each redundant element to be constructed as a set of distributed communicating processes known as an atomic activity. Multiple molecular activities can execute simultaneously in a distributed system, and they can access and modify a common global data space without loss of consistency.

Molecular activities allow the domain of application of existing constructs for achieving software fault tolerance to be extended to include applications constructed as sets of communicating processes and involving access to global data. No methods have previously existed for allowing n-version programs to share global data, and no explicit work has addressed the viability of versions constructed as sets of communicating processes in a distributed environment. With respect to other proposed constructs for design diversity [4,5], molecular activities can also be used to support parallel execution of the interacting sessions of a conversion. Details are given in [6].

The potential use of spatial redundancy to allow simultaneous application of alternative algorithms or heuristics for solving a computationally difficult problem is largely unexplored. An extended example of this approach applied to a planning problem in artificial intelligence is given in [6]. The example demonstrates the viability of this technique. Spatial redundancy employed in this fashion exploits parallelism at a very high level. The molecular activity construct allows each activity to consist of a set of distributed processes. Hence, the use of spatial redundancy does not mitigate the exploitation of parallelism within individual versions of the algorithm or heuristic.

# POKER ON THE COSMIC CUBE: THE FIRST RETARGETABLE PARALLEL PROGRAMMING LANGUAGE AND ENVIRONMENT[†]

Lawrence Snyder
David Socha

Department of Computer Science, FR-35
University of Washington
Seattle, WA 98195

**Abstract** – This paper describes a technique for retargetting Poker, the first complete parallel programming environment, to new parallel architectures. The specifics are illustrated by describing the retarget of Poker to CalTech's Cosmic Cube. Poker requires only three features from the target architecture: MIMD operation, message passing inter-process communication, and a sequential language (e.g. C) for the processor elements. In return Poker gives the new architecture a complete parallel programming environment which will compile Poker parallel programs, without modification, into efficient object code for the new architecture.

## Introduction

Software portability for sequential computers became an issue in the early sixties as higher-level languages began to supplant the machine specific assembly languages and as machine varieties proliferated; it was a much harder problem than originally supposed and it remains a serious problem today. By comparison, portability of a parallel program should be substantially more difficult because:

- architectural differences among parallel computers are much more fundamental than among sequential machines, and
- the characteristic that makes portability difficult – the dependence of programs on machine specific features – arises often in parallel computation in order to get good performance.

We say "should be more difficult" because to date there is little experience: There is little production parallel software and there are few truly parallel languages, and few parallel machines. But in spite of the potential problems, there is some reason for optimism.

The Poker[1] language has been retargetted from the Pringle Parallel Computer [2] to the CalTech Cosmic Cube [3]. Thus, programs written for the CHiP [4] family of computers can run on one of the cube family of architectures *without modification.* This is possible because

- the Poker language uses a reasonably universal program abstraction,
- Poker programs have a (unique) structure that is both visible and simple, and
- the Poker language and environment is structured to make retargetting simple.

There is no impediment to porting the Poker language to other parallel computers as this paper will explain.

The benefit of portable parallel software is obvious: Programs can be written without regard for the underlying architecture. However, portability only guarantees that programs will *function.* With Poker, we are making a stronger claim: Poker programs will run with an efficiency that is comparable to that of programs which were specifically written for that architecture. This leads to a key point about the retargetable Poker parallel programming environment:

> Poker requires a small set of system functions of the host architecture and can thus serve as the definition of the basic software support required of a new parallel computer.

Simply by creating the few basic interface systems that Poker requires, an architecture automatically inherits the available Poker programs and a complete software environment. This vastly reduces the software development efforts for new parallel machines.

## Overview

Before explaining the details of the retarget, some familiarity with the Poker system must be acquired. Towards this end we present first a high level view of the Poker system pointing out some of the key components and their interactions. Later, we discuss the relevant software and hardware pieces, devoting a section each to: the Poker programming environment, the Cosmic Cube, and the new cross-compiler. Finally, we connect all the pieces and discuss the effects of the new extended system.

Figure 1 shows the relationship between the Poker Parallel Programming Environment and the parallel computers which can be programmed with it. Poker is a sequential system that makes extensive use of a relational database to represent programs. It is written in C[5] and built on top of UNIX[(a)].

To see how Poker works, focus on two components of the system: the cross-compiler and the debugging environment. The cross-compiler accepts a Poker program as input and produces an object version suitable for execution on one of three machines: the Pringle, the Cosmic Cube, or a simulator/emulator of a parallel machine that runs on whatever sequential machine is hosting Poker itself. The compiled version is then down-loaded to the target parallel computer and executed. During execution, the run-time support of the machine sends tracing information back to Poker's debugging environment so that the programmer can view the execution of the program within the Poker environment.

Thus, one writes and runs programs from an environment that provides flexible interactive graphic support and a view of the program consistent with its definition. During the program debugging activity there is communication between the front-end processor and the back-end parallel machine to facilitate program tracing. When the program is debugged, no tracing is requested and Poker serves as the operating system for the back-end machine, running the program "flat out."

Thus, Poker is both a language and an environment: A sequential system from which to compile, execute, and debug programs on parallel computers. A "port" of the Poker language entails retargetting the cross-compiler and constructing the run-time software to support the communication between the Poker environment and the parallel computer. Only the Poker programs and run-time system get ported to the new machine; the Poker environment runs on a sequential computer.[(b)] This paper will detail the activities required in crossing the vertical line of Figure 1.

## The Poker Programming Environment

The Poker programming environment is built around a programming abstraction that is common to non-shared memory parallel algorithms, as described in the next section. However, Poker's interface to the abstraction is quite non-standard. The section on Concrete Poker Programs outlines the structure and semantics of Poker programs. As we shall see, this formulation of parallel algorithms lends itself to easy retargetting for new parallel architectures.

### Abstract Poker Programs.

A non-shared memory parallel algorithm is conceptualized as a finite graph. The graph's vertices are labeled with process names corre-

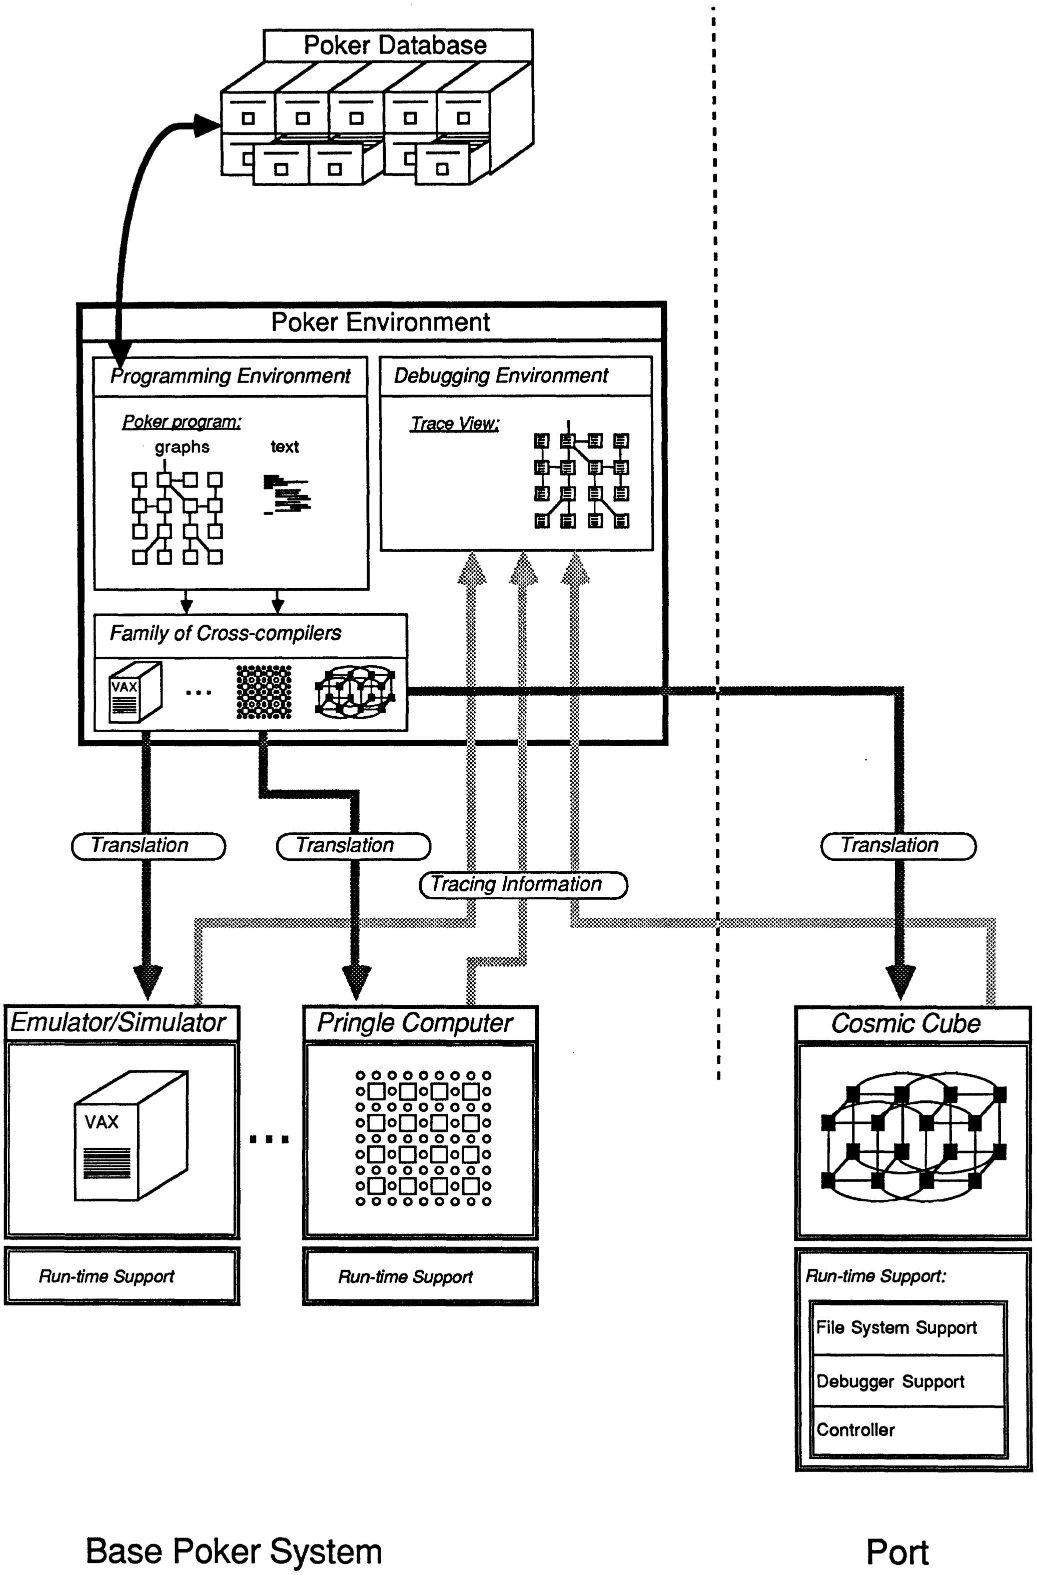

Figure 1: An Overview of the Poker System.

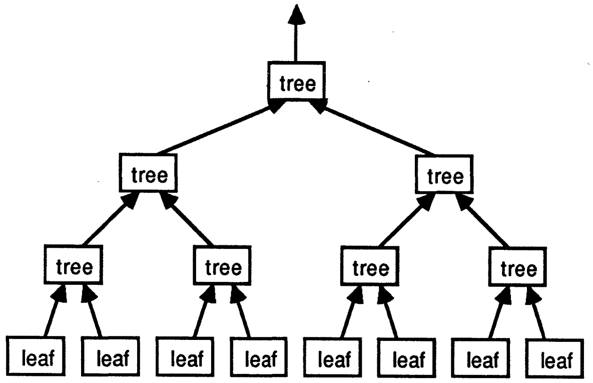


tree: parent <- max ( myValue, leftValue, rightValue)
leaf: parent <- myValue

Figure 2: The Maximum Algorithm.

sponding to sequential programs. The graph's edges are of two types: Edges between vertices are communication paths between processes, and edges "dangling" off of the graph are channels through which streams of data pass to or from the graph. (Technically, graphs cannot have dangling edges, of course, but it is convenient to abuse the definition.)

For example, Figure 2 shows the maximum algorithm. The graph is a binary tree. The vertices are labeled with one of: the name of the `leaf` process, which passes its local value to its parent, or the name of the `tree` process, which receives two values from its children, finds the maximum of these values and its local value, and passes the result to its parent. The dangling edge is a stream containing a single output value produced at the root.

A problem is not generally solved by a single algorithm of this form. Rather this form is usually one "phase" of a computation. The problem is partitioned into a series of phases, each possibly with a different graph structure. Inter-phase communication is permitted only among those that share the same "location" as described by a one-to-one mapping function. Values from previous phases may be inherited by the vertex executing in the corresponding vertex in the next phase.

## Concrete Poker Programs.

Unlike a C or Pascal program, a Poker *phase program* is not a monolithic piece of text. Rather, it is composed of five components that correspond closely to the abstraction just presented (Figure 3 shows the five components of the maximum algorithm encoded as a Poker phase program).

- *Communication Graph:* A finite graph with dangling edges. The boxes correspond to processes and thus will be the vertices of the graph. The circles, which are switches for the CHiP computer [4], can be ignored for the present discussion.

- *Process Definition:* A (usually small) set of processes written in a sequential language, in this case a slightly modified version of C[5]. These can be thought of as standard procedures with formal parameters called at the beginning of a phase.

- *Process Assignment:* A labeling of the vertices of the graph with the names of the processes and actual parameters, if any, to be executed at that processing site.

- *Port Name Assignment:* A labeling of the edges of the graph, but from the point of view of the vertex, *i.e.* each edge has two names, one for each end, or "port".

- *Stream Name Assignment:* A labeling of the dangling edges of the graph giving names to the input and output streams; these names will subsequently be bound to files.

The correspondence of the five Poker program components to the phase abstraction given above should be clear.

A Poker program is composed of a finite set of phase programs together with an execution scheduler that describes the sequence in which they are to be invoked. Those vertices of different phases which occupy the same location in the Switch Setting View may communicate across phases through the use of inter-phase variables.

Inter-phase variables live for the duration of the Poker program and exist separately from the variables declared local to a phase. The local process codes may access the values of inter-phase variables by the `import` and `export` statements:

`import` *local* `from` *inter-phase*
`export` *local* `to` *inter-phase*

`Import` copies the value of the inter-phase variable into the local variable. `Export` copies the value of the local expression into the inter-phase variable. This is the only way to pass information between phases. It provides a well-defined interface to inter-phase communication and lets process codes load from and store to inter-phase memory during the course of computation.

Two other features of Poker C are the trace list and inter-process communication. The optional trace list found in the declaration section of each routine specifies the variables whose values will be traced in the debugging environment, if a traced execution of the program is requested. Trace "variables" are not restricted to the conventional "variables" of Poker C. They may include variables, labels, and other items such as the current procedure and depth of recursion.

Process input and output, respectively, are given by expressions of the form:

*variable* <- *port*
*port* <- *variable*

The values transmitted are simple scalar values from the language, and arrays and structures not containing pointers. Messages are tagged with their type so that process I/O may be type checked using structural type equivalence.

## The Programming Environment.

The Poker system is the set of facilities that assist the programmer in writing and running Poker programs. Poker uses two displays: One is a bit-mapped display having the general form shown in Figure 4 and used for interactive graphical programming of the parallel aspects of the program. The second terminal is used with a standard editor to write the sequential C process text.

Poker stores programs as a database, displaying the program in one of several views [6]. Figure 4 shows the display for the Switch Setting View; the other views are analogous, with the appropriate Poker program constituent displayed in the lower half of the screen. The seven views are

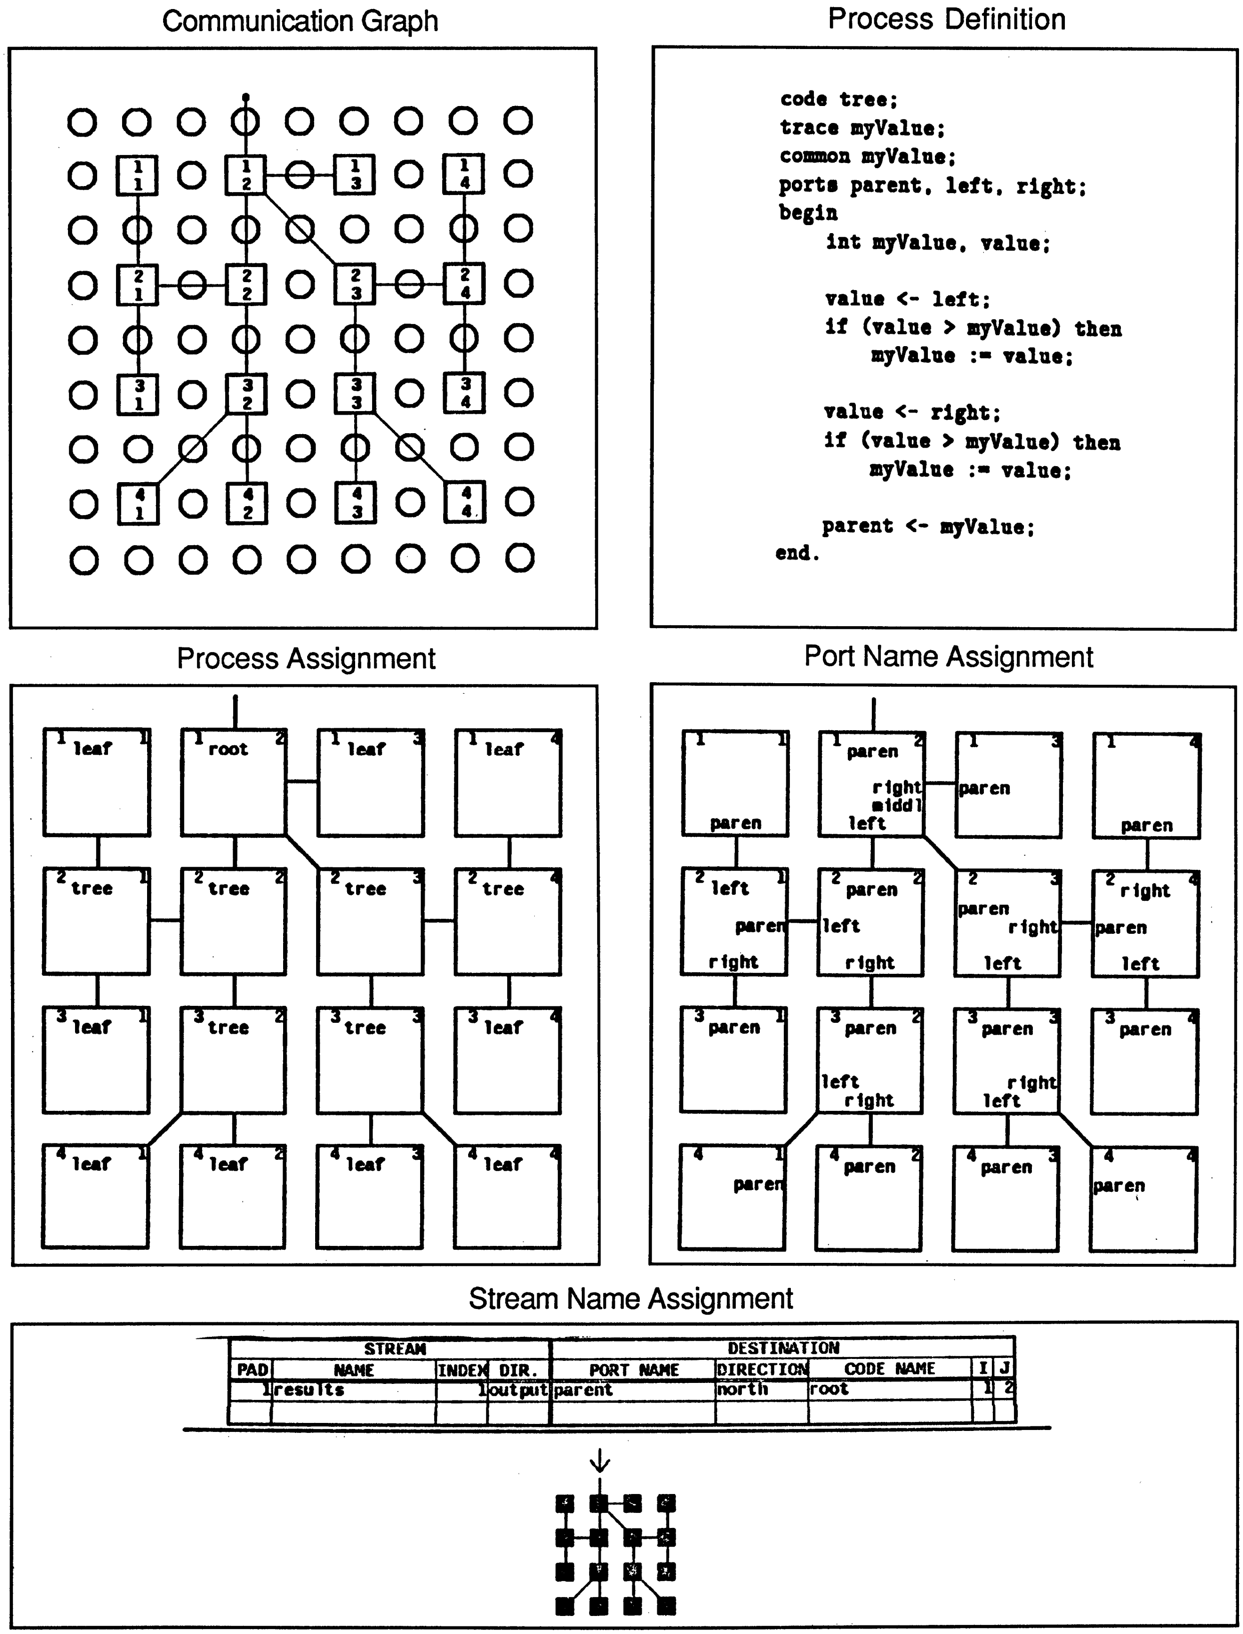
- *Switch Setting View:* Used to define the Communication Graph (Figure 3); the programmer uses a mouse or keypad to draw a picture of the graph by connecting the boxes with lines.

- *Code Names View:* Used to define the Process Assignment (Figure 3); the programmer moves from box to box entering the names of the process and actual parameters, if any.

- *Port Names View:* Used to define the Port Name Assignment (Figure 3); the programmer moves from box to box entering the names of the ports.

- *IO Names View:* Used to define the Stream Names Assignment (Figure 3); the programmer enters the names of the streams and their directions.
- *Command Request View:* Used to compile, assemble, link, load, etc. Poker programs. The bottom of the display shows the progress of the computation.

- *Trace View:* Used to display the execution of the Poker program; the programmer can start, stop, and single step the program while watching the successive changes of the traced variables.



Communication Graph

Process Definition

```
code tree;
trace myValue;
common myValue;
ports parent, left, right;
begin
    int myValue, value;

    value <- left;
    if (value > myValue) then
        myValue := value;

    value <- right;
    if (value > myValue) then
        myValue := value;

    parent <- myValue;
end.
```

Figure 4: The Poker Display showing the Switch Setting View.

- *CHiP Parameters View:* Used to describe the logical CHiP architecture being programmed. This includes parameters such as the number of processors in the processor grid (16 in Figure 3).

Notice that the display of most of the program constituents includes information defined in other program views; two examples (see Figure 3) are the graph shown in the Code Names View (Process Assignment) which is derived from the graph defined in the Switch Settings View (Communication Graph), and the material in the right half of the table of the IO Names View (Stream Name Assignment) which is gathered from the other views.

## The Cosmic Cube

The Cosmic Cube [3] provides flexible processing facilities that easily adapt to hosting the more structured Poker abstraction. Each Cosmic Cube program is also a graph: a set of processes, with non-shared memory, communicating through logical links mapped onto the underlying hardware [7]. However, instead of the static graphs of the phase program found in Poker, the Cosmic Cube programs consist of a single, perhaps dynamically changing, graph. Processes may create new communication links (edges), if the creator knows the address[c] of the other process, or destroy old links in order to build the best graph for the moment. This gives the Cosmic Cube programs more flexibility than we need.

This abstraction is implemented on a MIMD non-shared memory computer with a binary n-cube interconnection; the processors and their local memory, or "nodes", sit at the corners of the n-dimensional cube while the edges of the n-cube are formed from physical wires connecting the node processors. Each node may host zero or more processes, living in separate address spaces, communicating by message-passing over the physical wires connecting adjacent nodes. The operating system automatically forwards messages between non-adjacent nodes, preserving the message order between the sending and receiving processes.

A Cosmic Cube program starts as a single process on the host machine[d] connected to one corner of the Cosmic Cube. This host process "spawns" the processes in the initial program graph, placing them on the nodes of the cube and establishing the graph edges by forwarding process addresses to the processes on the cube. These processes may then spawn more processes of their own or create new communication links by sending known process addresses to other processes.

Typically, process codes are written in Cosmic Cube C, a version of the C programming language [5] extended with calls to routines in the Cosmic Cube's operating system, or one of the other extended sequential languages supported for the Cosmic Cube.

## The Poker to Cosmic Cube Cross-Compiler

Retargetting the Poker language and porting the run-time system to the Cosmic Cube changed nothing in the existing Poker environment; neither the Poker programs nor the Poker environment needed modification (process codes written in *XX* [2] are preprocessed into Poker C). Instead we only needed to (1) retarget the cross-compiler to translate Poker C process codes into a single Cosmic Cube C program, using the information in the database to determine the configuration of the resultant graph, and (2) extend the run-time software on the Cosmic Cube to include a few routines interfacing to, and controlling, the Cosmic Cube program. This Cosmic Cube C program from the translator is then treated as any other Cosmic Cube C program, compiling, loading, and executing it using the facilities provided for the Cosmic Cube. The difference is that the extra interface routines know about the Poker system, so that the user of Poker need not know which underlying architecture is executing the user program – no matter which target architecture is used, the creation and execution of the program will be the same. This retarget and run-time system port is the topic of the remainder of this paper.

### Converting Poker C to Cosmic Cube C.

The first task of the cross-compiler is to convert the Poker C process codes into a form acceptable for the processors of the target architecture. There are at least three ways to support a sequential language on the processors of a new architecture. One is to directly generate object code for the target machine's processor elements. A second method is to provide a kernel that runs on the processors of the new architecture and interprets the sequential language (or an intermediary language derived from it). This method could easily support a number of interpretive languages such as LISP [8] and Prolog [9]. The third approach is to translate the source process codes into a language already supported on the new architecture. This last approach works best when the languages are similar in structure, as is the case with Poker C and Cosmic Cube C.

Translating one sequential language into another, source-to-source translation, is well understood. In our case, the only major translation problems come from tracing the variables in the trace list and from reducing all of the Poker phase graphs into one more general and less structured Cosmic Cube graph.

Trace variables are handled by the first part of the cross-compiler which uses a Yacc [10] based C-to-C compiler to insert calls to a run-time trace routine after every instance of a traced variable. The C-to-C compiler does not look for aliases; instead it only inserts a trace command after each assignment whose left-hand-side is an instance of a literal in the trace list. If aliases are a concern, Poker will, at the user's discretion, insert a special trace call after each suspect assignment, exhaustively checking for any changes in the traced variables. Exhaustive traces are expensive at run time but, presumably, a great benefit for debugging.

The C-to-C compiler also replaces instances of the Poker's interprocess communication statements

*variable* <- *port*
*port* <- *expression*

with calls to the Cosmic Cube `send()` and `receive()` routines.

[c] On the Cosmic Cube a process' address consists of two numbers: the number of the physical node in which it resides, and its process number on that node.

[d] A typical host machine is a Sun Microsystems workstation.

The C-to-C compiler is more complex than a simple pre-processor such as UNIX's cpp. To see why, consider tracing a variable that is modified twice in a single expression. We want to trace both changes, but to capture both values of the traced variable we have to insert trace calls *into* the expression. We cannot simply append a trace call onto the expression since the value of the expression may be needed for an assignment or conditional test. Instead, we have to store the expression value in a temporary variable, trace the changed trace variables, and then append the temporary variable to return the expression value.

For instance, given the variables

```
float f;
int i, j;,
```

and a request to trace f and j, the C-to-C compiler converts the conditional expression

```
(((f += 4.3) < 10) ?
f++ + j++, i-- :
f--)
```

into

```
(((_tempint = ((f += 4.3) < 10)), _Trace(&f, FLOAT),
      _tempint) ?
f++ + j++, _Trace(&f, FLOAT), _Trace(&j, INT), i-- :
((_tempfloat = f--), _Trace(&f, FLOAT), _tempfloat))
```

where _Trace is a trace routine taking a pointer to a value and a constant telling it the type of the value and _tempint and _tempfloat are reserved variables declared in the enclosing routine.

In the first line, _tempint determines which of the next two expressions to execute: the comma expression before the colon, or the simple expression after the colon. We have to insert a trace of f immediately after the < expression, since if we waited to trace the value of f until after executing the entire conditional expression, we would miss the first value of f.

For the same reason we needed _tempint, the value of the expression was used outside of the expression, we also need to use _tempfloat to save the value of the conditional expression before tracing f's new value.

Clearly, this is not a simple textual substitution. Before we insert a temporary variable, we have to know the type of the expression. This requires keeping a symbol table, to hold the types of the variables, and using a parse tree to calculate the types of expressions. In other words, the C-to-C compiler is truly a compiler even though the languages it consumes and generates are nearly identical.

The end result of the C-to-C compiler is two code segments from each of the Poker C process codes. One segment contains information about the inter-phase variables imported to, and exported from, that process code. The other segment contains the routines defined for that process code. These code segments are used by the cross-compiler, as discussed in the next Section.

### Compiling the Poker Database.

The second part of the cross-compiler combines the pieces of the newly translated code with the rest of the information in the Poker program's database to create a single Cosmic Cube C program. The first problem here is to figure out how to collapse the phases of the Poker program into one graph, while maintaining efficient inter-phase communication$^{(e)}$. This is easily achieved by the technique suggested in Figure 5. When the phases are stacked as in Figure 5 the processes above one another are exactly those processes that share inter-phase variables. Combining them into one "aggregate" process keeps the Poker processes in a single process space. Inter-phase variables are globally declared for that process so that inter-phase communication requires no extra computation.

Building these aggregate processes is done as follows. The cross-compiler computes the inter-phase data space of each aggregate process from the inter-phase variables required by each of the Poker processes being placed into the aggregate process. The main() routine of each aggregate process is simply an infinite loop containing a call to the controlling host process asking for the number of the phase to execute, followed by a switch statement to call the main routine of the appropriate phase (see Figure 6). Since Poker C does not allow externally declared variables, the only potential source of name conflicts among different phases come from the routines, typedef's, and externally defined structures and unions. Prefixing these names with a unique phase ID eliminates any possible name conflicts. Linking the main() code with the routines from the phases and routines supporting the calls to receive(), send(), and the like, results in the Cosmic Cube C code for the aggregate process.

The last problem with the aggregate processes is mapping the edges of the different phases onto one graph. Since the Cosmic Cube does not have any restriction on the degree of the vertices (processes) in its program graph, we can project all of the phase graphs onto one graph. In actuality, each aggregate process gets a different logical interconnection map for each phase. The map holds the eight pairs of (process address, port number) that correspond to the terminal ends of the wires connected to the ports of the process for that phase. Since process addresses are known only after the processes are placed on the Cosmic Cube nodes, these tables are initialized at run time.

This packing results in extremely efficient inter-phase communication and phase change. One of the advantages of Poker programs is that the phase graphs are known at compile time so that the processors do not have to expend any run-time effort constructing or modifying the program graph or dynamically allocating more processes.

After spitting out the aggregate vertex codes, the cross-compiler runs them through the Cosmic Cube C compiler to get executable versions ready to be placed on the Cosmic Cube.

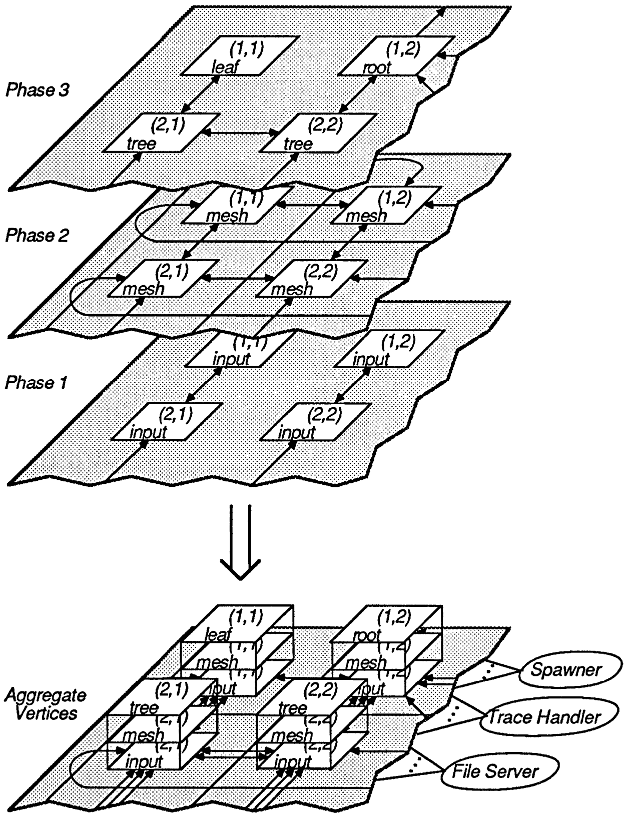

Figure 5: Collapsing the phases of a Poker program to create the aggregate processes.

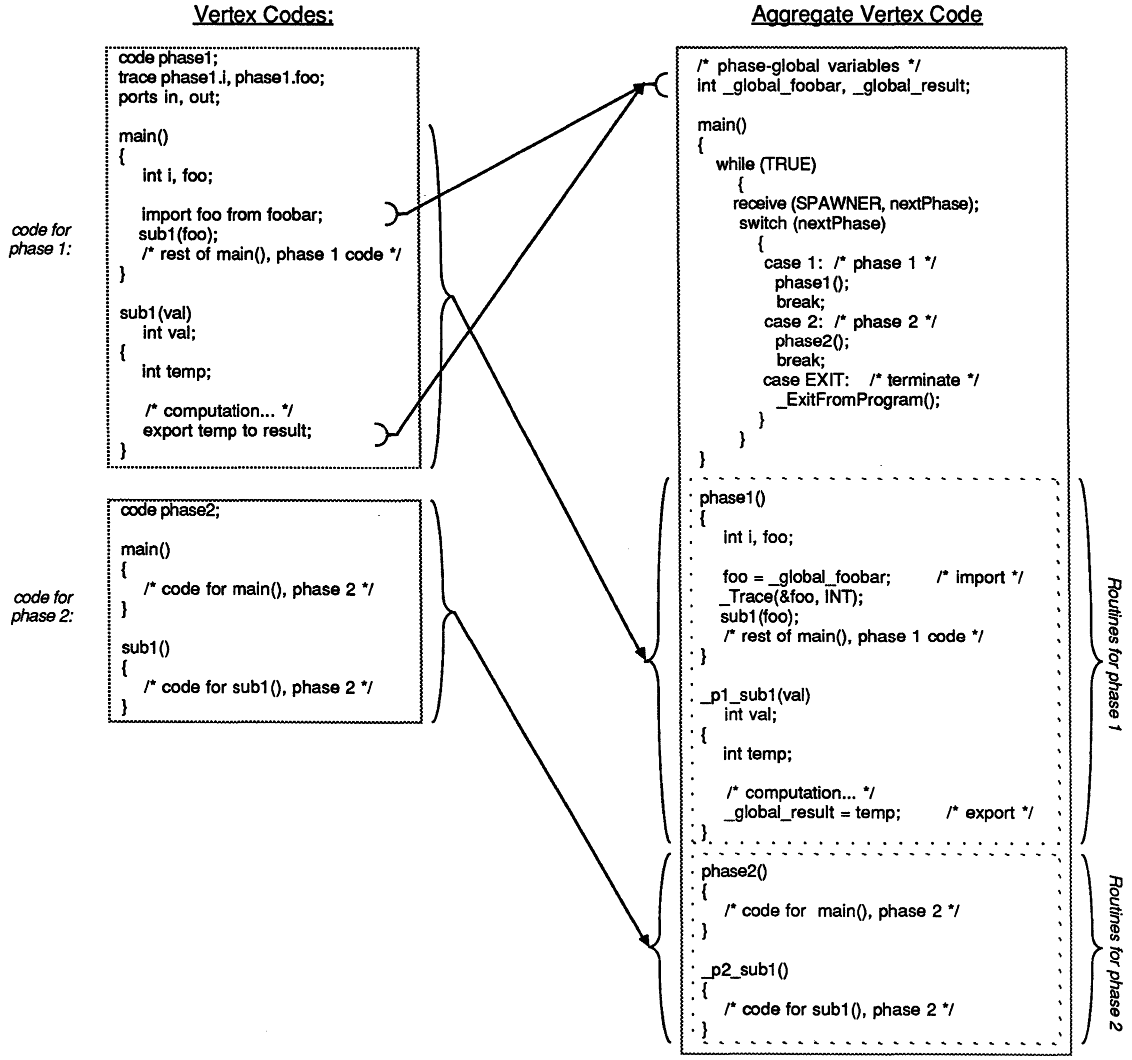
[e] Keeping efficient inter-*process* communication is a much more complex issue, discussed in the Results.

Extending the Cosmic Cube's Run-time System.

The third task of the cross-compiler is to augment the operating system of the target computer with special processes implementing the features we need for the source language. In the case of Poker, we have three such special processes: the File Server providing file system support, the Spawner acting as the controller, and the Trace Handler providing debugger support. All three of these special processes live on the host computer attached to the Cosmic Cube.

- *Spawner:* The Spawner has two tasks:
  - *Initializing a Poker program onto the Cosmic Cube.* This includes:
    - *Mapping aggregate processes to Cosmic Cube nodes.* Currently, the aggregate processes are mapped naively onto Cosmic Cube nodes, with no attention to the interconnection between the processes. Better allocations are often possible, but the realization of one of these is a complex matter discussed in the Results.
    - *Placing the aggregate processes on the Cosmic Cube nodes.* The Spawner, takes the executable codes for the aggregate processes and places ("spawns") them on the Cosmic Cube nodes.
    - *Initializing the edge maps of the "aggregate" processes.* After the Spawner places all of the aggregate processes on the Cosmic Cube the Spawner sends each aggregate process a message containing the addresses of the processes on the other end of its edges, so that the aggregate processes can initialize their edge mapping tables. The Cosmic Cube operating system provides these addresses as a result of the Spawner placing the aggregate processes.
  - *Controlling execution order of the phases.* The Spawner is the Master Control Program that sends messages to all of the aggregate processes telling them which phase to execute. When each aggregate process finishes its phase code, it sends a "Done!" message to the Spawner. The Spawner waits to hear the "Done!" messages from all of the processes before sending the next "Execute phase *n*!" message to all of the aggregate processes.



```
code phase1;
trace phase1.i, phase1.foo;
ports in, out;

main()
{
    int i, foo;

    import foo from foobar;
    sub1(foo);
    /* rest of main(), phase 1 code */
}

Figure 6: Packaging the Poker C process codes into a Cosmic Cube C aggregate process.

- *File Server:* Processes access Poker's file system through dangling edges. The File Server keeps "input" edges filled with values from files and stores values from "output" edges into files. All messages on dangling edges route through this File Server.[f]
- *Trace Handler:* Trace variables are variables whose values are always known to the outside world where a programmer may view them in a special Trace View within Poker. The Trace Handler collects messages from the processes indicating new values for the traced values and sends them to Poker's debugging environment. These values come from `send()` statements that the C-to-C compiler inserts after each assignment to a traced variable.

The Cosmic Cube Poker Program.

In summary, the Cosmic Cube program corresponding to a Poker program consists of the aggregate processes on the Cosmic Cube nodes and three special processes running on the host computer: the Spawner, the File Server, and the Trace Handler. These processes implement the run-time support, while Poker provides the programming environment, traces program execution via the Trace Handler, and cross-compiles the Poker program to create the Spawner, the File Server, and the aggregate processes that run on the Cosmic Cube.

## Results

Machine dependencies. Most of the Poker system is machine *in*dependent. The machine dependent pieces fall into three parts:

- *The Cross-compiler.* The C-to-C compiler inserts calls to runtime routines for inter-process communication, inter-phase communication, tracing, and execution control. Changing these calls requires slight changes to the C-to-C compiler. If the target processors support C, the C-to-C compiler should not need any changes. However, if the target language is not C, the C-to-C compiler may need major reworking.
- *The Run-time system.* The routines supporting the interface between the Poker environment and operating system of the target processors are highly machine dependent. Large parts of these may have to be written from scratch.
- *The mapper from logical to physical interconnections.* Not only is this the least efficiently implemented feature of the system, as described below, but it also is extremely machine dependent.

Changing these three parts is sufficient to retarget the Poker language to a new architecture.

Mapping interconnections. When the programmer defines a communication graph in Poker and it is run on the Pringle (or, one day, the CHiP Computer), the graph is "directly implemented" in the sense that the figures produced in the Switch Setting View will be quite literally compiled into the object code of the machine. This is because the machines are configurable: The switches route messages according to the interconnection drawn in the Switch Set View. For any fixed-interconnection machine, such as the Cosmic Cube, the situation is different: The communication graph, which will be considered the logical communication structure, must be mapped onto the physical interconnection structure of the architecture. Of course, programmers *implicitly* perform this mapping when programming in other parallel languages.

As described in the section on extending the Cosmic Cube's run-time system, the mapping is done by the Spawner using an arbitrary allocation. If the programmer defined a logical cube graph, the system might not, as things now stand, allocate it so that logically adjacent vertices are physically adjacent. In general, the best allocation is not so obvious, yet the system should try to minimize the distance between communicating processes. The problem of automatically finding an optimal allocation instead of our *ad hoc* allocation remains unsolved. Moreover achieving optimality is complicated by multiple phases with the one-to-one correspondence of vertices between phases; a good mapping for one phase may be quite poor for another phase of the same algorithm. We are hopeful that the work of Berman and colleagues [11] will lead to an automated solution, though the retargetting in no way depends on Berman's software; it only improves the quality of the end result. Presently, we advocate a programmer assisted mapping, but we have not yet provided the software for it. No matter what enhancement is chosen, there is an entry point in Poker for the appropriate software.

## Conclusion

We have shown that it is easy to port Poker to a new parallel architecture, the Cosmic Cube, in such a way as to produce object code as efficient as any written for that architecture. Furthermore, Poker can easily be ported to *any* parallel computer simply by providing three basic features for the new architecture:

- MIMD operation,
- message passing facilities, and
- a compiler for the process codes.

These are very modest requirements considering that a small amount of work would then provide the new architecture with a complete, easy to use programming, debugging, and cross-compiling environment, as well as all of the existing Poker parallel programs. It is for this reason that we claim that Poker can be the definition of the basic software support required by a new parallel computer.

[f] This is, of course, a potential bottleneck. Multiple File Servers could be used, but the architecture of the Cosmic Cube still requires all messages between the Cosmic Cube and the host machine, and thus the file system, to pass through the single physical edge connecting the host computer to the Cosmic Cube. Without additional hardware or a different basic IO design, Cosmic Cube programs risk becoming IO bound even with "reasonable" IO overhead.

# Performance of the Direct Binary *n*-Cube Network for Multiprocessors

## Abstract

*A mathematical model for predicting the performance of the direct binary n-cube interconnection scheme in a packet switched environment is presented. These predictions are checked against simulations of a comparable system. The results for the network are compared to known results for indirect interconnection schemes like the crossbar and indirect binary n-cube networks. Several modes of operation of the network are analyzed and, it is shown that the direct cube performs better than its indirect counterpart for reasonable sizes of switches in the latter.*

## 1. Introduction

In the current climate of increased focus on large concurrent computer systems, it is recognized that one critical segment of such systems is the communication network used to connect the processing elements together. Various network schemes have been proposed for this purpose, including crossbars, indirect binary *n*-cube networks (also referred to as omega networks [Lawr75] [Peas77]), and direct binary *n*-cube networks [Seit85] (also referred to as the hypercube connection scheme). These interconnection schemes can be classified as *direct* or *indirect*. A direct interconnection scheme is one in which nodes (processing elements) are connected together by point-to-point links. In an indirect interconnection scheme on the other hand, the network is a separate entity with inputs and outputs; processors and memories are connected to the inputs and outputs respectively (most commonly in a shared memory architecture), or processors are connected to both inputs and outputs of the system (message passing architecture). Examples of the direct interconnection scheme are the ring, mesh, and binary *n*-cube architectures. Examples of the indirect interconnection scheme, other than the crossbar, are various multistage interconnection networks of the omega type, listed above.

Indirect binary *n*-cube type networks have been analyzed extensively in the literature ([DiJu81], [Pate81], [KrSn83]) for various aspects of their performance under different operating conditions. In this paper we analyze the performance of an important direct connection scheme, the direct binary *n*-cube network, in a packet switched mode of operation. We develop several mathematical models for the network, provide simulation results, and compare its performance with that of the indirect binary *n*-cube network.

## 2. Principles of Operation

The *binary d-cube* [Peas77] consists of $N = 2^d$ nodes connected together using dedicated edges. If the nodes are numbered 0 to $2^d-1$, then the *d*-cube connection is defined by the statement that two nodes whose binary representations differ in exactly one bit position are connected together. The graph of such a svstem has degree *d*. See [Peas77] and [Seit85] for detailed discussions of the binary *d*-cube interconnection scheme.

Each node in the *d*-cube consists of a processing element (PE) and a $(d+1)\times(d+1)$ crossbar switch as shown in Figure 1a. An input-output line pair constitutes an edge in the binary *d*-cube and the switch is connected to *d* of its neighbors using *d* such pairs. (See Figure 1b for the implementation of a binary 2-cube.) When a switch receives a message, the message's destination address is compared to the current node address. If there is a match, then the switch will attempt to route the message to the node's PE. Otherwise, the message will be routed to one of the node's neighbors, chosen at random from the bit positions that differ between the message and node addresses. When the switch attempts to route multiple packets to a single output line at the same time, either the multiple messages must be buffered at the output or all but one will be lost. We will analyze the performance of the network with and without buffers at the switch outputs.

Two versions of the switch will be considered for analysis: the *single-accepting PE scheme,* (Figure 1a) where one message can be accepted by the PE each cycle, and the *multiple-accepting PE scheme,* where multiple (up to *d*) messages can be accepted by the PE in a single cycle. The latter is more realistic in a scheme where the routing is done in software [SEIT 85] and the PE takes on the switching functions.

For simplicity of analysis, all nodes will be assumed to be identical. Furthermore, in Sections 3 and 4 each node will be assumed to generate requests for other nodes in an egalitarian fashion. As the traffic is being generated by identical nodes, for uniform destinations, it is reasonable to conclude that at each node the traffic received from any neighbor is identical to that received from any other neighbor. (In Section 5, we generalize the results to arbitrary distributions of message destinations.)

Let us define $m_g$ to be the message generation rate at each PE. (It is also equal to the probability of receiving a message from the PE in each cycle.) The rate at which messages arrive from a particular neighboring node is defined to be $m$. ($m$ is also the probability of receiving a message from a particular neighbor in a cycle.) Also, let the rate of messages going to the PE be defined as $m_a$. (If the single-accepting PE model is used, then $m_a$ is also the probability of a message being accepted by the PE in a cycle.) Furthermore, let $P_t$ (the probability of termination) be the probability that a message received from a neighboring node is for the PE.

## 3. Analysis of Unbuffered Networks

The performance measures we are interested in are the probability of acceptance of a generated message, and the bandwidth of the network as a whole. When multiple messages for the same output line are received at a switch in an unbuffered network, one randomly selected message "wins", and the rest of the messages are blocked. All blocked messages are lost from the system.

Let $P_A$ be the probability that a generated message is ultimately accepted. The total number of messages generated in the cube in one cycle is $Nm_g$. The total number of messages accepted in the cube in one cycle is $Nm_a$. Thus $P_A = Nm_a/Nm_g = m_a/m_g$. Network bandwidth is simply $Nm_a$. $m_a$ is computed in the following two sections.

### 3.1. Calculating the termination probability, $P_t$

We define the *distance* between two addresses on a cube to be the number of cycles needed to travel from one node to the other. This is exactly the number of differing bit positions in the two addresses. Hence the distance between any two node addresses is an integer between 0 and *d*. Given a node address, the number of node addresses that differ by exactly *k* bits is $\binom{d}{k}$. Let the distance between the message destination and the current node be defined as the *hopcount* of the message.

Starting with an empty network, on cycle 1 each PE can generate a message that will have hopcount *i* with probability $\binom{d}{i}/(N-1)$. At all subsequent cycles, this will also be the distribution of messages coming from each PE. $1/d$ of these messages will be sent to each of the neighboring nodes where it will be combined with the messages from $d-1$ other nodes. Let us define $P_a$, the probability that a (non-terminating) message

0190-3918/86/0000/0636 $01.00 © 1986 IEEE

received from a node is successfully passed on to another node, to be

$$P_a = \frac{\text{Messages going out to the nodes}}{\text{Messages trying to go out to the nodes}} = \frac{dm}{dm(1 - P_t)+m_g} .$$

(Recall that $m$ is the rate at which messages arrive at an input to the switch.) At the end of cycle 2 the distribution of messages sent to the neighboring nodes will be as follows:

$$\begin{array}{lccccc} \text{Hops:} & 0 & \dots & i-1 & \dots & d-1 \\ \text{Prob:} & \dfrac{P_a\binom{d}{1}+P_a^{\,2}\binom{d}{2}}{A} & \dots & \dfrac{P_a\binom{d}{i}+P_a^{\,2}\binom{d}{i+1}}{A} & \dots & \dfrac{P_a\binom{d}{d}}{A} \end{array}$$

where $A = P_a^{\,2}(N-1-d)+P_a(N-1)$. The first term in each probability is contributed by the PE on cycle 2, and the second term is contributed by the $d$ neighboring nodes. In general, at the end of cycle $i$, messages from node distance $i-1$ away $(0<i-1<d)$, can have hopcounts from 0 to $d-i$. (This is because a message can travel no further than distance $d$.) After $d$ cycles, the distribution reaches steady state. This distribution is given by

$$\Pr[\text{hopcount} = i-1] = \{\sum_{j=i}^{d} \binom{d}{j} P_a^{\,j-i+1}\} / \{\sum_{k=1}^{d}\sum_{j=k}^{d} \binom{d}{j} P_a^{\,j-k+1}\}$$

Thus the probability of receiving a message with hopcount = 0 (i.e., the termination probability) can be derived to be

$$P_t = \{(P_a-1)((1 + P_a)^d - 1)\} / \{P_a((1 + P_a)^d - N)\} .$$

### 3.2. Calculating message rates $m$ and $m_a$

Given a message from some other node, it terminates at this node with probability $P_t$. Otherwise, it is passed to one of $d-1$ other nodes as it is never passed back to the node it came from. Therefore, with probability $(1-P_t)/(d-1)$ a message is routed to one particular output line. (Actually, the message is routed to one of $k$ outputs, where $k$ is the number of differing bit positions between node and message addresses. However, this is a reasonable assumption, as comparisons with simulations will show.) The probability of getting a message from the PE is simply $m_g$. This message is routed to one particular output line with probability $1/d$.

Considering one particular output, the probability that no message arrives at this output is $(1-m_g/d)(1-m(1-P_t)/(d-1))^{d-1}$. Since the output line of this node is the input line for some other identical node, the rate at which messages leave the node must be equal to the rate messages arrive at the node. Thus,

$$m = 1 - (1 - m_g/d)(1 - m(1-P_t)/(d-1))^{d-1} .$$

Using the single-accepting PE model and employing a similar argument,

$$m_a = 1 - (1-mP_t)^d .$$

When the multiple-accepting PE model is used we obtain:

$$m_a = dmP_t .$$

### 3.3. Unbuffered network results and discussion

These results, along with corresponding simulations are presented in Figures 2 and 3. Figure 2 plots the probability of acceptance of a message in a direct binary cube as a function of the message generation rate for various network sizes. (A multiple-accepting PE model is assumed.) The model and the simulations agree to within 5% in all cases. The performance of the direct cube compared with that of the crossbar and indirect binary cube networks is presented in Figure 3. (Fairly standard models are considered for the crossbar and indirect binary cube networks, as for instance [KrSn83] and [Pate81].) Since the crossbar and indirect cube networks are by definition single accepting networks, a single-accepting PE model is assumed for the direct network figures in these graphs. Indirect networks can be constructed out of switches of different sizes and the choice of switch size affects both cost and performance. Figure 3 considers indirect binary $n$-cube networks constructed using switches of size 2, 4, and 8. We notice that it takes a switch size of about 8 in the indirect network to equal the performance of the direct network.

Various measures of cost for these two types of networks are shown in the table below (where the symbol "k" means multiplied by 1024).

| | Direct binary *n*-cube | | | Indirect binary *n*-cube | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| Network Size | 256 | 1024 | 4096 | 256 | | 1024 | | 4096 | | |
| Switch Size | 9 | 11 | 13 | 2 | 4 | 2 | 4 | 2 | 4 | 8 |
| Switches | 256 | 1k | 4k | 1k | 256 | 5k | 1280 | 24k | 6k | 2k |
| Lines | 2304 | 11k | 52k | 2304 | 1280 | 11k | 6k | 52k | 28k | 20k |
| Crosspoints | 20736 | 121k | 676k | 4k | 4k | 20k | 20k | 96k | 96k | 128k |

The ability of the direct binary cube to outperform its indirect counterpart comes at the expense of increased hardware (using any of the cost measures), as the table illustrates. However, the hardware is not used in the most effective manner, as a comparison with the indirect cube using 8x8 switches shows. (The two networks have similar performance.) Thus it would seem that given a certain amount of hardware (essentially a number of switches and PEs), it would be preferable to connect them in the form of an indirect binary cube. It should be pointed out that this observation applies to the equiprobable reference model where a PE wishes to talk to any of the others with equal probability. To our knowledge, this is the mode in which existing implementations of the system software for direct cube architectures operate (for example, the Intel Hypercube). A more complex allocation of tasks to PEs, utilizing knowledge about locality of communication, would improve the performance of the direct binary cube.

## 4. Analysis of Buffered Networks

In a buffered network, multiple messages heading for the same output in a cycle are saved up in a queue at the output side of the switch. The line going to the PE needs a buffer only in the single-accepting PE model; the multiple-accepting PE model assumes some mechanism of giving up to $d$ messages to the PE at once. In the first part of this analysis, the queue lengths are assumed to be infinite; finite length queues are analyzed in Section 4.5.

When infinite buffers are assumed, no messages are lost. ($P_A = 1$, and bandwidth $= Nm_g$.) A good measure of network performance in this case is $T$, the mean message delay time. This time is defined to be the average time a message spends in the system before reaching the destination PE.

### 4.1. Calculating the termination probability, $P_t$, and message rate, $m$

By following an analysis similar to that for unbuffered networks (setting $P_a$ to 1) we obtain $P_t = (2N - 2)/(dN)$.

To derive expressions for $m$ and $m_a$, we observe that with infinite length queues, no messages can be lost. Hence, $m_a = m_g$. If we allow multiple messages to be accepted by the PE, then $m_a = dmP_t$. Therefore,

$$m = m_g/(dP_t) = Nm_g/(2N-2).$$

If the PE accepts only single messages in each cycle, then the above expression for $m$ is still valid if we consider $dmP_t$ to be the rate at which messages are sent to the PE's buffer.

### 4.2. Multiple-accepting model

In order to determine $T$ for the multiple-accepting model, we first must determine the length of the buffers at the switch outputs of each node. Consider a single output queue and associated output line. We say this system is in state $i$ (with probability $b_i$) when there are $i$ messages in the system. Examining first only the messages received from outside the node, the probability of receiving $i$ messages at a particular output line of the queue is given by

$$q(i) = \binom{d-1}{i}(1 - m(1-P_t)/(d-1))^{d-1-i}(m(1-P_t)/(d-1))^i$$

for $0 \le i < d$. (We assume that a message does not go back to the node it came from.) Considering generated messages also, the probability of getting $i$ messages at an output line is given by:

$$a_i = \begin{cases} (1 - m_g/d)q(0) & i=0 \\ (1 - m_g/d)q(i)+(m_g/d)q(i-1) & 0<i<d \\ (m_g/d)q(d-1) & i=d \\ 0 & i>d \end{cases}$$

Given these arrival rates at an output queue, the state distribution for the queue are

$$b_i = \sum_{j=0}^{i} a_j b_{i-j+1} + a_i b_0 \ .$$

Then the mean number of messages in the system can be shown to be

$$\bar{b} = m + \{m^2(d(1 - P_t^2) - 2(1 - P_t))\} / \{2(d - 1)(1 - m)\}.$$

Using Little's identity, the mean time a message spends at an intermediate node is given by $\bar{b}/m$. As an average message goes through $\frac{1}{N-1}\sum_{j=1}^{d} j \binom{d}{j} = \frac{1}{P_t}$ nodes, the delay to reach the destination node is $\bar{b}/(mP_t)$. Including an additional cycle for the message to be transferred to the PE from the switch, the total delay is obtained as

$$T = 1 + \bar{b}/(mP_t).$$

**4.3. Single-accepting model**

Now we consider the case where only one message can be accepted at the PE at a time. We need to determine the length of the PE's buffer and this can be done in the same manner as before. For the PE's queue, the arrival rates are given by

$$a_i' = \binom{d}{i}(1 - mP_t)^{d-i}(mP_t)^i$$

for $0 \le i \le d$, and $a_i = 0$ otherwise. The probability of being in state $i$ is $b_i'$. Using this and following the same procedure as before the mean message delay can be derived as:

$$T = \bar{b}/(mP_t) + m_g(d-1)/(2d(1-m_g)) + 1.$$

**4.4. Buffered network results and discussion**

Figure 4 presents the results in the infinite buffered model and compares them with the same model for indirect binary cube networks. Figure 4a verifies the accuracy of the analytical model vis a vis simulations. We notice that with the multiple-accepting model, about a 30% increase in delay results from a fully saturated network. With a single-accepting PE model however, (Figure 4b), the receiving queue at each PE does blow up in size with increasing generation rates just as in the case of the indirect network. However, at high request rates, the difference between the direct and indirect networks is substantial. As in the case of the unbuffered networks, we notice that a switch size of at least 8 is needed before the indirect networks can exceed the performance of the direct network. The cost-performance discussion in Section 3.3 for unbuffered networks holds for buffered networks also.

**4.5. Finite buffers**

We now consider buffered systems where the queue lengths at the outputs of switches are finite. We define $Q$ to be the length of the queue. Recalling our definition of state from section 4.2, such a queue and associated output line has $Q + 1$ states. The expressions for $a_i$ and $b_i$ in section 4.2 still apply ($b_i = 0$ for $i > Q$); however, the rest of the analysis in that section is particular to the infinite buffer case. For the finite buffer case, we still must derive an expression for $m$ (and $P_t$). Since the associated output line emits a message whenever the system is not in state 0, $m = 1 - b_0$. $b_0$ may be calculated by solving the system of linear equations described by the state transitions. (When $Q = 0$, $m = 1 - a_0$ which corresponds to section 3.2.) Given this value for $m$, $P_t$ and $P_a$ may be calculated using the expressions of section 3.1.

For the multiple-accepting PE model, $m_a = dmP_t$ just as in section 3.2. When using the single-accepting PE model, $m_a = 1 - b_0'$, where $\{b_i'\}$ is the state distribution for the PE's queue. (As before, when $Q = 0$, $m_a = 1 - a_0'$ which corresponds to section 3.2.)

Figure 5 displays the results for the finite buffered network for varying values of $Q$. Note that fairly small buffer sizes yield more than 90% of infinite buffer performance. The performance difference between the single-accepting and multiple-accepting models is due to a bottleneck at the node to PE connection in the single-accepting model. This bottleneck is most constraining when the message generation rate approaches 1 and message delays increase (refer to Figure 4b). The behavior of the finite buffered direct cube is similar to that of the indirect binary cube network, as presented in [DiJu81]: small buffers capture the effective performance of the infinite buffers, in all but the saturated mode of network operation.

**4.6. Saturation value of message generation rate, $m_g$**

In Section 3.3 we observed that while a direct binary $n$-cube network had more hardware then an indirect network, there was not a corresponding performance gain. If we let $m_g = 1$, we obtain $m = N/(2N - 2)$ (Section 4.1). For maximum utilization of the network links, $m$ should approach 1, and this happens when $m_g$ approaches $2(N - 1)/N$ [AbPa86]. Thus, a multiple-accepting PE requires a *multiple-generating* PE to allow full utilization of all the network links.

## 5. General Distributions

It is possible to generalize our expressions in the previous sections to arbitrary reference patterns [AbPa86]. Let $h_i$ be the probablility that a message generated at a node will have hop-count $i$. Figure 6 shows the message delay for three distributions of hopcount. $h_i = 1/d$ corresponds to a uniform distribution of hopcounts, while the harmonic reference pattern is given by $h_i = 1/\alpha i$, where $\alpha = \sum_{i=1}^{d} 1/i$. Clearly, exploiting the locality of reference in a program results in substantial performance increases.

## 6. Summary and Conclusions

We have presented in this paper an analytical model and simulation results for the performance of the direct binary $n$-cube interconnection scheme for multiprocessors. The results show that with the equiprobable reference model for interprocessor communication, the direct cube performs better than the indirect cube networks constructed using switches of size less than 8 for all modes of operation that we have considered. The indirect networks require fewer switches, especially as the switch sizes begin to increase. However, it is possible in the direct case, for each processing element to take on some or all of the switching function at each node. In the latter case, the direct binary $n$-cube performs especially well in a mode called the multiple-accepting PE mode of operation. Furthermore, this multiple-accepting PE mode, coupled with a multiple message generating PE will fully utilize all the network bandwidth; this bandwidth is greater than that of the indirect cube networks, due to the presence of more links in the direct cube.

Results regarding buffering of packets at nodes generally are similar to known results in the indirect network case: not buffering packets leads to a significant loss of packets in the network, and a small buffer size (1 or 2) dramatically reduces loss of packets. When processor allocation is done intelligently to exploit locality of communication, our analysis shows that significantly better performance can be realized. This will have to be done for the performance/cost ratio to be better in the direct cubes than in their indirect counterparts.

## Abstract

High communication bandwidth in standard technologies is more expensive to realize than a high rate of arithmetic or logic operations. The effective utilization of communication resources is crucial for good overall performance in highly concurrent systems. In this paper we address two different communication problems in Boolean $n$-cube configured multiprocessors: 1) broadcasting, i.e., distribution of common data from a single source to all other nodes, and 2) sending personalized data from a single source to all other nodes. The well known spanning tree algorithm obtained by bit-wise complementation of leading zeroes (referred to as the SBT algorithm for *Spanning Binomial Tree*) is compared with an algorithm using *multiple spanning binomial trees* (MSBT). The MSBT algorithm offers a potential speed-up over the SBT algorithm by a factor of $\log_2 N$. We also present a *balanced spanning tree* algorithm (BST) that offers a lower complexity than the SBT algorithm for Case 2. The potential improvement is by a factor of $\frac{1}{2}\log_2 N$. The analysis takes into account the size of the data sets, the communication bandwidth, and the overhead in communication. We also provide some experimental data for the Intel *iPSC/d7*.

## 1. Introduction

Broadcasting of data from a single source to all other nodes in a multiprocessor system is an important operation. It is used in many parallel algorithms, for instance, in matrix multiplication, the solution of irreducible linear systems, and forming transitive closure. Examples of a variety of algorithms using specific forms of communication are contained in [6, 12, 11]. The reverse operation, reduction, occurs, for example, in computing inner products, solving linear recurrences, [14], and parallel prefix computation. A different situation occurs if the source node distributes personalized information to all other nodes. In this case no replication of information takes place during distribution (or reduction in the reverse operation). The collection of data to a single node and distribution of personalized messages to all other nodes is a useful operation for the solution of tridiagonal systems under certain combinations of start-up times for communication, communication bandwidth, and problem sizes [13]. Matrix transposition is another example of personalized communication in that every node sends different data to every other node [11].

Data communication in Boolean cubes has received significant interest recently due to the success of the Caltech Cosmic Cube project [20] and the availability of Boolean cube configured concurrent processors from Intel Scientific Computers, NCUBE, Ametek, Floating-Point Systems and Thinking Machines Corp. [7]. The embedding of complete binary trees is treated in [22, 11, 18, 3, 2]. Wu also discusses the embedding of $k$-ary trees, and Bhatt the embedding of arbitrary binary trees. Efficient routing using randomization for arbitrary permutations has been suggested by Valiant [21] . Broadcasting of data from a single source to all other nodes is studied in [18]. We propose a lower bound algorithm that offers a speed-up of a factor of $\log N$[1] over the algorithm in [18]. We also present lower bound algorithms for personalized communication. We give routing algorithms, and analyze the complexity in detail. The analysis is compared with experimental data.

A Boolean $n$-cube has $N = 2^n$ nodes, diameter $\log N$, $\binom{\log N}{i}$ nodes at distance $i$ from a given node, and $\log N$ disjoint paths between any pair of nodes. The paths are either of the same length as the Hamming distance between the end points of the paths, or the Hamming distance plus two [19]. The fanout of every node is $\log N$, and the total number of communication links is $\frac{1}{2}N\log N$. Any spanning tree can be used to broadcast data from a single source to all other nodes.[2] A node replicates the data as many times as correspond to the out-degree of the node in the spanning tree. In broadcasting one element (or packet), the minimum number of routing steps is $\log N$. Any spanning tree with height $\log N$ can achieve this lower bound, if each node can send out data through all the links connected to it during one step. In case each node can send or receive data through only one link during one step, then only the class of *spanning binomial trees* can attain the lower bound, since after each broadcasting step the number of nodes that own the desired data is at most twice that of the previous step. The $\log N$ lower bound is attained only if the number of nodes that own the desired data doubles at each step. This is exactly the definition of a binomial tree. A 0-level binomial tree has only 1 node. An $n$-level binomial tree is constructed out of two $(n-1)$-level binomial trees by adding one edge between the roots of the two trees, and by making either root the new root, [1, 4]. It follows from this recursive construction that:

1. An $n$-level binomial tree has $\binom{n}{i}$ nodes at level $i$.
2. The $n$-level binomial tree is composed of $n$ subtrees[3] each of which is a binomial tree of $0, 1, \ldots, n-1$ levels respectively. The $k$-level subtree has $2^k$ nodes.
3. An $n$-level binomial tree can be obtained from a $k$-level binomial tree, $k < n$, by replacing each node of the $k$-level binomial tree by an $(n-k)$-level binomial tree. The child nodes of a node in the $k$-level tree become children of the root of the replacing $(n-k)$-level binomial tree.

Since an $n$-level binomial tree can be embedded in an $n$-cube as a spanning tree, we call it a *Spanning Binomial Tree* (SBT). Note that the number of nodes at each level $i$ of the binomial tree is equal to the number of nodes at distance $i$ from a node in an $n$-cube.

In broadcasting $M$ elements using a packet size of $B$ elements, and by pipelining the communication from the root towards the leaves along any $\log N$ height spanning tree, the number of routing steps becomes $\lceil \frac{M}{B} \rceil + \log N - 1$, which is not optimal. Since each node has a fanout of $\log N$, a lower

[1] $\log N = \log_2 N$ throughout this paper.

[2] In particular, a Hamiltonian Path is also a spanning tree.

[3] In this paper "subtree" refers to "subtree of the root" unless stated otherwise.

bound for the number of routing steps is $\lceil \frac{M}{B \log N} \rceil + \log N - 1$. In order to achieve this lower bound, the data set has to be split into $\log N$ subsets, each of which is communicated over a distinct communications link from the source node. It follows that the nodes adjacent to the source node must be roots of subtrees spanning all but one node of the cube (the source node). The depth of the subtrees is $\log N$, and a tight lower bound for the number of routing steps, assuming concurrent bi-directional communication, is $\lceil \frac{M}{B \log N} \rceil + \log N$.

In sending personalized information from a single source to all other nodes, no replication of information takes place and the total number of packets that the source must send is $\lceil \frac{(N-1)M}{B} \rceil$ for $M$ elements per destination node. The number of routing steps for the *Spanning Binomial Tree* algorithm (SBT) is $\log N$ if the maximum packet size is sufficiently large $(NM/2)$; even so, the communication bandwidth is poorly utilized since the transfer time is at least proportional to $NM/2$. In the SBT, half of the nodes belong to one subtree, one quarter to another subtree, etc. A *Balanced Spanning Tree* (BST) is defined in that each subtree has approximately $\frac{N}{\log N}$ nodes. The data transfer on any link is limited to approximately $\frac{N}{\log N}M$. The BST algorithm offers a potential $\log N$ speed-up over the SBT algorithm in sending personalized information from a single source to all other nodes. In fact, lower bound algorithms for broadcasting from every node to every other node and sending personalized data from every node to every other node on a Boolean cube can be attained by using $N$ BST's rooted at each node concurrently. See [8] for details.

In section 2 we introduce the notation and some definitions used throughout the paper. Section 3 considers broadcasting from a single source to all other nodes, and section 4, personalized communication from a single source to all other nodes. Experimental results on the Intel *iPSC/d7* are presented in section 5.

## 2. Notation and Definitions

In the following, $N$ denotes the number of nodes in the Boolean $n$-cube and $n = \log_2 N$ the dimension of the cube. Nodes in the cube are assigned binary addresses such that adjacent nodes differ in precisely one bit. Address bits are numbered from 0 through $n-1$ with the lowest order bit being *bit 0*. Node $i$ is the node that has a binary address equal to $i$, i.e., $i = (a_{n-1}a_{n-2}\ldots a_0)$. Let $\oplus$ be the bit-wise exclusive-or operation. The $j^{th}$ port of a node $i$ connects to the node $k$ that differs from $i$ in the $j^{th}$ bit, i.e., $i \oplus k = (00...01_j0...0)$. There is a port for each address bit, and ports are numbered from 0 through $n-1$. Let $|i|$ denote the number of bits with value one in the binary number $i$; hence $|i \oplus j|$ denotes the Hamming distance between the binary numbers $i$ and $j$.

Let $i = (a_{n-1}a_{n-2}\ldots a_0)$. Define $R$ to be the right rotation function, i.e., $R(i) = (a_0a_{n-1}a_{n-2}\ldots a_1)$, and $R^j = R^{j-1} \circ R$ to mean a right rotation of $j$ steps. The *rotation* of a graph with binary node addresses is accomplished by applying the same rotation function to all its addresses. This is similarly the case for the *translation* of a graph. Clearly, adjacency is preserved under rotation and translation. The period of a binary number $i$, $P_i$, is the least $j$ such that $i = R^j(i)$. For example, the period of (011011) is 3. A binary number is *cyclic* if its period is less than its length; otherwise it is *non-cyclic*. A *relative address* of node $i$ in a spanning tree rooted at node $s$ is $i \oplus s$. A *cyclic node* is a node with cyclic relative address.[4] If one binary number can be derived by rotating another binary number, then they are in the same *generator set* $G$ (or *necklace* [15]). For example, (001001), (010010) and (100100) are in the same generator set. The number of elements in the generator set $G_i$ of $i$ is $P_i$.

In the graph model of the Boolean cube there is a node (vertex) for each node (processor with local memory) of the cube, and a pair of directed edges for each pair of nodes that differ in precisely one bit. The directed edges between a pair of nodes form a communication link. A *source node*, or a *root node*, is a node that only has edges directed away from it. A *sink node*, or a *leaf node*, only has edges directed to it. Nodes that are neither source (root) nor sink (leaf) nodes are *internal nodes*. The root of a tree is at *level 0* and traversing the edge away from the root increases the level by one. The height of a tree is equal to the label of the last level. The MSBT and BST are constructed out of $n$ subtrees labelled 0 through $n-1$ (from left to right in the Figures of this paper).

The communication is assumed to be packet switched. $M$ denotes the number of elements to be received by a node, $t_c$ the transfer time for an element, and $\tau$ the start-up time for the communication of a packet of maximum $B$ elements. With concurrent bi-directional communication we assume that a pair of adjacent nodes can exchange a pair of messages during the same communication step, or cycle. In a *port-oriented* routing algorithm, all information to be communicated over a port is sent before any communication is performed on any other port. In *packet-oriented* communication, a piece of information corresponding to a packet is communicated on all ports before a second packet is sent on any port.

## 3. Broadcasting

In this section, we will describe and compare routing algorithms for broadcasting based on a Spanning Binomial Tree (SBT) and Multiple Spanning Binomial Trees (MSBT). We first define the SBT and MSBT topologies, then state the communication complexity of the routing algorithms for the two topologies, assuming communication on only one port at a time (which, effectively, is the case with the Intel *iPSC*), and on all $\log N$ ports concurrently.

### 3.1. Spanning Binomial Trees

The familiar spanning tree rooted at node 0 of a Boolean $n$-cube contains the edges that connect a node $i$ with the subset of its neighbors having addresses obtained by complementing any bit of leading zeroes of the binary encoding of $i$, [5, 11, 16, 18, 19]. For an arbitrary source node $s$ the spanning tree is simply translated by a bit-wise exclusive-or operation on all addresses with the address of the source node; i.e., $c = i \oplus s$ is formed. Complementation of those bits of $i$ that correspond to the leading zeroes of $c$ defines the edges of the translated spanning tree. More precisely, let $s = (s_{n-1}s_{n-2}...s_0)$, $i = (a_{n-1}a_{n-2}...a_0)$, and $c = (c_{n-1}c_{n-2}...c_0)$, where $c_m = s_m \oplus a_m$. Let $c_k = 1$ and $c_m = 0, \forall m > k$ with $k = -1$ for $c = 0$, i.e., $k$ is the highest order bit of $c$ that is 1. Let $children(i, s)$ be the set of child nodes of node $i$ in the SBT rooted at node $s$ and $\mathcal{M}_{SBT}(i \oplus s) = \{k+1, \ldots, n-1\}$. Then,

$$children_{SBT}(i,s) = \{(a_{n-1}a_{n-2}\ldots\overline{a}_m\ldots a_0)\}, \quad \forall m \in \mathcal{M}_{SBT}(i \oplus s)$$

In implementing the routing algorithm for the SBT topology it is also convenient to introduce the inverse function, i.e., a

[4] A cyclic node is defined in terms of a spanning tree.

function that for each node defines its parent. Let $parent(i,s)$ be the parent of node $i$ in the spanning tree rooted at node $s$. Then

$$parent_{SBT}(i,s) = \begin{cases} \phi, & i = s; \\ (a_{n-1}a_{n-2}\ldots\overline{a}_k\ldots a_0), & i \neq s. \end{cases}$$

It is easy to verify that the parent and children functions are consistent. Figure 1 shows a spanning tree generated by the children (or parent) function for the root located at node 0 in a 4-cube.

### 3.2. Multiple Spanning Binomial Trees

The Multiple Spanning Binomial Trees (MSBT) graph can be viewed as being composed of $\log N$ SBT's with one tree rooted at each of the nodes adjacent to the source node. The SBT's are rotated such that the source node of the MSBT graph is in the smallest subtree of each SBT. The MSBT graph is then obtained by reversing the edges from the roots of the SBT's to the source node. After the edge reversal each SBT becomes an ERSBT (Edge Reversed Spanning Binomial Tree). The MSBT graph is not a tree. The diameter of the MSBT graph is $\log N + 1$, since the source node is adjacent to all the roots of the SBT's used in the definition of the MSBT graph, and each SBT is of height $\log N$. The total number of edges in the $\log N$ SBT's is $(N-1)\log N$, which is $\log N$ less than the total number of directed edges in the cube. Hence, if the $\log N$ SBT's are edge-disjoint, then all edges are used, except the edges directed from the roots of the SBT's towards the source node. The SBT's used for the construction of the MSBT graph can be obtained by translation and rotation of the SBT defined before. We refer to the SBT rooted at node $(00\ldots01_j0\ldots0)$ as the $j^{th}$ SBT of the MSBT graph. The $j^{th}$ ERSBT is obtained from the $j^{th}$ SBT by reversing the edge directed to node 0 (the source).

Let $i = (a_{n-1}a_{n-2}\ldots a_0)$ and $k$ be such that $a_k = 1$, and $a_m = 0, \forall m \in \mathcal{M}_{MSBT}(i,j)$ where $\mathcal{M}_{MSBT}(i,j) = \{(k+1) \bmod n, (k+2) \bmod n, \ldots, (j-1) \bmod n\}$. Hence, $k$ is the first bit to the right of bit $j$, cyclically, which is equal to one, if $k \neq j$. For the special case of $i = 0$ we define $k = -1$. For the $j^{th}$ ERSBT of the MSBT graph with source node 0, the set of child nodes, and the parent node, of node $i$ are defined as follows:

$$children_{MSBT}(i,j,0) = \begin{cases} (a_{n-1}a_{n-2}...\overline{a}_j...a_0), & \text{if } k = -1; \\ \{(a_{n-1}a_{n-2}...\overline{a}_m...a_0)\}, & \\ \quad \forall m \in \mathcal{M}_{MSBT}(i,j) \bigcup \{j\}, & \text{if } a_j = 1,\ k \neq j; \\ \{(a_{n-1}a_{n-2}...\overline{a}_m...a_0)\}, & \\ \quad \forall m \in \mathcal{M}_{MSBT}(i,j), & \text{if } a_j = 1,\ k = j; \\ \phi, & \text{if } a_j = 0, k \neq -1. \end{cases}$$

$$parent_{MSBT}(i,j,0) = \begin{cases} \phi, & \text{if } k = -1; \\ (a_{n-1}a_{n-2}...\overline{a}_j...a_0), & \text{if } a_j = 0, k \neq -1; \\ (a_{n-1}a_{n-2}...\overline{a}_k...a_0), & \text{if } a_j = 1. \end{cases}$$

All nodes with bit $j$ equal to zero are leaf nodes of the $j^{th}$ ERSBT, except node 0. Conversely, all nodes with $a_j = 1$ are internal nodes of the $j^{th}$ ERSBT. Figure 2 shows an MSBT graph with source node 0 in a 3-cube.

It can be shown that the $\log N$ directed ERSBT's are edge-disjoint and the height of the MSBT graph is minimal among all possible configurations of $\log N$ edge-disjoint spanning trees[8].

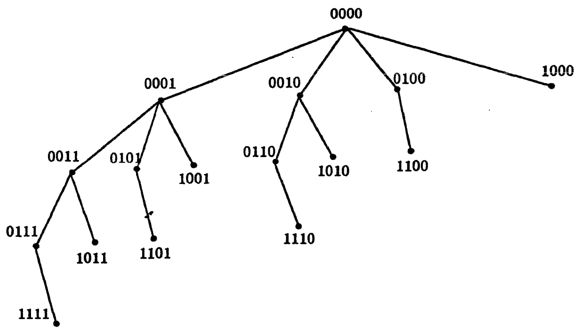

**Figure 1:** A spanning tree in a 4-cube.

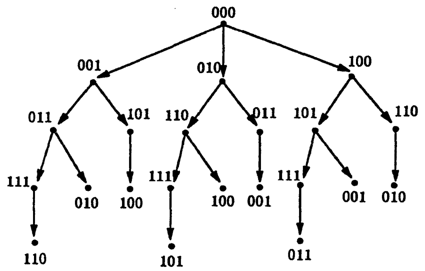

**Figure 2:** Three edge-disjoint directed spanning trees in a 3-cube.

For an arbitrary source node $s$ an MSBT graph is defined by translating the MSBT graph rooted at node 0. The only difference in the definition of the *parent* and *children* functions is that $k$ is determined from $c = i \oplus s$. Hence, for a source node $s$, $k$ is such that $c_k = 1$, and $c_m = 0, \forall m \in \mathcal{M}_{MSBT}(i \oplus s, j)$. For the special case of $c = 0$, $k = -1$.

$$children_{MSBT}(i,j,s) = \begin{cases} (a_{n-1}a_{n-2}...\overline{a}_j...a_0), & \text{if } k = -1; \\ \{(a_{n-1}a_{n-2}...\overline{a}_m...a_0)\}, & \\ \quad \forall m \in \mathcal{M}_{MSBT}(i \oplus s,j) \bigcup \{j\}, & \text{if } c_j = 1,\ k \neq j; \\ \{(a_{n-1}a_{n-2}...\overline{a}_m...a_0)\}, & \\ \quad \forall m \in \mathcal{M}_{MSBT}(i \oplus s,j), & \text{if } c_j = 1,\ k = j; \\ \phi, & \text{if } c_j = 0, k \neq -1. \end{cases}$$

$$parent_{MSBT}(i,j,s) = \begin{cases} \phi, & \text{if } k = -1; \\ (a_{n-1}a_{n-2}...\overline{a}_j...a_0), & \text{if } c_j = 0, k \neq -1; \\ (a_{n-1}a_{n-2}...\overline{a}_k...a_0), & \text{if } c_j = 1. \end{cases}$$

### 3.3. Communication Complexity of SBT- and MSBT-based Broadcasting

#### 3.3.1. Spanning Binomial Trees

With the communication restricted to one port at a time the data is first sent to the node that is the root of the largest subtree. Since the binomial tree is composed of two $(n-1)$-level binomial trees, the broadcasting operation is now reduced to the broadcasting of data in two same-sized, disjoint, subtrees of the cube. The process is repeated $\log N$ times and the complexity is $T = \lceil \frac{M}{B} \rceil (\tau + Bt_c) \log N$. Clearly $B_{opt} = M$ and $T_{min} = \log N(\tau + Mt_c)$. The data transfer time is independent of the packet size, but the number of start-ups decreases.

With a capability of concurrent communication on all ports, pipelining can be employed extensively. The propagation time to the node farthest away from the source is at least $\log N(\tau + Bt_c)$. When this node has received all packets the broadcasting is terminated. Hence, $T = (\lceil \frac{M}{B} \rceil + \log N - 1)(\tau + Bt_c)$, $B_{opt} = \sqrt{\frac{M\tau}{t_c(\log N - 1)}}$, and $T_{min} = (\sqrt{Mt_c} + \sqrt{\tau(\log N - 1)})^2$. The communication complexity estimates for the SBT are also given in [18] and are included here for easy reference.

### 3.3.2. Multiple Spanning Binomial Trees

We consider the cases with communication restricted to one send *or* one receive operation at a time, one send *and* one receive operation concurrently, and concurrent communication on all ports. The minimum number of routing steps to broadcast $\log N$ packets is $2\log N$ with communication restricted to one send *and* one receive operation at a time. To realize this lower bound it is required that a routing algorithm be found that allows concurrent communication within all subtrees without violating the constraint on concurrent communication. We describe such a routing algorithm in terms of labelling the MSBT graph with the least label being 0. A valid labelling for the restriction of one receive and one send operation concurrently (per node) and allowing pipelining every $\log N$ cycles, requires that the following three conditions be satisfied:

1. For any node of each subtree the least label on the output edges is greater than the label on the input edge.
2. For any cube node the labels on its input edges are distinct modulo $\log N$. (If there is more than one packet per subtree then the root can send out a new packet to every subtree every $\log N$ cycles.)
3. For any cube node the labels on the output edges are distinct modulo $\log N$.

Let $i = (a_{n-1}a_{n-2}...a_0)$ and $f(i,j)$ be the label of the input edge of node i in the $j^{th}$ subtree for an MSBT graph with source node $s$. Let $c = i \oplus s$, $c_k = 1$ and $c_m = 0, \forall m \in \mathcal{M}_{MSBT}(i \oplus s, j)$. If $c = 0$ then $k = -1$. Define

$$f(i,j) = \begin{cases} \phi, & \text{if } k = -1; \\ j + n, & \text{if } c_j = 0, k \neq -1; \\ k, & \text{if } c_j = 1, k \geq j; \\ k + n, & \text{if } c_j = 1, k < j. \end{cases}$$

It can be proved that function $f$ satisfies these three conditions[8]. From the labelling scheme, the largest label of all the input edges is $2n - 1$, i.e., broadcasting the first $\log N$ packets (one packet per subtree) can be done in $2\log N$ steps. The MSBT graph allows $M$ elements to be broadcast in $\lceil \frac{M}{B} \rceil + \log N$ routing steps under the constraint of one receive operation concurrent with one send operation. This is a strict lower bound for $\frac{M}{B} > 1$[8]. Figure 3 shows an MSBT graph for a 3-cube labelled by the function $f$ defined above.

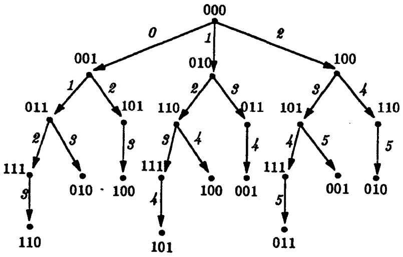

**Figure 3:** Routing in an MSBT graph with communication on one port at a time.

For communication restricted to one send *or* one receive operation per node, we can transform each previously defined cycle into two cycles. Notice that in the previous routing algorithm, all the communication links are used in only one direction during the first $n$ routing steps, and in the last routing step. Hence the MSBT graph allows $M$ elements to be broadcast in $2\lceil \frac{M}{B} \rceil + \log N - 1$ routing steps under the constraint of at most one receive or one send operation during each step. This is a strict lower bound for $\frac{M}{B} > 1$[8].

With a maximum packet size of $B$ and one receive operation concurrent with a send operation the communication complexity for MSBT-based broadcasting is $T = (\lceil \frac{M}{B} \rceil + \log N)(\tau + Bt_c)$, which is minimized for $B_{opt} = \sqrt{\frac{M\tau}{t_c \log N}}$. $T_{min} = (\sqrt{Mt_c} + \sqrt{\tau \log N})^2$. Restricting the communication to one send *or* one receive operation at a time, $T = (2\lceil \frac{M}{B} \rceil + \log N - 1)(\tau + Bt_c)$ and $T_{min} = (\sqrt{2Mt_c} + \sqrt{\tau(\log N - 1)})^2$.

For the case in which communication on all ports can take place concurrently the communication complexity is $T = (\lceil \frac{M}{B \log N} \rceil + \log N)(\tau + Bt_c)$. With optimal packet size $B_{opt} = \frac{1}{\log N}\sqrt{\frac{M\tau}{t_c}}$, $T_{min} = (\sqrt{\frac{Mt_c}{\log N}} + \sqrt{\tau \log N})^2$.

### 3.4. Comparison and Conclusion

In the following, we also compare the MSBT algorithm with the one based on a Two-rooted Complete Binary Tree (TCBT) [2] or a Hamiltonian Path (HP) as a broadcasting tree respectively. Table 1 shows the propagation delay of various algorithms. Interestingly, broadcasting through a Hamiltonian Path on a hypercube may be faster than broadcasting based on the SBT or even the TCBT, depending on the values of $M$, $t_c$, $\tau$ and $N$. With communication on all the ports concurrently, the MSBT-based algorithm can send out $\log N$ distinct packets every cycle while the SBT- and TCBT-based algorithms can only send out one distinct packet every cycle. Table 2 compares the number of cycles per distinct packet for various algorithms. Some variations exist, such as using two Hamiltonian paths with opposite directions sending distinct data, or using one Hamiltonian path such that the source node is at the center of the path. However, these variations only affect (either increase or decrease) delays, and the number of cycles per packet, by at most a factor of two.

The complexity estimates are summarized in Table 3. A potential for concurrent communication on all ports reduces the number of sequential start-ups and the bandwidth requirement by a factor of approximately $\log N$ for an arbitrary packet size in both SBT- and MSBT-based broadcasting. TCBT-based broadcasting does not fully utilize the bandwidth of a cube. The reduction in communication complexity for concur-

| Algorithm | 1 $s$ or $r$ | 1 $s$ and $r$ | all ports |

**Table 4:** Communication complexity compared to the MSBT routing.

rent communication on all ports is a factor of 2 or 3. Optimizing the packet size for each situation brings the number of start-ups to $O(\log N)$, irrespective of whether communication on one port or $\log N$ ports at a time is possible.

The MSBT-based broadcasting always offers a reduction in the bandwidth requirement for individual communication links by a factor of approximately $\log N$ over SBT-based broadcasting. With communication on all ports concurrently, the MSBT-based broadcasting has a communication complexity that is lower than that of TCBT-based broadcasting by a factor of $\log N$. Even with communication only on one port at a time, MSBT-based broadcasting still is faster than TCBT-based broadcasting by a factor of 1.5 or 2. The communication complexities of broadcasting based on the SBT and the TCBT are compared with that based on the MSBT in Table 4.[5]

## 4. Personalized Communication

In personalized communication no replication of information takes place during distribution, nor is there any reduction during the reverse operation. In broadcasting, the bandwidth requirement grows with the distance $i$ from the source node precisely as the number of nodes grow. In personalized communication the bandwidth requirement instead decreases in proportion to the number of nodes less than or equal to distance $i$ from the source. The root is the "bottleneck" in personalized communication. In this section we define a pruning strategy for the MSBT graph that generates a *balanced spanning tree* (BST) of height $\log N$. If concurrent communication on all $\log N$ ports (of the root) is possible, then a lower bound for the transmission time is $\frac{N}{\log N}Mt_c$, and a lower bound for the number of start-ups is $\log N$. The BST makes possible personalized communication in a time corresponding to this lower bound.

### 4.1. A Balanced Spanning Tree

In the SBT topology a node $i$ belongs to the $j^{th}$ subtree iff $a_j = 1, a_k = 0, k < j$. In the MSBT graph a node is an internal node of the $j^{th}$ ERSBT if $a_j = 1$. Bit $j$ can be considered as a *base* for $j^{th}$ subtree. For the BST we define the base as follows:

Let $J_i = \{j_1, j_2, \ldots, j_m\}$, where $j_1 < j_2 < \ldots j_m$, $R^u(i) = R^v(i)$, $u, v \in J_i$, and $R^u(i) < R^l(i)$, $u \in J_i$, $l \notin J_i$. $|J_i| = n/P_i$ where $P_i$ is the period of $i$. Then $base(i) = j_1$ and node $i$ is assigned to subtree $j_1$, i.e., the value of the base equals the minimum number of right rotations such that the rotated number has a minimum value among all the rotated values.[6] For example, $base((011010)) = 3$ and $base((110110)) = 1$. The period of (011010) is 6 and the period of (110110) is 3. For ease of notation we omit the subscript on $j$ in the following. For the definition of the *parent* and *children* functions we first find the position $k$ of the first bit cyclically to the right of bit $j$ that is equal to 1, i.e., $a_k = 1$, and $a_m = 0, \forall m \in \mathcal{M}_{MSBT}(i,j)$, ($k = j$, if every bit but $j$ is 0). For $i = 0$, $k = -1$. Then

$$parent_{BST}(i,0) = \begin{cases} \phi, & \text{if } i = 0; \\ (a_{n-1}a_{n-2}...\overline{a}_k...a_0), & \text{otherwise.} \end{cases}$$

$$children_{BST}(i,0) = \begin{cases} \{(a_{n-1}a_{n-2}...\overline{a}_m...a_0)\}, \forall m \in \{0,1,\ldots,n-1\}, & \text{if } i = 0; \\ \{q_m = (a_{n-1}a_{n-2}...\overline{a}_m...a_0)\}, & \\ \quad \forall m \in \mathcal{M}_{MSBT}(i,j) \text{ and } base(q_m) = base(i), & \text{if } i \neq 0. \end{cases}$$

[5] Notice that the entry for the last column and the last row in the table is based on the assumption that $B = B_{opt}, \tau \log^2 N \ll Mt_c$.

[6] The notion of *base* is similar to the idea of distinguished node used in [15] in that *base* = 0 distinguishes a node from a generator set (necklace).

The $parent_{BST}$ function preserves the base, since for any node $i$ with base $j$, $a_k$ is the highest order bit of $R^j(i)$. Complementing this bit cannot change the base. It is also readily seen that the $parent_{BST}$ and $children_{BST}$ functions are consistent.

Figure 4 shows the spanning tree generated by the algorithm above for the root located at node 0 in a 5-cube.

For an arbitrary source node $s$ we translate the BST rooted at node 0 to node $s$ by performing for each node the bit-wise exclusive-or function of its address and the address of the source node. The base of a node is determined from $c = i \oplus s$, and the children and parent functions are readily modified.

Let $J_{i,s} = \{j_1, j_2, \ldots, j_m\}$, where $j_1 < j_2 < \ldots j_m$, $R^u(c) = R^v(c)$, $u, v \in J_{i,s}$, and $R^u(c) < R^l(c)$, $u \in J_{i,s}$, $l \notin J_{i,s}$. Then $base(c) = j_1$. Then $k$ is defined by $c_k = 1$ and $c_m = 0, \forall m \in \mathcal{M}_{MSBT}(i \oplus s, j)$ with $k = -1$ if $c = 0$.

$$parent_{BST}(i,s) =$$
$$\begin{cases} \phi, & \text{if } c = 0; \\ (a_{n-1}a_{n-2}\ldots\overline{a}_k\ldots a_0), & \text{otherwise.} \end{cases}$$

$$children_{BST}(i,s) =$$
$$\begin{cases} \{(a_{n-1}a_{n-2}\ldots\overline{a}_m\ldots a_0)\}, \forall m \in \{0,1,\ldots,n-1\}, & \text{if } c = 0; \\ \{q_m = (a_{n-1}a_{n-2}\ldots\overline{a}_m\ldots a_0)\}, & \\ \quad \forall m \in \mathcal{M}_{MSBT}(i \oplus s, j) & \\ \quad \text{and } base(q_m \oplus s) = base(i \oplus s), & \text{if } c \neq 0. \end{cases}$$

**Lemma 4.1.** *The number of nodes in a subtree is of order* $O(\frac{N}{\log N})$.

*Proof.* With $A$ cyclic nodes there are at least $(N - A)/\log N$ nodes in a subtree. Denoting the number of generator sets for cyclic nodes by $B$ it follows that the maximum number of nodes in a subtree is $(N-A)/\log N + B - 1$. To derive bounds on $A$ we use the complex plane diagram used by Hoey and Leiserson [9] in studying the shuffle-exchange network. Leighton[15] shows that $B = O(\sqrt{N})$.

Full necklaces, i.e., non-cyclic nodes, are mapped to circles. Degenerate necklaces, i.e., cyclic nodes, are mapped to the origin. In the context of the shuffle-exchange graph each node that is mapped to the origin of the complex plane is adjacent (via an exchange edge) to a node at position (1,0) or (−1,0). Hence, for every full necklace of $\log N$ nodes there are at most 2 cyclic nodes. Node 0 is adjacent to a node of a full necklace, and so is node $N - 1$ (for $\log N > 2$). It follows that an upper bound on $A$ is $2\frac{N-\log N}{2+\log N}$ and the number of nodes in a subtree is at least $\frac{N+2}{2+\log N}$. The relative difference in the number of nodes in the maximum and minimum subtrees approaches 0 for $N \rightarrow \infty$. ∎

**Table 5:** A Comparison of maximum subtree sizes of the Balanced Spanning Tree and values of $(N-1)/\log N$.

Table 5 gives the sizes of the maximum subtrees generated according to the definition of the BST for up to 20-dimensional cubes. The relative difference approaches 0 rapidly. The last column contains the ratio of BST(max) to $(N-1)/\log N$.

Some properties of the BST are listed below. For detailed proofs see [8].

1. The height of one subtree is $\log N$, and the height of all other subtrees is $\log N - 1$.
2. The maximum fanout of any node at level $i$ in a BST is $\lceil\frac{\log N - i}{2}\rceil$ for $1 \leq i \leq logN$.
3. Let $\phi(i,j)$ be the number of nodes at distance $j$ from node $i$ in the subtree rooted at node $i$. Then, $\phi(i,j) \geq \phi(k,j)$ where node $k$ is a child of node $i$.[7]
4. Excluding node $i \oplus s = (11\ldots1)$, all the subtrees of the BST are isomorphic if $\log N$ is a prime number.
5. Subtrees $P$ to $\log N - 1$ contain no cyclic nodes with period $P$.
6. Any cyclic node is a leaf node of the BST.

## 4.2. The Complexity of Personalized Communication Based on the SBT and BST Topologies

### 4.2.1. Spanning Binomial Trees

For SBT-based distribution restricted to communication on one port at a time, the communication complexity for a maximum packet size of $B$ is $T \simeq (N-1)Mt_c + \tau(NM/B + \log\lceil\frac{B}{M}\rceil - 1)$, $M \leq B \leq NM/2$, which is minimized for $B = NM/2$ yielding $T = (N-1)Mt_c + \tau \log N$. For $B \leq M$, $T \simeq (NM/B - 1)(Bt_c + \tau)$. There exist several algorithms of this complexity. One such algorithm sends the cumulative data for the largest subtree to the root of this subtree first. Both nodes then recursively execute the same algorithm in their own $(n-1)$-subcube.

**Lemma 4.2.** *In distributing data from the root in a level-by-level order starting from level* $\log N$, *the time to complete the*

[7] This property is required in deriving the communication complexity for the BST routing.

*distribution is determined by the root, which terminates the distribution in a time proportional to the lower bound for a sufficiently large packet size.*

*Proof.* With potential concurrent communication on $\log N$ ports, the root can send data for level $\log N - i$ during step $i$, $0 \leq i \leq \log N - 1$, assuming a sufficiently large packet size. The amount of data sent from the root during step $i$ to the largest subtree is $\binom{\log N-1}{i}M$. The amount of data sent during the same step from the node at level $j$ to its largest subtree, which is the largest subtree at that level, is $\binom{\log N-1-j}{i-j}M$, where $1 \leq j \leq \log N - 1$. Since $\binom{\log N-1}{i} \geq \binom{\log N-1-j}{i-j}$ for all $i, j \geq 1$, and any other subtree rooted at level $j$ is isomorphic to a subgraph of the highest subtree rooted at level $j$, the transfer time is determined by the transfer time of the root. For a sufficiently large packet size, i.e., $B \geq \binom{\log N-1}{\frac{\log N-1}{2}}M \approx \frac{NM}{\sqrt{2\pi(\log N-1)}}$, $T_{min} = N/2Mt_c + \log N\tau$.

∎

With a potential for concurrent communication on $\log N$ ports, a reduction in the transfer time by a factor of 2 is possible compared to communication on one port at a time. We conclude that for SBT-based algorithms the packet size is of greater importance than concurrent communication on all ports.

### 4.2.2. Balanced Spanning Trees

With BST-based personalized communication restricted to one port at a time the root can send data to the subtrees cyclically. With a maximum packet size $B > M$, data for several nodes can be merged into one packet. The receiving node has sufficient time to retransmit pieces on all its ports, should that be required, since a new packet only arrives every $\log N$ cycles. The root requires a time of $T \simeq \frac{(N-1)M}{B\log N}(\tau + Bt_c)\log N$, which, if the data to the most remote nodes is transmitted first, is also the time to completion. For $B = M$, $T = (N-1)(\tau + Mt_c)$, i.e., the same as in the SBT algorithm. For $B \geq \frac{N}{\log N}M$ the root of the BST need only perform one communication per subtree, and it completes the communication in a time of $T = \tau\log N + (N-1)Mt_c$. But, unlike the SBT algorithm, the communication is not terminated when the root is done. The message to the last visited subtree needs to traverse $\log N - 2$ communication links. The bandwidth requirement of each subtree can be shown to be $\approx \frac{2N\log\log N}{\log N}$ (see [8] for detailed proof). An upper bound on the time for personalized communication based on the BST with unbounded packet size is $T = (2\log N - 2)\tau + N(1 + \frac{2\log\log N}{\log N})Mt_c$. The number of start-ups is almost twice that of the SBT-based personalized communication, and the total transfer time is higher by a lower order term. The time for personalized communication based on the BST is minimized for $B \geq \frac{N}{\log N}M$.

With a potential for communication on $\log N$ ports at a time, the time for personalized communication based on the BST topology is $T \simeq \frac{(N-1)M}{B\log N}(\tau + Bt_c)$ for $B \leq M$ and $T \simeq \sum_{i=1}^{\log N}(\lceil\binom{\log N}{i}\frac{M}{B_i\log N}\rceil + B_it_c)$, $B_i = min(B, \lceil\binom{\log N}{i}\frac{M}{B_i\log N}\rceil)$ for $B > M$. This complexity estimate is valid if data for nodes at distance $i$ are sent during step $\log N - i$, $1 \leq i \leq \log N$. If $B = M$ then $T \simeq \frac{N-1}{\log N}(\tau + Mt_c)$. The communication time is minimized for $B \geq \frac{N}{\log^{3/2} N}M$ by using a *level-by-level* algorithm as in lemma 4.2. By property **p3** of the BST, it follows that the amount of data sent from the root to any subtree during step $i$ is no less than the amount of data sent from any node during the same step. Hence, $T_{min} = \tau\log N + \frac{N-1}{\log N}Mt_c$, the minimum possible.

### 4.3. Comparison and Conclusion

With communication on one port at a time, if the fixed maximum packet size $B \leq M$ holds, then the complexity of SBT- and BST-based personalized communication is the same. For $B > M$, the SBT-based routing algorithm yields a lower complexity than the BST-based routing. For a sufficiently large maximum packet size the SBT-based algorithm has $\log N$ start-ups compared to $2\log N - 2$ start-ups for the BST-based algorithm. The transmission times are comparable, though the transmission time for the BST routing is higher. Note that, as in broadcasting, the minimum number of start-ups can be accomplished for sufficiently large maximum packet size.

With concurrent communication on $\log N$ ports the number of start-ups and the transmission time of BST-based routing is lower than that for the SBT by a factor of $\frac{1}{2}\log N$ for a maximum packet size $B \leq M$. With a sufficiently large packet size all routings yield a minimum of $\log N$ start-ups, but the BST routing has a total transmission time that is lower than that of SBT by a factor of $\frac{1}{2}\log N$. Moreover, it is achieved at a maximum packet size of $\frac{N}{\log^{3/2} N}M$, compared to a maximum packet size of $\frac{N}{\sqrt{2\pi(\log N-1)}}M$ for the SBT routing. We conclude that if communication can be performed on all $\log N$ ports concurrently, the communication complexity of the BST routing may be lower by a factor of $\frac{1}{2}\log N$ compared to the SBT routing. Table 6 lists the communication complexity for optimal packet size. The timing for TCBT routing is also included for easy comparison. See [8] for detailed analysis.

| Algorithm | $T_{min}$ |
|---|---|
| SBT, 1 port | $(N-1)Mt_c + \log N\tau$ |
| SBT, $\log N$ ports | $N/2Mt_c + \log N\tau$ |
| TCBT, 1 port | $\leq (2N - 2\log N - 1)Mt_c + (2\log N - 2)\tau$ |
| TCBT, $logN$ port | $(\frac{3}{4}N - 1)Mt_c + \log N\tau$ |
| BST, 1 port | $\leq N(1 + \frac{2\log\log N}{\log N})Mt_c + (2\log N - 2)\tau$ |
| BST, $\log N$ ports | $\simeq (N-1)/\log NMt_c + \log N\tau$ |

**Table 6:** Communication complexity of personalized communication.

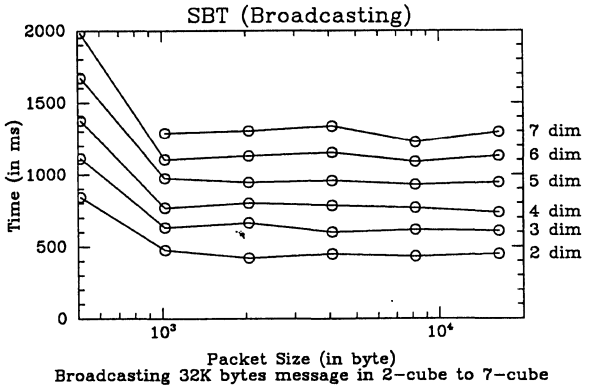
## 5. Experimental Results

### 5.1. Single Source Broadcasting Based on the SBT and MSBT

Figure 5 shows the measured time to completion of a broadcasting operation based on the SBT topology for cubes of various dimensions and a number of different external packet sizes. As expected, the communication time increases almost linearly for external packet sizes below $1k$ bytes. Figure 6 shows the measured time of SBT- and MSBT-based broadcasting for a message of $60k$ bytes with each packet being $1k$ bytes and for cube dimensions ranging from 2 to 6. Figure 7 shows the speed-up of broadcasting based on the MSBT topology over the SBT topology. The measured speed-up is approximately $\log N$, as predicted.

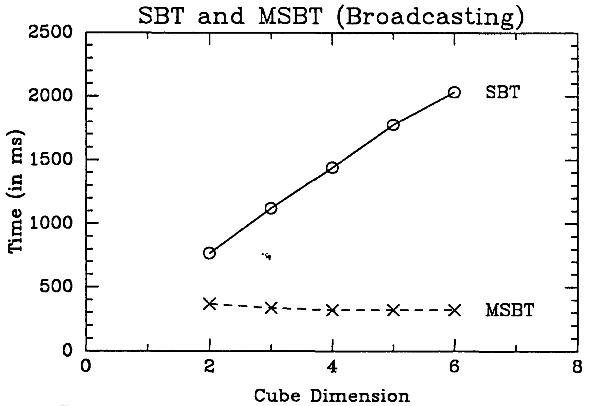
### 5.2. Single Source Personalized Communication

In implementing the SBT routing on the Intel *iPSC*, the root processes the data in descending order starting with the relative address $N - 1$. This order implies that data is transmitted over ports in an order corresponding to the transition sequence in a binary-reflected Gray code[17]. Hence, port 0 is



Broadcasting 32K bytes message in 2–cube to 7–cube

**Figure 5:** Broadcasting using SBT.



Broadcasting 60K bytes message in 2–cube to 6–cube

**Figure 6:** Broadcasting using SBT and MSBT.

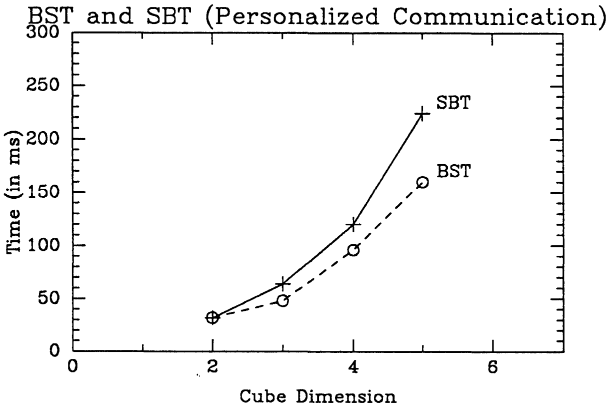
packet size = 1 K, solid line = measured speed–up
dashed line means "speed–up = logN"

**Figure 7:** Speed up of MSBT vs. SBT.



message size = 1 K bytes per node

**Figure 8:** Personalized communication using BST and SBT.

used every other cycle, port 1 every fourth cycle, etc. Internal nodes retransmit a message on a port chosen from among the ones that correspond to the leading zeroes in its relative address. The choice is made according to a binary-reflected Gray code on the leading zeroes.

For the implementation of the BST-based algorithm the routing order needs to be determined for each subtree of the root. Excluding cyclic nodes, the subtrees are isomorphic. The root only needs to keep one table of length $\approx \frac{N}{\log N}$ with each entry of size $\log N$ bits. The order of the entries corresponds to the transmission order for each port. The table entry points to the messages transmitted over port 0. The pointers for the other ports are simply obtained by (right) cyclic shifts of the table entries. The cyclic nodes can be handled by finding the period $P$ for each cyclic table entry, and not transmitting the message corresponding to this table entry for ports with index $j \geq P$.

For each subtree a depth-first or a reversed breadth-first order are viable transmission orders. With reversed breadth-first order we mean a breadth-first traversal of the subtree starting from the last level ($\log N - 1$ or $\log N - 2$ depending on subtree). The source node determines the order, and internal nodes can either route according to the destination address if it is included, or by the use of tables. If tables are used, then in the case of depth-first communication order it suffices for each internal node to keep a count for each port. Since the number of ports used in each subtree is at most $\frac{\log N}{2}$, and the number of nodes in the entire subtree is approximately $\frac{N}{\log N}$, a bound on the table size in each node is $\log^2 N$ bits. A breadth-first communication order can be implemented by internal nodes keeping a table of how many nodes there are at a given level in each of its subtrees. The table has at most $\log^2 N$ entries. An upper bound for the number of nodes in a subtree at any level is $\frac{N}{\log^{3/2} N}$, and the total table size in a node is approximately $\log^3 N$ bits. Hence, without a more sophisticated encoding the depth-first communication order is more effective with respect to table space. The measurements presented in Figure 8 are based on an implementation using a depth first order.

With communication on one port at a time the expected time for personalized communication based on the SBT topology or the BST topology is the same. The observed advantage of the BST- over the SBT-based communication is due to the fact that the BST can take better advantage of the overlap between communication on different ports. In the SBT case, the node with relative address (00...01) is not yet finished retransmitting the last packet received when a new packet arrives. In the BST a subtree receives a packet once every $\log N$ cycles, and full advantage of the 20% overlap in communications actions is taken.

## 6. Conclusion

We have shown that the Boolean $n$-cube topology allows for the embedding of $n$ edge-disjoint binomial trees, and we presented routing algorithms for broadcasting that have a complexity equal to the lower bound both for communication restricted to one port at a time and for concurrent communication on all $n$ ports of a node. We have also defined a balanced spanning tree for personalized communication. Each subtree of the balanced spanning tree we have defined has approximately $\frac{N}{\log N}$ nodes. For communication on one port at a time, personalized communication based on the balanced spanning tree has the same complexity as personalized communication based on a binomial tree for certain maximum packet sizes, and has at most a factor of 2 higher complexity in other cases. With concurrent communication on all ports, the routing based on the balanced spanning tree is superior by a factor of $\frac{1}{2} \log N$ for a variety of combinations of maximum packet sizes, start-up times, transfer rates, and data sizes.

Experimental results on the Intel *iPSC/d7* confirm the results of the analysis.

# The Architecture of a Homogeneous Vector Supercomputer

John L. Gustafson, Stuart Hawkinson, and Ken Scott

Floating Point Systems, Inc.
Beaverton, Oregon, 97005

## Abstract

A new homogeneous computer architecture developed by FPS combines two fundamental techniques for high-speed computing: parallelism based on the binary *n*-cube interconnect, and pipelined vector arithmetic. The design makes extensive use of VLSI technology, resulting in a processing node that can be economically replicated. Processor nodes incorporate high-speed communications and control, vector-oriented floating-point arithmetic, and a novel dual-ported memory design. Each node is implemented on a single circuit board and can perform 64-bit floating-point arithmetic at a peak speed of 16 MFLOPS. Eight nodes are grouped together with a system node and disk support to form modules. These modules, housed in cabinet-sized packages, are capable of 128 MFLOPS peak performance and make up the smallest homogeneous units of larger systems. The new FPS system achieves a careful balance between high-speed communication and floating-point computation. This paper describes the new architecture in detail and explores some of the issues in developing effective software.

## Introduction

The quest for increased computational power in scientific computing and the limits of physical electronic devices have lead to the exploration of new architectures as alternatives to traditional monolithic designs [9,2]. *Multiprocessor* designs hold the promise of tremendous performance increases, provided the interconnection network can support the parallelism inherent in the computation. *Vector pipelines* provide significant performance increments, exploiting finer grained parallelism. Further advantage is gained by using *parallel functional units* to overlap address calculations with memory references, floating-point adds, and floating-point multiplies [1].

Large scientific applications are sometimes easily partitioned among processors using a shared memory, yet most are just as amenable to distributed memory designs [3,4]. Shared memory systems are expensive when scaled to large dimensions because of the rapid growth of the interconnection network; the distance from memory to the processing elements also degrades performance by increasing latency [8]. Large system configurations are most readily realized with distributed memory based on a limited form of interconnection, such as the pyramid or binary *n*-cube [5]. Memory latency can be greatly reduced when each processor has its own high-speed store. Moreover, the cost of switching and the time to route messages is much smaller on such statically configured systems. With this view, much current computer architecture research has focused on the use of ensembles of identical processors in homogeneous configurations that employ message passing over limited forms of static interconnects [7,8].

Floating Point Systems (FPS) has developed a *homogeneous computer*, the FPS T Series, based on the *binary n-cube interconnection* scheme. The individual nodes are 64-bit floating-point computers that combine vector arithmetic, dual-port memory, and fast communications links between nodes. The peak performance of these nodes is 16 MFLOPS. The FPS T Series is built from modules containing eight of these nodes connected to each other and to a system support ring. These modules, with an aggregate performance of 128 MFLOPS, may be combined to form even larger systems that promise orders of magnitude increases in computing speed per dollar over today's supercomputers.

## Processor Node Architecture

An individual processor element is called a *node*. It contains a control processor, floating-point arithmetic, dual-port memory, and communication links to other nodes. The FPS T Series design provides all of these functions on a single printed-circuit board. Each of the major elements of the node has been implemented with advanced, cost-effective VLSI technology, in contrast with more traditional bit-slice designs.

### Control

The ability to interpret and execute programs resides in the central control unit. The T Series control unit is a 32-bit CMOS microprocessor with the following functional features:

- 7.5 MIPS instruction rate
- Byte addressability (4 GByte address space)
- 2048 bytes of on-chip RAM (single processor cycle)
- 3-cycle minimum access time for off-chip memory
- Four bidirectional serial communications links
- Stack-oriented instruction set with variable operand sizes
- Two-level process priority and interrupt services

The control processor executes system and user applications code and it also serves to arrange vector operands to be sent to the vector arithmetic hardware. The control processor can execute integer arithmetic and gather/scatter operations in parallel with the vector unit, and it provides inter-node communications via the serial links.

0190-3918/86/0000/0649 $01.00 © 1986 IEEE

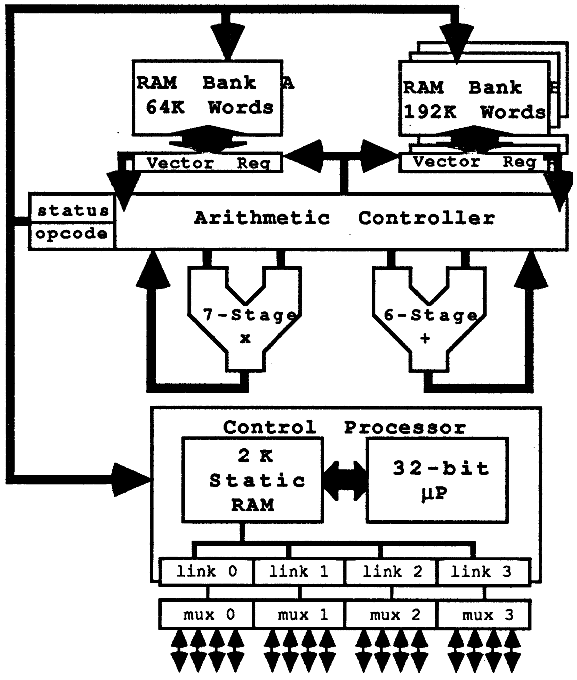

Figure 1. The FPS T Series processor.

All features of the microprocessor are directly accessed through a high-level language called *Occam*. Occam differs from languages like Pascal or C in that it directly provides for the execution of parallel, communicating processes, Channel commands can make direct data transfers between concurrent processes. A single process can be constructed from a collection by specifying *sequential*, *alternative*, or *parallel* execution of the constituent processes. This combination of program structure and integrated communication allows Occam to describe the control and data flow for virtually any scientific computing algorithm, and to control the high-level operation of the vector arithmetic unit (see below).

## Memory

An essential feature of a computer's architecture is its central memory, which supplies both instructions and operands to the processing units. The main memory of each FPS T Series node consists of 1 MByte of dual-ported dynamic RAM. The control processor and communications links read and write 32-bit words through a conventional random-access port, while the vector arithmetic unit makes use of a collection of *vector registers* closely coupled with main memory. A vector register can be loaded with an entire 1024-byte row of memory, in parallel (see Figure 1), in the same time that it would have taken to read or write a single 32-bit word. There is one parity bit for each byte in memory.

The control processor views the memory as a single bank of 256K words (32-bit). The vector arithmetic unit views memory as two banks of vectors, with 256 vectors in one bank and 768 vectors in the other, aligned on 1024-byte boundaries. Thus, for 32-bit operations, the vectors are 256 elements long, while for 64-bit operations, the vectors are 128 elements in length. The division of memory into two banks permits two inputs in parallel to the arithmetic unit on each cycle (125 ns). The output of the arithmetic unit shifts results into either or both banks. Hence, operations such as SAXPY, Vector Add, and Vector Multiply proceed at the full speed of the arithmetic components, without being limited by available memory bandwidth. This dual-bank memory organization allows the node to function without the need for auxiliary data registers or cache.

The control processor can access a 4-byte word in 400 ns. Its effective bandwidth is therefore

$$(4 \text{ bytes}) / (0.4\ \mu\text{s}) = 10 \text{ MB/s}$$

A primary use for the control processor is to gather operands into a contiguous vector, and scatter results back to random locations in memory. To move a 64-bit operand from one memory location to another requires two 32-bit reads and two 32-bit writes, which take a total of 1.6 µs. This is the gather-scatter time within a node. For 32-bit operands, it is 0.8 µs per element.

An entire row of data can be moved to or from a vector register in only 400 ns; this means that the effective bandwidth between memory and a vector register is

$$(1024 \text{ bytes}) / (0.4\ \mu\text{s}) = 2560 \text{ MB/s}$$

An application might make use of this extraordinary speed by moving data physically, rather than keeping linked lists of pointers to vectors, as for example, in pivoting rows of a matrix or sorting records.

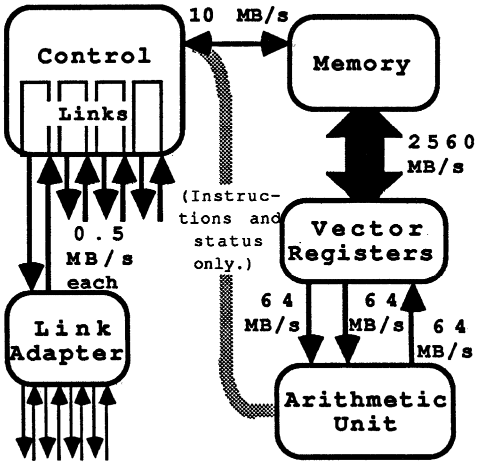

Figure 2. Processor bandwidths.

The vector registers each supply data to the arithmetic unit at a maximum rate of one 32-bit word every 62.5 ns, or one 64-bit word every 125 ns. The vector register bandwidth supports two vector inputs and one vector output every 125 ns in 64-bit mode. Thus, its bandwidth is

(3 words)x(8 bytes/word)/(0.125 μs) = 192 MB/s.

## Arithmetic

The ability to perform high-speed arithmetic is essential in scientific computing. The arithmetic hardware in the FPS T Series consists of a floating-point adder, floating-point multiplier, interconnection hardware, and some sequencing hardware. The adder and multiplier each can produce a 32- or 64-bit result every 125 ns, yielding peak performance of 16 MFLOPS per node. Floating-point operations are performed using the proposed IEEE floating-point standard format; however, gradual underflow is not supported. In 64-bit mode, the mantissa has approximately 15 decimal digits of precision and a dynamic range of roughly $10^{-308}$ to $10^{+308}$.

The arithmetic units operate in pipelined mode. The adder has a six-stage pipeline. It can perform floating-point addition and subtraction in 32- and 64-bit modes, comparisons and data conversions. The multiplier is five-stage in 32-bit mode and seven-stage in 64-bit mode. These pipeline lengths are appropriate for the vector access described above. Scalar operations can be efficiently performed by grouping like operations for level-order evaluation.

The arithmetic parts are supervised by a preprogrammed micro-sequencer, that implements a collection of vector arithmetic operations referred to as *vector forms*. The programmer only needs to describe the input and output vectors and the vector form desired. This frees the control processor for other tasks while vector operations are being executed. Scalars can be held in the input registers on each floating-point part, and outputs from the parts can be fed directly back as inputs to perform operations such as dot products and sums. This provides a wide range of useful vector forms without memory reference limitations. The complete arithmetic unit operates in parallel with the node control processor. The arithmetic unit only interrupts the controller when a vector operation has completed, or an error has occured.

## Communications

In a distributed computer system, communications channels are required for passing data between processors participating in a common computational process. The control processor of the FPS T Series contains drivers for four serial, bidirectional communications links each with a nomi- nal rate of 0.9375 Mbyte/s. Every 8-bit byte is sent with two synchronization bits and one stop bit, and requires two acknowledge bits from the receiver. This results in a maximum effective unidirectional bandwidth of over 0.5 MB/s per link. The total bandwidth of the four links is thus over 4 MB/s. With all links operating, the control processor performance is degraded only slightly. The links operate via DMA transfers with a startup time of about 5 μs.

Each link is multiplexed four ways to provide a total of 16 bidirectional sublinks per node. With software support, these sublinks divide the available bandwidth. Two sublinks are used for system communication, and two will often be utilized for mass storage and/or external I/O. This will typically leave 12 sublinks available for connection to other compute nodes.

A convenient way to interpret the relative bandwidths is with respect to the arithmetic processing time for 64-bit operations:

(ArithmeticTime):(GatherTime):(LinkTransferTime)
.125 μs          1.6 μs          16 μs

that are in the approximate ratios 1 : 13 : 130. Thus, a vector should enter into about 13 operations while gathering the next vector into an aligned, contiguous order. With this provision, the control processor can completely overlap the gather time with vector arithmetic, and the node can approach peak speed. Of course, if vectors are always aligned and elements contiguous, no such restriction applies. Similarly, roughly 100 operations should result from every 64-bit word that must be moved between nodes over a link.

## System Description

The T Series consists of a number of node processors connected as a binary *n*-cube. There are $2^n$ processors, with *n* connections per node. Numbering the processors from 0 to $2^{n-1}$, each processor is directly connected to all others whose numbers differ in only one binary digit. The binary *n*-cube can be mapped onto many important applications topologies, including meshes (up to dimension *n*), rings, cylinders, toroids, and even FFT butterfly connections of radix 2 [5,6]. Since the maximum number of connections between any two processors is *n*, long-range communication costs grow only as $O(\log_2 n)$.

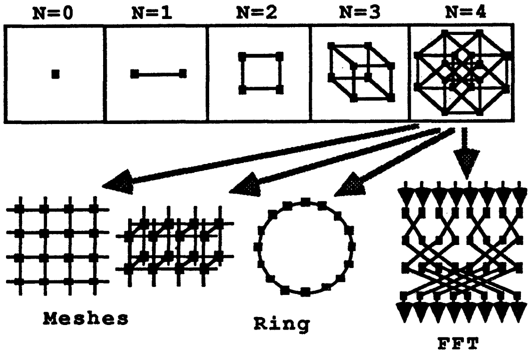

Figure 3. Binary *n*-Cube Mappings.

## Modules and System Ring

A processor node is constructed on a single etched circuit board. Eight nodes are combined with disk storage and a system board to form a *module*. Such a module has 128 MFLOPS peak floating-point performance, and 8 MB of user RAM. The local inter-node communications bandwidth is over 12 MB/s, while the system board can support 0.5 MB/s to an external connection.

The system board provides input/output and management functions. It is connected to the nodes by a thread of communications links that traverses the eight processor nodes. The system boards are directly connected by communications links to form a ***system ring*** that is independent of the binary *n*-cube network (connecting the processor nodes). The primary function of the system disk is to record memory "snapshots" which checkpoint computations for error recovery, and to backup snapshots from other modules. The user is able to specify the interval between snapshots. About 10 minutes provides a good compromise between time spent to record memory and interval between restart points. It takes about 15 seconds to take a snapshot, regardless of configuration.

The module requires three links for intramodule hypercube network communications, while the system board connections require two links from each processor node. This reduces remaining links to 11 for hypercube and external communications.

Two modules (16 nodes) form a *cabinet*, or 4-cube (a tesseract). A cabinet is modular and self-contained in a standard 19-inch rack-mounted assembly. With power supplies, system disks, and air cooling fans, it does not require any special "computer room" facilities. Larger systems are simply assembled from these units by interconnecting cables. Connections up to 40 feet can be made without special consideration.

## Larger Configurations

A four-cabinet (64-node) system has an aggregate peak speed of 1 GFLOP and total user memory of 64 MBytes. Eight system-disk units provide backup and restart capability. This configuration of the FPS T Series can be located in many laboratory and computing facilities. The air-cooled unit requires no special facilities beyond normal air conditioning, and the power requirements are supplied by typical 220 VAC services.

There are enough links per node to permit a 14-cube to be constructed as the largest T Series configuration. Using two links per node for external I/O and mass storage systems, a maximum-sized 12-cube consists of 4096 nodes arranged as 256 cabinets (4-cubes). Such a system has over 65 GFLOPS peak processing performance and 4 GBytes of primary RAM storage. Special facilities would be required to house the largest configurations.

Because the system is homogeneous, i.e., each module is identical and contains identical connections to other modules, programming is greatly simplified. This homogeneity also insures that the balance between computing speed, main storage, mass storage, and external I/O can be preserved as configurations become large. The specifications of any sized FPS T Series can be derived from the properties of the individual modules.

## Conclusion

The incorporation of high-speed vector processing into a homogeneous parallel architecture has resulted in a scientific computer with performance scalable over three orders of magnitude. The use of a dual-ported dynamic RAM achieves a new level of processor integration that eliminates the need for separate data registers or cache. Parallel floating-point adders and multipliers, accessed by standard vector operations, provide a close match to scientific computing algorithms.

With nodes organized into eight-processor modules, each with system disk and I/O services, the new architecture can be viewed as a truly homogeneous system. The FPS T Series, incorporating VLSI components to make the system both cost-effective and compact, provides a careful balance between processor speed, memory access, and interprocessor communications bandwidth.

**Abstract:** The implementation of massively parallel computers based on hypercube architectures is discussed in this paper. It is argued that such machines offer an alternative to traditional supercomputers at far lower cost. The rationale for using hypercube machines for supercomputing applications is examined, including cost, node performance, communication speed, packaging, reliability, and programming requirements. These issues are illustrated by a recently introduced commercial hypercube supercomputer, the NCUBE/ten. The major design decisions underlying the NCUBE/ten's implementation technology, system architecture and operating system are described.

## 1. Introduction

A hypercube or (binary) $n$-cube computer is a multiprocessor characterized by the presence of $N = 2^n$ processors interconnected as an $n$-dimensional binary cube. Each processor $P_i$ forms a node (vertex) of the cube and is a self-contained computer with its own CPU and local main memory. $P_i$ has direct communication paths to $n$ other processors (its neighbors), which correspond to the edges of the cube that are connected directly to $P_i$. $2^n$ distinct $n$-bit binary addresses or labels may be assigned to the processors so that each processor's address differs from that of each of its $n$ neighbors in exactly one bit position. Figure 1 illustrates the hypercube topology for $n < 4$; note that a zero-dimensional hypercube is a conventional SISD computer. An $n$-dimensional hypercube $Q_n$ for $n \geq 2$ can be defined recursively in terms of the graph product operation $\times$ as follows [4], where $K_2 = Q_1$ is the complete 2-node graph:

$$Q_n = K_2 \times Q_{n-1}$$

As illustrated by Fig. 1, $Q_n$ is composed of two copies of $Q_{n-1}$. Every node $P_{0x}$ in one copy of $Q_{n-1}$ is the neighbor of a node $P_{1x}$ in the other copy.

For some time, it has been known that the hypercube structure has a number of features which make it a useful architecture for parallel computation. For example, meshes of all dimensions and trees can be embedded into a hypercube so that neighboring nodes are mapped to neighbors in the hypercube. The communication structures used in the Fast Fourier Transform and Bitonic Sort algorithm can similarly be embedded into the hypercube. Since a great many scientific applications use mesh, tree, FFT, or sorting interconnection structures, the hypercube is a good candidate for a general-purpose parallel architecture. Even for problems with less regular communication patterns, the fact that the hypercube has a maximal internode distance (the graph diameter) of $n = \log_2 N$ means any two nodes can communicate fairly rapidly. This diameter is larger than the unit diameter of a complete graph $K_N$, but is achieved with nodes having only degree or fanout of $\log_2 N$, as opposed to the $N - 1$ degree of nodes in $K_N$. Other standard architectures with small degree, such as meshes, trees, or bus systems, either have a large diameter ($N^{1/2}$ for a 2-dimensional mesh) or a resource which becomes a bottleneck in many applications because too much communication must pass through it (as occurs at the apex of a tree, or at a large shared bus). Thus, from general topological arguments it can be concluded that hypercube architectures offer a good balance between node connectivity, communication diameter, algorithm embeddability, and programming ease. This balance makes them suitable for an unusually wide class of computational problems.

Based on various considerations of the foregoing kind, proposals to build large hypercube computers have been made for more than twenty years. In 1962, Squire and Palais at the University of Michigan, motivated by the hypercube's rich interconnection geometry and programming ease, carried out a detailed paper design of a hypercube computer [13,14]. They estimated that a 4096-node (12-dimensional) version of their machine would require about 20 times as many components as the IBM Stretch, one of the largest and most complex contemporary computers. Around 1975 IMS Associates, an early manufacturer of personal computers, announced a 256-node commercial hypercube based on the Intel 8080 microprocessor, but its design details were not published and the machine was never produced. In 1977, Sullivan et al. presented a thorough analysis of hypercube architectures, and a proposal to build a large hypercube

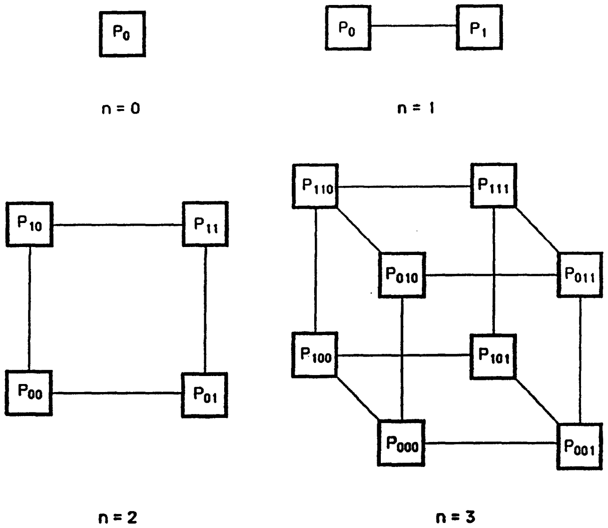

**Fig. 1.** $n$-dimensional hypercube for $n$=0,1,2,3.

0190-3918/86/0000/0653 $01.00 © 1986 IEEE

called CHOPP (Columbia Homogeneous Parallel Processor) containing up to a million processors [15,16]. In the same year, Pease published a study of the "indirect" binary *n*-cube architecture, in which a multistage interconnection network of the omega type is suggested for implementing the hypercube topology [8]. A number of other interesting architectures closely related to the hypercube have also been proposed, for example, the cube-connected-cycles structure [11].

It is clear that the early hypercube designs were impractical because of the the large number of components (logic and memory elements) they required using the then available circuit technologies. The situation began to change rapidly in the early 1980's as advances in VLSI technology allowed powerful 16/32-bit microprocessors to be implemented on a single IC chip, and RAM densities moved into the $10^5$–$10^6$ bits/chip range. A working hypercube computer was not demonstrated until the completion in 1983 of the first 64-node Cosmic Cube at Caltech [12]. For the hypercube node processor, it uses a single-board microcomputer containing the Intel 8086 16-bit microprocessor and the 8087 floating-point co-processor. Since then, Caltech researchers have built several similar hypercubes, and successfully applied them to numerous scientific applications, often obtaining impressive performance improvements over SISD machines of comparable cost [3].

Influenced primarily by the Caltech work, a number of commercial hypercubes have been developed since 1983. In July 1985, Intel delivered the first production hypercube, the 128-node iPSC (Intel Personal Supercomputer) which has a 16-bit 80286/287 CPU as its node processor. Assuming a peak performance of 0.07 MFLOPS per node, the 128-node iPSC has a potential throughput of about 8 MFLOPS, far below that of a traditional vector supercomputer such as the Cray-1 (160 MFLOPS). Other commercial hypercubes were also introduced in 1985 by Ametek Inc. and NCUBE Corp. The Ametek System/14 hypercube can have up to 256 nodes, which employ an 80286/287-based CPU similar to that of the iPSC, with the addition of an 80186 processor for communication management. The NCUBE/ten can accommodate up to 1024 nodes, each based on a VAX-like 32-bit custom processor with a peak performance of 0.5 MFLOPS. Thus a fully configured NCUBE system has a throughput potential of around 500 MFLOPS. This high performance level is supported by extremely fast communication rates (both input/output and node-to-node) making the NCUBE/ten a true supercomputer. NCUBE machines have been installed at several beta test sites, including the University of Michigan, since early 1985, and have been in general production since December 1985. Several other hypercube-style machines with supercomputing potential are presently under development, including the Caltech/JPL Mark III [9] and the Connection Machine [5]. Much faster successors to the current commercial hypercubes can also be expected to appear over the next few years. Because of the effort being devoted to the development of hardware and software for these machines, and their relatively low cost, hypercube supercomputers seem likely to provide an increasingly attractive alternative to conventional pipelined supercomputers for many applications.

This paper explores the architectural and technological issues influencing the design of supercomputing hypercubes, with the NCUBE/ten serving as an example. Particular attention is devoted to the influence of component packaging, reliability, communication speed, and the operating system environment on the system implementation. Section 2 discusses the general design requirements of hypercube supercomputers, while the specific design decisions made for the NCUBE/ten are covered in Sec. 3. Software issues are discussed in Sec. 4.

## 2. General Design Issues

Supercomputing performance requires extremely high integer and floating-point execution rates, as well as extremely high I/O throughput. Very large primary (RAM) and secondary (disk) memory spaces are also usually required. For the principal user base of scientific programmers, the programming environment needs to provide FORTRAN, and a powerful operating system such as UNIX. Low cost and high reliability imply minimizing the component count at all levels, particularly the numbers of chips and boards used. Some degree of fault tolerance is also very desirable. Since a very large amount of RAM storage is needed, memory fault detection and correction via an error-correcting code (ECC) is an important consideration, despite the fact that it increases the chip count. Reliability is increased, and operating cost decreased, by employing an air-cooled configuration suitable for a standard office environment. Based on an examination of various existing computer systems, it can be concluded that the air cooling limits the machine complexity to under 50,000 chips. Off-the-shelf parts decrease costs and usually increase reliability. If custom chips are needed, then computer manufacturers who rely on outside suppliers should use conservative design rules which will be accepted by multiple silicon foundries. In large-scale numerical calculations, the possibility of large error accumulation forces the individual calculations to be as accurate as possible. Numerical accuracy can be increased by adhering to the IEEE 754 floating-point standard and providing double-precision floating-point operations.

A key decision in the design of a parallel computer is the choice of the interconnection network to be used. Multistage interconnection networks have been advocated as simplifying the programming process by providing a global shared memory, but it did not seem possible to build a large multistage network using the technology available in 1983 without suffering significant delay in passing information through the network. Since this strongly affects performance, it was felt that to achieve supercomputer performance it would be necessary to use a direct connection network with local memory at every node. Many direct interconnection schemes have been analyzed and implemented but, as discussed in Sec. 1, the hypercube structure has a number of inherent advantages. The ease with which efficient application programs were developed for the hypercubes at Caltech has also shown the hypercube to be superior to alternative architectures such as meshes or trees. The neighbor-to-neighbor links of the hypercube provide almost the same communication capabilities as a complete graph, while using nodes with only a logarithmic degree. The achievable degree is constrained by a variety of packaging considerations, but with current technology it is possible to build hypercubes with thousands of nodes. In contrast, a complete graph connection of a few tens of nodes may not be possible.

There are additional features of the hypercube that are particularly useful in designing a supercomputer, but have not been previously exploited. For example, the hypercube is homogeneous in that all nodes look the same, hence it is natural to attach an I/O channel to each node. This provides the potential of extremely high system I/O rates. Also, since there are numerous ways to divide a hypercube into subcubes, it is easy to support multiprocessing where each user has a dedicated subcube. These subcubes can be allocated so that all processor-to-processor and I/O communications occur without using processors or communications lines in other subcubes. Further, by writing programs in which the size of the subcube is a user-defined parameter, it is possible to develop programs in small subcubes and then do production runs in larger subcubes. This partitionability also makes it easier to tolerate faults, since the operating system can allocate subcubes which avoid faulty processors or faulty communication lines.

As discussed in Sec. 1, technology developments have enabled a hypercube computer to be built reliably with a large number of processors. A fine-grained supercomputer architecture, i.e., one with a large number (over 1000) of very simple processors, has a high ratio of communication to computation. The Connection Machine is an example of a fine-grained hypercube-class computer, but its suitability for scientific computations is unclear. A very coarse-grained architecture with, say, 10 to 100 large and fast processors, requires that the nodes achieve extremely high performance. For example, to achieve $10^9$ instructions/sec with 10 processors requires processors capable of $10^8$ instructions/sec. The Caltech/JPL Mark III will be an example of a coarse-grained hypercube. It was felt by the designers of this machine that achieving $10^9$ instructions/sec is best done with 1000 processors running at $10^6$ instructions/sec.

Experience with the Caltech machines has demonstrated that a medium-grain MIMD hypercube architecture can attain high efficiency on a variety of scientific problems, with a tolerable amount of revision of serial code and algorithms [3]. This can be contrasted with the much greater amount of program and algorithm redesign required of users of fine-grained SIMD machines such as the MPP [10]. MIMD machines require each node processor to perform instruction fetching, decoding, and other functions that are not performed by SIMD nodes. Distributed-memory MIMD machines must supply a program to each node, so that MIMD machines may pay a large penalty in chip area and chip count. In general, for the same chip area and number of chips one can build more SIMD processors and have a greater potential system throughput; however, the gain in programming simplicity obtained by using an MIMD machine more than compensates for this, except for a narrow range of applications in which almost any penalty can be tolerated if it yields the required speed. Furthermore, MIMD machines can accommodate multiple independent users, while SIMD machines cannot.

Since there may be hundreds or thousands of nodes in a hypercube supercomputer, their chip count is the most significant component of the total system chip count. Using the densest possible memory chips available is the key factor in decreasing the number of chips. The NCUBE/ten, for example, uses 256K DRAM chips to implement the local memories of the hypercube nodes. The next most significant reduction in chip count can be achieved by putting all node functions onto a single chip. This implies that the processor chip must perform all communication, memory management, floating-point operations, and other data-processing functions. Unlike RAMs, there is not yet widespread market pressure to produce standard processor chips of this type, consequently, they are not available off the shelf. In 1983, when design of the NCUBE/ten started, the only way to achieve supercomputer performance with a one-chip node processor was to undertake the risky step of custom-designing such a complex chip. INMOS made a similar decision with the Transputer processor chip, with the important difference that the initial version of the Transputer does not provide floating-point operations, and has four rather than eleven I/O channels [6]. The performance and functionality demands on the NCUBE processor chip are quite severe, and numerous tradeoffs were needed to enable it to be built with current technology.

## 3. NCUBE/ten Architecture

The overall goal of the NCUBE designers was to use massive parallelism to build an inexpensive and reliable range of software-compatible machines achieving supercomputer performance at the high end. The largest model in the series, the NCUBE/ten, is a 10-dimensional hypercube containing 1024 powerful 32-bit processors of custom design, each with a 128-Kbyte local memory. Up to eight front-end host processors are used to manage I/O operations under control of a multiuser UNIX-based operating system. An unusually high level of system integration is employed that allows 64 processors with their memories and interconnections to be placed on a single printed-circuit board. A maximum-sized NCUBE/ten system is composed of 16 processor and 8 I/O boards (including host processors) and is housed in a small air-cooled enclosure.

The NCUBE node processor provides the functions of a 32-bit supermini-class CPU, including a full floating-point instruction set, and all the logic needed for memory management and interprocessor communication on a single VLSI chip; see Fig. 2. The design of the processor was started by NCUBE in 1983, constrained by the desire to use conservative design rules acceptable to several silicon foundries. The chip was designed using 2 $\mu$m (approx.) nMOS design rules, and contains about 160,000 transistors. It is housed in a pin-grid-array package with 68 pins. Combined with six 256K-bit DRAM chips (each of which is organized as 64K x 4 bits), an entire NCUBE/ten node requires only seven chips. Because of this, a 6-dimensional hypercube with 64 nodes and 8 Mbytes of memory can be packed into a single 16″ X 22″ board, a photograph of which appears in Fig. 3. The backplane connections are rather formidable since each node has off-board bidirectional channels to four more processors of the hypercube, plus one bidirectional channel to an I/O board, resulting in 640 backplane connections just for communication channels.

The instruction set of the NCUBE/ten is conventional and quite orthogonal, being similar to the VAX instruction set without the latter's 3-address addressing modes [7]. There are three main classes of information: addresses (unsigned integers), integers and floating-point numbers (reals). Addresses are 32 bits long, but the current node implementation only supports a 17-bit physical address space. Integers can be 8, 16 or 32 bits long. Floating-point numbers can contain either 32 or 64 bits, and conform to the IEEE 754 floating-point standard. There are 16 general-purpose registers of 32 bits each. A variety of addressing modes are available, including literal (immediate), register

direct, autodecrement/increment, autostride, offset, direct, indirect, and push/pop. The instruction set contains a full complement of logical, shift, jump, and arithmetic operations (including square root). One instruction of particular use in hypercube routing is Find First One, which finds the bit position of the first 1 in a word, via a right-to-left scan. Using a 10-MHz clock, nonarithmetic instructions can be executed at about 2 MIPS, with single-precision floating-point operating at 0.5 MFLOPS, and double-precision at 0.3 MFLOPS. (These performance figures assume that register-to-register operations predominate.) A 32-byte instruction cache allows loops of up to 16 bytes to be executed directly from the cache. The node processor has a vectored interrupt facility, and generates different interrupts to indicate program exceptions such as numerical overflow or address faults, software debugging commands such as breakpoint and trace, I/O signals such as input ready, and hardware errors such as correctable or uncorrectable memory errors.

Pin and silicon space limitations forced a number of design compromises in the selection of the width of various system data paths. The node memory supplies data in 16-bit halfwords, plus an extra byte containing ECC check bits. The processor performs single-error correction and double-error detection (SECDED) on all memory words, generating an interrupt in case of an error. This is an example of a situation where the pin limitations affect performance, for it requires two memory fetches to obtain a full 32-bit word. It also increases the number of memory chips required, since the SECDED code used for 32-bit data could be supplied by five RAM chips organized as 32K × 8 bits, if such chips were available.

Communication with other nodes is performed via asynchronous DMA operations over 22 bit-serial I/O lines. The I/O lines are paired into 11 bidirectional channels, which permit formation of a 10-dimensional hypercube, and also allow one connection to an I/O board. Each node-to-node channel operates at 10 MHz with parity check, yielding a data transfer rate of about 1 Mbyte/sec per channel in each direction. A channel has two 32-bit write-only registers associated with it: an address register for the message buffer location in the node RAM, and a count register indicating the number of bytes left to send or receive. There is also a ready flag and an interrupt enable flag for each channel. Once a send or receive operation has been initiated by a processor checking its flags and setting the appropriate registers, the processor can continue with other operations while the DMA channel completes the internode communication operation. Interrupts can be used to signal when a channel is ready for a new operation. For general applications, this requires less processor overhead than would occur in a polling communication protocol. An interrupt is also generated if there is a channel overrun, which can occur only on an input operation if more than 9 channels are transmitting data into the node. To reduce DMA activity, a broadcasting feature is supported which transmits the same data word along an arbitrary set of output channels in a single DMA operation.

The NCUBE/ten's I/O boards provide the connections between the hypercube and the external world. Each system must have at least one host board, and may have as many as eight. The host board uses an Intel 80286 to run the operating system, and has 4 Mbytes of RAM used as a shared memory by the various processors on the host board. It has support for a variety of different peripherals, including eight ASCII-standard terminals, four SMD disks (which can currently be as large as 500 Mbytes), and three Intel iSBX connectors that can accept daughter boards for functions such as graphics control or networking. Miscellaneous functions found on the host board include a real-time clock, and temperature sensors for automatic shutdown on overheating. Besides the host board, other I/O boards currently available are a graphics board with a 2K × 1K × 8-bit frame buffer, an intersystem board to connect two NCUBE systems, and an open system board with about 75% of the board left for custom design.

A distinguishing feature of the I/O boards in the NCUBE/ten is the fact that each has 128 bidirectional channels directly connected to a subcube of the hypercube; see Fig. 4. This permits extremely high I/O data-transfer rates into the hypercube enabling, for example, a single I/O board to transfer 1024 × 1024 × 8-bit images at video rates (30 frames per second). To accomplish this, each I/O board contains 16 NCUBE processors chips, each of which serves as an I/O processor and is connected to eight nodes in the main hypercube. Like the hypercube node processors, an I/O processor has a 128-Kbyte RAM which occupies a fixed slot in the 80286 host's 4-Mbyte memory space. An input operation from the outside world, e.g., a disk read, is performed by first transferring the input data to the host's 4-Mbyte memory. Then the data is transferred through the DMA channels of the I/O processors directly to the target hypercube nodes. Output operations are handled in a similar fashion. In addition to sharing access to the host's memory, the 16 I/O processors on each I/O board are interconnected as two disjoint 3-dimensional cubes, (this disjointness occurs because each node has only 11 bidirectional channels.) Note that in a maximum-configuration NCUBE/ten system, the hypercube nodes do not have to redistribute I/O data to other nodes. This is not the case in smaller NCUBE systems where fewer channels are available for external I/O operations.

An NCUBE system has from one to eight I/O boards (at least one of which must be a host board), from one to 16 processor boards, and attached peripheral devices. All the I/O and processor boards of a fully configured system, along with their fans and power supplies, fit into a single enclosure that is less than 3′ on each side. A full-sized system dissipates about 8 kW, and can be housed in a standard air-conditioned environment. A peripheral enclosure is about 3′ × 2′ × 3′ and contains a 65-Mbyte cartridge tape drive and up to four disk drives. A minimal standalone NCUBE system consists of one host board and one processor board containing a 6-dimensional hypercube, and can handle up to 8 user terminals. By adding a second processor board, one obtains a 7-dimensional hypercube. Since the operating system can allocate subcubes of arbitrary size, it is possible to have a number of processor boards which do not form a complete hypercube. For example, three boards provide a 7-dimensional and a 6-dimensional hypercube, which could also be allocated as three 6-dimensional hypercubes or as numerous smaller hypercubes. A full-sized system (Fig. 4) contains a 10-dimensional hypercube (which explains the "ten" in NCUBE/ten). The 1024 processors of such a system together have a potential instruction execution rate of about 2 billion instructions/second, or about 500 MFLOPS. The total amount of memory in the nodes is 128 Mbytes. If

all of the I/O boards are host boards, it is possible to support 64 terminals, and provide as many as 16 billion bytes of storage. A host board can provide input or output at up to 90 Mbytes/sec, giving a system input or output rate of about 720 Mbytes/sec.

Figure 5 summarizes the results of some performance experiments designed by D. Winsor at the University of Michigan, which compare the NCUBE node processor to two other representative CPU's with floating-point hardware: the Intel 80286 (the NCUBE host processor served for this) and Digital Equipment Corp.'s VAX-11/780. The measurements were made with the NCUBE node and host processors running under 8 MHz clocks. Extrapolated figures for the 10 MHz version of the NCUBE node processor now nearing production are also given, assuming no wait states. Two widely used synthetic benchmark programs were employed in this study, the Dhrystone and the Whetstone codes [2,18]. The Dhrystone benchmark is intended to represent typical system programming applications and contains no floating-point or vectorizable code. The original Dhrystone Ada code [18] was translated into a FORTRAN 77 version with 32-bit integer arithmetic that attempts to preserve as much of the original program structure as possible. This entailed changes such as replacing Ada records by FORTRAN arrays which produce a substantial performance degradation compared to Dhrystone benchmarks in Ada, Pascal or C. However, any such degradation here appears to apply uniformly to all processors considered, since all were given the same FORTRAN source code and used very similar FORTRAN compilers. The Whetstone benchmark, which aims to represent scientific programs with many floating-point operations, was used in a single-precision FORTRAN 77 version that closely resembles the original ALGOL code [2]. The Dhrystone results in Fig. 5 are reported in "Dhrystones per second," each of which corresponds roughly to one hundred FORTRAN statements executed per second. The Whetstone figures represent the number of hypothetical Whetstone instructions executed per second. It can be concluded from the data of Fig. 5 that the NCUBE node processor is quite fast and fully meets its performance targets cited above.

### 4. System Software

The emergence of several commercial hypercube computer has demonstrated the feasibility of constructing low-cost massively parallel machines. The focus of research can now be expected to shift to the issue of how these machines can be programmed effectively. Indeed, the recent report on the Supercomputing Research Center concludes that the absence of appropriate parallel programming languages and software tools is the single biggest impediment to the successful use of parallel machines [1]. The operating system is also a major design issue, since memory management and interprocessor communication are critical to the functioning of the programming languages. Three software issues need to be considered. The first is the operating system that is used for developing application programs for the hypercube. The second is the operating system that provides run-time support for application programs running on the hypercube nodes. The third is the set of application languages to be used.

| Processor | FORTRAN Dhrystones/sec | FORTRAN Whetstones/sec |
|---|---|---|
| NCUBE node processor at 8 MHz | 999 | 381,000 |
| NCUBE node processor at 10 MHz (est.) | 1,249 | 476,000 |
| Intel 80286 (NCUBE host) at 8 MHz with 80287 floating-point co-processor | 510 | 101,000 |
| DEC VAX-11/780 with floating-point accelerator | 741 | 426,000 |

**Fig. 5.** Summary of processor benchmark results.

An attractive choice for a development operating system that provides the kind of environment associated with a "programmer's workbench" is UNIX. Unfortunately, there are two different versions of UNIX (System V and bsd 4.2), and a large number of lesser-known variants. This leaves the system designer with something of a dilemma: on the one hand UNIX offers a proven development environment that is widely known; on the other hand a UNIX standard has yet to emerge. The solution chosen by NCUBE was to develop a UNIX-like operating system called AXIS [7] that embodies the features common to the major UNIX dialects. Subsequent change or additions can be readily made to AXIS when a true UNIX standard is agreed upon. There are two features of AXIS that we shall elaborate on here because they are pertinent to the management of a very large hypercube. The first is the ability to share files, and the second is the way in which the main cube array is managed.

AXIS runs on the 80286 host processor that acts as the CPU for each I/O board. (Recall that up to eight I/O subsystems can be accommodated in a 1024-processor NCUBE/ten). It provides the large number of utilities for editing, debugging and file management that one has come to expect in a UNIX-like operating system. Consistent with the UNIX philosophy, the file system is the most prominent feature of AXIS, and almost all of the system resources are treated as files. Massively parallel systems require high I/O bandwidth if they are to be useful for applications that are not simply computation-intensive. This problem of I/O management was not foreseen in the earlier generation of massively parallel machines, and has proved to be a great limitation [10]. The ability to incorporate up to eight I/O subsystems in the NCUBE/ten is intended to avoid this problem. However, it introduces the potential for eight separate file systems. To avoid this, AXIS provides the capability to organize the eight file systems as one distributed file system; AXIS further allows complete systems to be networked through iSBX connections to provide a single multiuser file system. The principal mechanism for doing this is the device directory pointer (ddir). ddirs are items that can be placed in a file directory. Instead of representing a file name, they are pointers to disk drives. Each disk drive has a unique device identifier, which includes a *system number*, an I/O *board number*, and a *drive number*. Within a disk drive, the files are organized as a typical UNIX tree. ddirs can be placed in the root directory of a disk to point to the root of the other drives. This permits file sharing across all physically connected NCUBE systems. Figure 6 illustrates how the directory structure for two host boards, each having two physical disk drives, might be organized, if logical disk0 and disk4 are shared systemwide. Typically, the device directory of a physical disk0 (called "//") will contain the following:

1. The name of another directory which acts as the real root of the file structures on disk0 ("cb0" on host 0)
2. ddir's for the other drives connected to the same host
3. ddir's of disk directories on any other host board in the system
4. ddir's for disks on any other physically connected NCUBE system. Since *system number* is one of the components of a ddir, it can refer to disks on other NCUBE systems.

AXIS manages a hypercube of node processors as a device, which is simply one type of file. It can be opened, closed, written to, and read from as if it were a normal file. AXIS permits users to allocate subcubes that have the appropriate size for their application. Thus, one or two large problems, or several small problems may share the hypercube. This flexibility greatly increases the system efficiency, and gives a hypercube supercomputer a significant advantage over conventional supercomputers. Partitioning the main hypercube into subcubes is simplified by the fact that each subcube is protected from access by any other subcube.

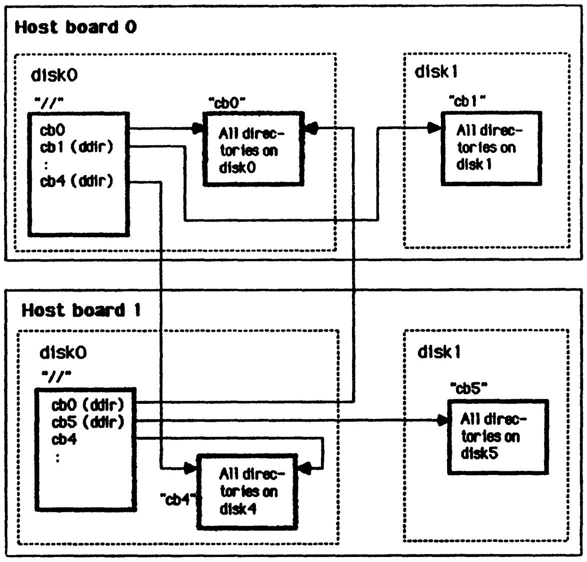

**Fig. 6.** Distributed files on the NCUBE/ten.

VERTEX, the operating system for the hypercube node processors, is a small nucleus (less than 4K bytes) that is resident in each of the NCUBE/ten nodes. Its primary function is to provide communication between the nodes, in the form of send and receive functions that transfer messages between any two nodes in the hypercube. The node processor has instructions that are used as primitives in the VERTEX communication calls, **nwrite** and **nread,** which implement the internode send and receive functions, respectively. The messages transferred by **nwrite** and **nread** are arrays of bytes having four associated attributes: source, destination, length and type. The first two attributes are numbers in the range 0 to 1023, and indicate the logical nodes being used for source and destination. The length attribute is the number of bytes in the message; messages as long as 64K bytes are supported. Finally, the type attribute can be used to distinguish messages, and so permit their selective reception at a destination node.

The subroutine **nwrite** may be represented as

**nwrite** *(length, messages, dest, type, status, error)*

where *length* is length of the outgoing message in bytes, *message* is the name of the buffer from which the message is to be taken, *dest* is the logical number of the node in hypercube that is to receive the message, *type* is the type number of the message, *status* indicates when the message has left the buffer, i.e. when the buffer is reusable, and *error* is an error code. Message transmission breaks the message into packets of 512 bytes (or some other user-defined size), and sends them to the destination node using the following routing algorithm. Assume that in an $n$-dimensional cube, the logical number of the source node is $s_n s_{n-1} \ldots s_2 s_1$ and that of the destination is $d_n d_{n-1} \ldots d_2 d_1$. The bit-wise exclusive-or $x_n x_{n-1} \ldots x_2 x_1$, of the two numbers is formed as follows: $x_i = s_i \oplus d_i$ for $i = 1, \ldots, n$. The values of the $x_i$'s are used to control the routing process. Those values of $i$ for which $x_i = 1$ indicate the dimensions that must be traversed to transfer a message from source to destination. The routing algorithm was chosen for its simplicity; however, as noted by Valiant [17], there is a potential for congestion in some situations. He defines an alternative routing algorithm that avoids congestion by routing each message to a randomly chosen node; from there the message is forwarded to its originally intended destination. The randomization assures that message congestion at nodes will be dispersed. Unfortunately, Valiant's router does not perform as well as the straightforward algorithm in many routine parallel processing tasks, and its more complex implementation requirements discouraged use of it in the initial NCUBE/ten design. Future insights into the behavior of parallel algorithms may change this, however.

In addition to determining the routing path, VERTEX must perform the store-and-forward function at each node along the path. At the destination node the message is placed in a queue that is allocated from a heap of 20K bytes. The receive function, which can be represented by

**nread** *(length, message, source, type, status, error)*

looks for the first message from *source* of type *type* in the input queue, and copies it to buffer *message*. Don't care conditions are indicated for *source* or *type* by setting these parameters to -1. This allows the next message from a particular source to be received regardless of type, it allows the next message of a particular type to be received from any source, and it allows the next message of any type from any source to be received. Messages with negative types other than -1 are system messages for VERTEX and are used for process control at a node, e.g., for node program debugging. In summary, the calls **nwrite** and **nread** provide a fast internode message communication mechanism. The main contributers to this speed are the machine instructions provided explicitly for internode communication, and the fact that messages enter nodes through DMA channels. Measurement of the internode communication performance of the NCUBE system is presently under way.

The current NCUBE/ten application languages, apart from the node and host assembly languages, are FORTRAN 77 and C. The choice of FORTRAN 77 and C was made because the computer is targeted for a user community interested primarily in scientific problems; this group has traditionally programmed in FORTRAN. Compilers for other languages, including Occam, are presently being developed. The programming model adopted for the initial set of languages (FORTRAN and C) is a simple extension of the conventional uniprocessor model. Each node is treated as a separate processor. No symbols are shared between nodes: the naming scope is contained within a node. Values of variables are shared by calls to the VERTEX subroutines **nwrite and nread.**

## 5. Conclusion

Hypercube architectures are well suited to implementing massively parallel supercomputers, given the constraints imposed by current technology. They offer an unusually good combination of high node connectivity, software flexibility, and system reliability. The NCUBE/ten is an example of a new generation of low-cost and compact hypercube machines with the capability of supercomputing performance. Unlike earlier machines, it exploits the inherent homogeneity of the hypercube to provide a multiuser UNIX-like programming environment, along with support for extremely high I/O data-transmission rates.

# Scalability of a Binary Tree on a Hypercube

Sanjay R. Deshpande and Roy M. Jenevein

Department of Electrical and Computer Engineering
University of Texas at Austin
Austin, Texas 78712.

## Abstract

The concept of scalability is important for the next generation of super-multiprocessors. Two aspects of scalability of an architecture are *resource scalability* and *application scalability*. Both types of scalabilities are qualitative measures of goodness of an inductive architecture [4]. The application scalability measures the utilization of resources and the efficiency of execution of application. The resource scalability is a measure of growth rate of architectural properties.

In this paper, the resource scalability characteristics of the hypercube architecture are assessed and the concept of application scalability is applied to it in the context of a binary tree structured application graph. The criterion used is the utilization of processing nodes. Results are also derived for a modification of the application graph. A logN[1] time complexity distributed algorithm that can be used to set up the modified structure is outlined. This algorithm is shown to be useful for handling a single node fault in the architecture as well.

## 1 Introduction

An important consideration in designing an architecture for a super-multiprocessor system is its scalabilities [4,5]. We recognize two types of scalabilities: resource scalability and application scalability.

By resource scalability we imply the asymptotic growth rates of architectural properties and their associated costs. The smaller the cost, the better scalable is the architecture. For example, the multistage interconnection networks such as the omega, the banyan and the baseline are preferred for multiprocessor systems over the crossbar for the reason that these networks scale better than the crossbar. The hardware cost increases as NlogN for these networks compared to $N^2$ for the crossbar, for N interconnected resources.

Application scalability is a measure of utilization of architectural resources and efficiency of execution for a particular application under asymptotic growth in their size. In other words, it is a measure of optimality of mapping between the application and the architecture for all sizes. This concept is of relevance for inductive architectures [4], which are regular in structure and have the number of processing resources as a parameter. Some examples of inductive architectures are TRAC [13], PASM [14], Hypercube [3], CHiP [15] etc.. For these, the mappings can be evaluated as a function of size. By evaluating their application scalability, we can predict the asymptotic execution behavior of an application.

Consider an application mapped on a given architecture. The mapping results in certain utilization of resources and execution efficiency. If, when the architecture and the application are equally increased in size, the same utilization and execution efficiency is achieved, the architecture is considered to be well scalable with respect to that application. Of course, in some cases, a drop in execution efficiency can be allowed if it is the result of increased hardware delays.

It is not sufficient for a super-multiprocessor architecture to have good resource scalability; it must also have good application scalability for a number of applications. For instance, a bus oriented architecture has excellent resource scalability, but its bandwidth is exceeded for even modest communication requirements per processor, as the number of processors is increased beyond a certain value. The evaluation process should therefore account for architectural constructs embedded in software as well as hardware. These include, but are not limited to, software communication switches, polling routines, priority encoders, data translators, etc.. If these constructs are not accounted for, they may result in bottlenecks and degraded performance as the application grows in size.

The evaluation of application scalability of an architecture involves mapping of an application graph on the architectural topology. Conventionally, the mapping implies embedding of an application graph within the resource graph of the supporting architecture. The mapping problem arises because the two graphs are topologically nonisomorphic [6]. The solution results in assignment of one or more computation nodes of the application graph to a processing node in the system such that the processing and storage requirements are satisfied.

[1] Throughout this paper, unless otherwise specified, logN is used as short for $\log_2 N$.

0190-3918/86/0000/0661 $01.00 © 1986 IEEE

We have chosen an application graph which has the structure of a balanced binary tree. Binary tree graphs are fundamental structures and appear in several computation graphs. They naturally result from *divide and conquer* methodology of formulating parallel algorithms for sorting, merging and min-max problems. A binary tree based algorithm is used for the recursive doubling method of computing a global histogram [7]. The Dictionary Machine of Atallah and Kosaraju uses a binary tree structured machine architecture [8]. Binary tree structures result from search trees in inference systems. Horowitz and Zorat suggest application of binary tree shaped interconnection networks for multiprocessor systems [9]. It would therefore be interesting to see how such an important computational topology is supported on a popular architecture.

Recently, substantial attention has been given to the hypercube architecture for multiprocessors [1, 2]. Many applications have been successfully implemented on it and impressive speed-ups have been obtained [3]. Most previous architectures have failed to furnish respectable speed-ups for more than just a few applications. On the other hand, the hypercube architecture seems to have lived up to its promise of being a good supporting architecture for a wide variety of application areas. This effectiveness of the hypercube architecture is seen to derive from the rich internode connection topology afforded by the underlying graph. But, before hypercube topology can be considered as a defining topology for a future generation super-multiprocessor, its resource scalability should be evaluated. Also of consequence to its applicability for a dedicated high performance computing engine is its application scalability for the targeted use. Binary tree structured algorithms being so common in the area of parallel processing, we focus here on their scalability on the hypercube.

## 2 Resource Scalability of Hypercube Architectures

A boolean or binary hypercube graph of order n (alternately called n-cube) has $2^n$ nodes connected with edges as defined in Appendix I. Figure 1 shows an example of a hypercube of order 3. In a hypercube based multiprocessor, nodes of the graph are occupied by independent processing elements. The edges between the nodes represent the point-to-point communication links between the processors. Each link or edge is dedicated to the corresponding node-pair. In some architectures, like the Intel's iPSC System, there is a separate processor called the Cube Manager to coordinate the parallel execution of a job [10]. The Cube Manager is connected to the processors in the cube by a broadcast bus for global communication, I/O and control. However, the concepts of Cube Manager and the global bus are not inherent to the hypercube architecture, and we will therefore ignore them. We will use the well-known rectangular, multistage, single-sided interconnection networks (MSINs) such as banyan, omega and baseline as a reference when comparing properties. These networks have been shown to be topologically isomorphic in [18]. We assume in this paper that the MSINs have logN stages of N/2 switches each, and that switches allow "turn-around". Thus a message going from one processor to another travels a certain number of levels into the network and then turns around and travels to the destination in the reverse direction.

### 2.1 Communication Interface Costs

Each processing element in an n-cube has communication links to n other processors. If we focus on the number of processors, $N = 2^n$, in the cube, then there are logN communication interfaces on each processor. Thus the total communication interface cost of the network is NlogN. This is the same as the cost of the MSINs, although there is one minor difference: when the size of the hypercube is doubled, each of the original nodes has to be modified to allow one more communication link. The nodes of the original cube could be provided with ports for extra links, and when the cube is doubled, one of these could be utilized. However, it is important to remember that modification is necessary throughout the original system in the case of hypercube; whereas in the multistage network architectures, the modifications are localized to the boundary of the original system.

### 2.2 Communication Reliability

The communication reliability of the hypercube ($n \geq 3$) is better than that of the MSINs. For them, unless extra stages are specifically provided for [16, 17], there are a constant number of disjoint paths (= out-degree of a node) between two processing nodes. On the other hand, in the hypercube architecture, there are (logN) disjoint paths available for any given pair of nodes [11].

Note that, in the hypercube architecture, the number of contingent paths and the reliability of interprocessor communication increases with logN, while those for the MSINs remain constant. Thus for the hypercube architecture, the communication reliability also scales better than that for the multistage networks.

### 2.3 Interprocessor Distance

The diameter of a network can be defined as that of the underlying graph structure in which the processing resources and switches are represented as nodes and the communication paths are represented as edges. For a graph, the diameter is the maximum distance between any pair of nodes. For the MSINs, the diameter is equal to twice the number of stages in the network; that is 2logN. For a hypercube network, the message passes at most logN links before reaching the destination [12], since for any given node, there is one node which is at distance logN from it. So for the hypercube, the diameter scales as logN.

It can be shown that the average distance from a given node, of all nodes including itself, is 2(logN-1) + 2/N, for MSINs. The same is logN/2 for a hypercube. Thus, under asymptotic growth, although both scale as logN, the hypercube has a better scaling coefficient[2].

## 3 Application Scalability for a Binary Tree

For the sake of this analysis, we will assume that the binary tree application is the sole task being executed in the system. Under this condition, we would like to execute the largest possible size of the application. Ideally, we would like to utilize the hypercube architecture fully, so that when the architecture and the application are scaled, no wastage results. If that is not possible, a constant resource overhead is allowable since the percentage of overhead would diminish with equal increase in the application size and architecture. The overhead that grows linearly with the number of nodes in the hypercube is unacceptable.

Let us consider mapping a binary tree on an order n hypercube. A balanced binary tree with n levels of nodes (called in this paper an n level tree), has a total of N-1 nodes of which N/2 are at the leaf level. It should therefore be possible to map an n level binary tree on an n-cube. This would result in all but one of the nodes being utilized and would represent constant under-utilization. If such mapping is possible for all n, the binary tree application could be considered well-scalable on a hypercube architecture. We ask precisely this question: Is such mapping possible?

It is possible to map a two-level binary tree on a 2-cube that has a square topology (See Figure 2). For all n $\geq$ 3, it is impossible to map an n level binary tree on a hypercube of order n. Appendix I contains the proof for this result. For n $\geq$ 3, the largest sized binary tree that can be mapped on an n-cube is of n-1 levels. Thus the tree occupies only about half ($2^{n-1}$-1) nodes out of the $2^n$ available. Resultant under-utilization of computing resources is $2^{n-1}$+1 nodes, which is slightly more than 50%. In terms of the total computing resource available in the system, the overhead is linear and therefore unacceptable.

Proof that an n-1 level binary tree can be mapped on an n-cube forms a part of Appendix II. In fact, two n-1 level binary trees can be simultaneously mapped on an n-cube.

The result obtained in Appendix I tends to question the suitability of hypercube topology for super-multiprocessor architecture on the grounds that it cannot support the scaling of a fundamental application. A question we may ask is: Is it possible to modify the application graph such that the new structure scales well on the hypercube architecture without introducing overheads that grow inordinately?

Appendix II shows that it is indeed possible to slightly modify the original tree graph and make it well-scalable on the cube. That is, a modified n level tree is optimally mappable on an n-cube. By the introduction of a single two-degree node as a son of its root, and thereby *stretching* (or equivalently double-rooting) it, the tree can be made to utilize the cube completely (see Figure 3b). The extra node so introduced is used only for communication between the root and one of its sons. It is interesting to note that only one such node is required for any n. This node therefore represents a constant overhead for all n $\geq$ 3 which diminishes in percentage as n becomes larger.

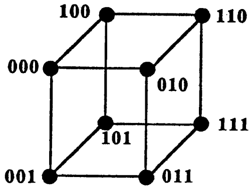

Figure 1.

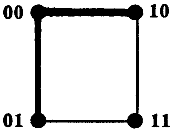

Figure 2.

Since each processing node in the cube accommodates a single computation node of the tree, equal increase in sizes of both application and architecture does not change the computational load on an individual processor. Upon scaling, the links between the processors continue to correspond to edges between neighboring nodes in the tree on a one-to-one basis and handle the same level of traffic as before. This ensures that the computational efficiency of the application too does not drop significantly, although a constant time is added because of the communication through the spacer node.

## 4 A Distributed Tree Set-Up Algorithm

In the previous section we saw that an n level stretched binary tree can be mapped onto a hypercube of order n. In order to prove that result, we have introduced transformations of the node labels. It is possible to use these transformations, namely FT3 and BT3, to obtain a distributed algorithm to set up the referred mapping. This algorithm has practical importance for executing a binary tree shaped application on a hypercube. It is used first to set up the communication topology among the processors of the cube, and then the application is executed. The algorithm does not require that the entire system be configured as a tree. It works as well within any subcube of the overall system. The algorithm is explained below.

The algorithm is executed by each processor in the hypercube. It is divided into two phases; namely compute and distribute. During the first phase, the nodes of the cube compute the loci of the mapped trees as they are transformed and merged to form larger trees. In the second phase, the port configurations of the nodes forming the final tree are sent to the appropriate nodes of the cube.

The algorithm starts by setting up initial $2^{n-3}$ three level trees having a predetermined configuration. That is,

[2] Certain other multi-tree networks, like the KYKLOS [19], are known to offer average interprocessor distances which are better than that for the MSINs.

every node in the cube is a member of a three-level tree; its position in the tree is determined by the least significant three bits of its ID. Each three-level tree is defined over a set of eight nodes which have identical n-3 most significant bits. The configuration of these trees are shown in Figure 5. The labels of the nodes of these mapped trees are henceforth referred to as *virtual addresses*. At each successive iteration of the algorithm, trees are merged to form larger trees until eventually the final tree is attained. These intermediate trees are not realized by activating links between appropriate nodes in the cube. However, the cumulative information available in the cube is sufficient to make this possible.

At the outset, the virtual address of a tree node corresponds to the label of the physical node in the cube to which it is mapped. After this, the physical nodes compute the loci in the n-cube of these initial tree nodes as the mappings are transformed and merged to form larger trees. At the end of the compute phase of the algorithm, each physical node holds the node label to which the virtual address would eventually be mapped, and also the port assignments required at this final node to configure the tree properly. These port assignments are relayed to the final node during the distribution phase of the algorithm.

For an n level tree in an n-cube, O(logN) iterations are required, and if we assume no collisions during the distribution phase, it too is O(logN) long, since each node in the cube emits one message. It therefore implies that the algorithm is of O(logN) time complexity. The algorithm is given in Appendix III.

## 5 Tree Mapping in Presence of a Node Fault

We consider here the mapping of a stretched binary tree topology in presence of single node faults. We make an assumption while formulating the strategies: the knowledge of this failure is global. That is, all processing nodes know before hand the label or Id of the failed node. This prior knowledge is not essential, and an algorithm to distribute the labels of the failed nodes can be formulated if necessary.

We will first consider a multiple step approach where each step represents one mapping of a portion of the computation graph and its subsequent execution. Clearly, an n-1 level sub-tree with a spacer node occupies $2^{n-1}$ nodes and thus is mappable into half of a hypercube of order n. By utilizing this partitioning of the cube, the corresponding computational graph must be segmented into three components: the root, the left sub-tree and the right sub-tree. In this way, each sub-tree segment of the graph can be mapped onto the valid half partition of the cube in which no nodes are faulty, while the faulty node is isolated to the other half.

Because the proof in Appendix II works inductively for successively higher order cubes, the reverse fragmentation to lower cubes follows directly, provided the cube partition is done on a dimensional boundary. Remembering that each successively higher order cube adds one bit to the node addresses, a mapping partition can consist of all nodes whose high order bit is the complement of that of the faulty node. In this way the problem is reduced to that of mapping a sub-tree to a subcube. Figure 6 shows the valid half of the cube as those nodes with the high order bit in their labels to be 1 since it is assumed that the faulty node has a 0 as the high order bit of its label.

The disadvantage with this approach, however, is that it may lead to a three-step process of map-and-execute (left tree, right tree and then root), and additionally, because of a single faulty node, $2^{n-1}$-1 nodes are left unutilized. This seems a high price to pay to avoid a fault. We now address the question of whether one can map-and-execute in a single step.

A three-level tree with the spacer node is shown in Figure 5. In this figure, we can see that the root of the tree occupies physical node ID 000 and the spacer node ID is 100. After mapping, only one node within the cube has no corresponding computational requirement in the stretched tree. We observe that the spacer node (S100 in Figure 4a) has as its only responsibility, the communication of results from the right sub-tree to the root. Certainly, this communication is an essential part of the computation graph. But, S100 is not the only node linking S000 and S110 within the hypercube, and because the node S010 likewise links them, it could be used instead.

Let us assume for the moment that we have a means to "force" the faulty node to be S100. In this way, all computation nodes are mapped to working processors and S010 doubles as both a computation node and an alternate link from the right sub-tree to the root (see Figure 9). In all of the tree algorithms discussed, at the time when this communication is needed all members of the right sub-tree have completed their computation and gone idle. This implies that no timing conflict arises as a result of this dual role for S010.

The remaining open question concerns the ability to "force" the faulty node to the spacer node. We answer this question via an example of a 3-cube. The method can be extended easily to an n-cube.

We will assume a single fault at node 001, which according to the mapping in Figure 7, is a computational node. We assume that the faulty node address (001) is available to all nodes in the cube. We now provide a means to remap the initial three level tree such that the fault will map to a logical node 100 and all other nodes will be transformed through three dimensional space conserving their adjacency relationships.

Figure 8 shows that an XOR bit mask controls the reflection or non-reflection of each bit in the node label. If the bit in the mask is 0, no reflection occurs; but if it is a 1, then a pair of node labels are swapped in that dimension.

Thus, a remapping of the labels occurs, but adjacency is preserved. This mask can be generated by taking the exclusive OR(XOR) between the fault node id and the spacer id (100). The XOR of this mask and each node id create virtual addresses which force the fault to be mapped to the spacer node as shown in Figure 9.

The above method can be extended to an n-cube if we can designate a particular label as that of the spacer node. The tree set-up algorithm of Appendix III always produces a spacer node at S100, where S is a string of n-3 zeros. Thus, in the case of an n-cube, all nodes use their own physical labels as virtual addresses to start with. Subsequent to the tree set-up algorithm, the resultant virtual addresses are XORed with the mask to obtain an appropriate tree with a spacer node mapped onto the faulty physical node.

## 6 Summary and Conclusions

In this paper the concept of application scalability was introduced and applied to an example of a hypercube architecture and a binary tree application. For inductive architectures like the hypercube, application scalability is an indicator of how well a given application will be supported with increasing sizes. The parameters of interest, while evaluating application scalability, are utilization of hardware resources and efficiency of execution. The first of the parameters is evaluated by mapping a maximum sized application graph onto the architecture graph and performing a calculation of the utilization as a function of size. The second is analyzed by measuring the growth of computation and communication delays as a function of size.

It was concluded that a balanced binary tree is not well scalable on a hypercube. It was also proved that a stretched binary tree results in a scalable mapping giving near 100% utilization of processing resource in the architecture. In addition, an O(logN) distributed algorithm was derived to generate a stretched binary tree in the hypercube. The tree construction algorithm was also shown to be adaptable to generate a mapping in presence of a single node fault by augmenting it with a subsequent fault-avoidance step.

Of the two approaches evaluated for executing the tree application in the presence of a single node fault, one provides complete utilization of fault-free nodes for an n level tree in an order n hypercube. Thus, even with single node fault, the binary tree application can be mapped and run with virtually no degradation in performance.

## Appendix I

Definition: A hypercube of order n (an n-cube) is an undirected graph with $2^n$ vertices labelled 0 through $2^n$-1. There is an edge between a given pair of vertices if, and only if, the binary representation of their labels differ by one and only one bit. Hypercube of order 3 is shown in Figure 1.

Definition: Parity of a node is odd or even and is determined by the number of 1's in the label of the node.

Lemma 1: If nodes a and b are connected by an edge, a and b have opposite parities.

If we try to map a binary tree on a hypercube, we can observe the following lemma:

Lemma 2: The node parities alternate over the levels of a mapped binary tree.

We now count the number of odd and even nodes necessary to map a binary tree, and the number of odd and even nodes available in a hypercube:

By symmetry, the number of odd and even nodes available in the hypercube is the same and is half the total number of nodes, that is $\frac{1}{2}(2^n) = 2^{n-1}$. For a binary tree, we get the following values:

**Case 1:** n is even.

Number of even nodes $= 2^0+2^2+....+2^{n-2} = \frac{1}{3}(2^n-1)$

Number of odd nodes $= 2^1+2^3+....+2^{n-1} = \frac{2}{3}(2^n-1)$

**Case 2:** n is odd.

Number of even nodes $= 2^0+2^2+....+2^{n-1} = \frac{1}{3}(2^{n+1}-1)$

Number of odd nodes $= 2^1+2^3+....+2^{n-2} = \frac{2}{3}(2^{n-1}-1)$

In both cases the number of even and odd nodes required by the tree do not match those of the cube. This completes the proof.

## Appendix II

Figure 3a shows a binary tree of n=3. The figure also shows the even and odd levels of the tree, assuming level 0 of the tree is at an even level. Figure 3b shows the construction of a 4-level tree out of two 3-level trees using an extra node at level 1 of the right hand subtree. The resultant tree has equal number of odd and even nodes which can be matched by those in a 4-cube. The following is a constructive proof that such a mapping is possible for n $\geq$ 3.

Definition: An n-cube is said to be k-dimensionally transformed when k bits in the label of each node of the cube are transformed according to a transformation. (Note that the bits undergoing transformation need not be contiguous.)

We define two 3-dimensional transformations, FT3 and BT3, as shown in Table 1. The $x_i$, $x_j$ and $x_k$ are the original values of the bits, and $y_i$, $y_j$ and $y_k$ are the corresponding resultant values.[3]

Definition: Distance between a pair of nodes in a graph is the minimum number of edges that have to be traversed when going from one node to the other. For an n-cube, this is also equal to the number of bits by which the binary representations of labels of the two nodes differ [11]. The *adjacency* in an n-cube is the distance relationship of a node with the rest of the nodes in the cube.

We state the following two theorems proved in [12].

Theorem 1: The FT3 preserves cube adjacency.

Theorem 2: The BT3 preserves cube adjacency.

We can now state the following corollaries:

Corollary 1: Nodes with distinct labels map to distinct resultant labels.

Corollary 2: If two nodes are neighbors and thus have labels differing in one bit position, their new labels after the transformations also differ in one bit position. Thus, neighborhood between the two nodes is preserved.

Theorem 3: A graph G mapped on an n-cube remains unchanged in structure after the transformations.

Proof: The proof follows as a direct consequence of corollaries 1 and 2, and is given in [12].

We can therefore state the following corollary:

Corollary 3: The transformations FT3 and BT3 preserve a tree structure mapped on an n-cube.

Theorem 4: A stretched binary tree (of the form shown in Figure 3b) of n levels can be mapped on an n-cube, for $n \geq 2$.

Proof: The case for n=2 is trivial. The case of n=3 is shown in Figure 5. The construction of a four level tree from a pair of 3-cubes can be found in [12]. We will now describe the inductive step. We assume that an n level stretched binary tree, as shown in Figure 4a, is mapped on an n-cube. To obtain an n+1 level tree in an n+1-cube:

- Duplicate the cube and the mapping. See Figure 4b.
- Apply FT3 to the duplicate mapping using bit-2 as $x_i$, bit-1 as $x_j$ and bit-0 as $x_k$ to obtain a new mapping as in Figure 4c.
- Form an n+1-cube by connecting the nodes with like labels in the two n order subcubes. Append a 0 to the left of labels in the original subcube and a 1 to the left of those in the duplicate subcube (see Figure 4d).
- Deallocate links: 0S100-0S110 and 1S100-1S000, and allocate links: 0S000-1S000, 0S110-1S110 and 0S100-1S100. See Figure 4e.
- Apply the BT3 to the n+1 cube to obtain an n+1 level stretched binary tree rooted at 0S000. While applying the BT3, use the most significant bit as $x_i$, the third least significant bit (bit-2) as $x_j$, and the least significant bit (bit-0) as $x_k$. Replace the string 0S by S' to obtain a structure similar to the base structure we started with. See Figures 4f and 4g.

## Appendix III

The tree set-up algorithm uses the following variables:

*current-port*: Every node in the cube has logN ports, each corresponding to a bit position. This variable keeps a running pointer to the current bit position being considered.

*physical-id*: Original label of a node.

*current-id*: A node label during current iteration.

*port-relation*(1..logN): An array of values specifying the current active connections of a node. All are initialized to "null" (inactive).

Following values are assigned to *port-relation(i)* variable:

| | |
|---|---|
| "null": | No active connection. |
| "f": | Connection to "father" node. |
| "s": | Connection to "son" node. |

The following is the compute phase of the tree set-up algorithm. This is followed by a distribution phase during which the connectivity information is sent to the appropriate physical node specified by the *current-id* variable.

```
for-all nodes do
  begin
  current-id = physical-id;
  {Set up $2^{n-3}$, 3 level trees.}
  case current-id( bits: 2..0) of
     0:  port-relation(0) = port-relation(2) = "s";
     1:  port-relation(0) = "f";
         port-relation(1) = port-relation(2) = "s";
     2:  port-relation(2) = "f";
     3:  port-relation(1) = "f";
     4:  port-relation(1) = "s";
         port-relation(2) = "f";
     5:  port-relation(2) = "f";
     6:  port-relation(0) = port-relation(2) = "s";
         port-relation(1) = "f";
     7:  port-relation(0) = "f";
```

[3] The two transformations define two of the many *rigid* transformations of a 3-cube. The rigid transformations include rotations and reflections of the original cube structure which preserve the adjacency between its nodes.

```
end-case
for current-port = 3 to logN-1 do
   begin
   {Form larger trees iteratively.}
   if (current-id(current-port) = 1) then
   begin
   Apply FT3 to current-id's bits 2, 1 and 0;
   end
   if (Bits 3 through current-port-1 are 0) then
   begin
      case current-id( bits: current-port, 2, 1, 0 ) of
      0:  port-relation(2) = "f";
          port-relation(current-port) = "s";
      4:  port-relation(2) = "s";
          port-relation(current-port) = "s";
          port-relation(1) = "null";
      6:  port-relation(1) = "null";
          port-relation(current-port) = "f";
      8:  port-relation(2) = "null";
          port-relation(current-port) = "f";
      12: port-relation(2) = "null";
          port-relation(current-port) = "f";
      14: port-relation(current-port) = "s";
      end-case
   end
   Apply BT3 to bits current-port, 2 and 0 of current-id;
   end
end
```

## ABSTRACT

We present systolic tree architectures for data structures such as stacks, queues, priority queues, deques and dictionary machines. Except for the dictionary machine, all data structures have a unit response time. In each node of the tree the mechanism for controlling the transmission and distribution of data is a finite state machine. The depth of a tree with n data elements is O(log n). For stacks, queues, and deques, no compress signals are required.

## 1. Introduction

Several researchers have explored systolic machines for implementing data structures. Leiserson [LEI79], and Guibas and Liang [GUI82] have given linear systolic array implementations of priority queues, stacks and queues. Ottman et. al. [OTT82], Atallah and Kosaraju [ATA85], and Somani and Agarwal [SOM85] have shown that dictionary operations can be implemented on a tree. These schemes require additional clock cycles[LEI79][GUI82], or extra connections[OTT82], or storage of several addresses [ATA85].

This paper presents a relatively uniform approach to handling several types of data structures. All the data structures use finite state control, and with exception of the dictionary machine, have a unit response time. The response time of the dictionary machine is O(logn). The input and output in these machines is done through the root of a tree. Throughout this paper, n is the number of data elements in the tree. We will first present a tree-based implementation of stacks, queues and deques. Using a different approach, a priority queue and a dictionary machine are developed with a wide repertoire of operations. Compress cycles are necessary in the second approach to allow successive deletions.

## 2. Stack, Queue, Deque

An output restricted deque(Knuth[KNU68]), shown in Figure 1, is a data structure which permits insertions to both the front and the rear. Deletions, however, are only permitted from the front. The output-restricted deque is a generalization of both the stack and the queue since restricting insertions from the rear makes this a stack while restricting deletions from the front makes this a queue.

Consider a binary tree each of whose nodes has a data register for storing data, a buffer for pipelining instructions to its children, and two flags. The root of the tree corresponds to the front of the output restricted deque. An instruction entering a node is executed, and the instruction to be pipelined is stored in the buffer of the node. In the next cycle, the buffer contents is sent to either the left child or the right child.

There are two insert instructions- a Stack Insert (SI) and a Queue Insert(QI). A Stack Insert into a node causes the inserted value to be stored in the node, while the previous contents are directed to one of the children. A Queue Insert causes the inserted data to be pipelined to one of the children while retaining the contents of the data register. Each node has two binary flags, a queue flag(QF) and a stack flag(SF). When an empty node receives an insert instruction, its flags are assigned 0. In every non-empty node a stack insertion is directed towards the left*(right)* subtree if the SF is 1*(0)*. A queue insert is directed left*(right)* if the Queue Flag(QF) is 0*(1)*. A deletion is from the left*(right)* subtree if the SF is 0*(1)*. The SF is complemented if either a Stack Insert or a Delete enters a node, while the QF is complemented if there is a Queue Insert. The behaviour of the output restricted deque is given in Table 1. Figure 2 shows the evolution of the output restricted deque under a sequence of instructions. A deque can be implemented by combining two output restricted deques [CHA85]. The complete implementation of the stack and queue is also described in [CHA85].

## 3. Priority Queue

In our tree implementation of a priority queue and a dictionary machine, each node stores upto three data elements. Data is 'snaked' as in [ATA85]. Balancing the tree is achieved by a flag at each node. All operations can be pipelined.

First let us consider the priority queue. Our implementation supports Deletemax and Deletemed in addition to Insert and Deletemin. Deletemin, Deletemax and Deletemed applied to a node x remove the smallest, largest and the $\lceil n/2 \rceil$th smallest (i.e. median) elements from the list of data elements contained in the subtree generated by x.

Every node x has three storage registers (L(eft), M(iddle) and R(ight)), the contents of which are denoted by x.L, x.M and x.R. Each non-leaf node x has x.L, x.M and x.R as the smallest, median and largest data elements respectively in the subtree generated by x. A non-leaf node is called "balanced" if the number of data elements of its left subtree is equal to that of its right subtree. A node is called "right biased" if its right subtree has one more data element than its left subtree. Every node is either "balanced" or "right biased" which is denoted by a flag. If a node x does not contain three data (i.e. it is a leaf node), insert and delete operations at that node are obvious. For example, if x has two data elements, x.L and x.M, and if I[Y] is to be executed, we only need to adjust x.L, x.M, and x.R, accordingly. No instruction will be pipelined further.

Consider operations on a node x which has three data elements. First consider I[Y] applied at a node x with the left child y and the right child z. Temporarily, we ignore the balancing.

(case 1) If Y< x.L, x sends I[x.L] to its left child y and sets x.L to Y.
(case 2) If x.L<Y< x.M, x sends I[Y] to its left child y.
(case 3) If x.M<Y< x.R, x sends I[Y] to its right child z.
(case 4) If Y>x.R, x sends I[x.R] to its right child z and sets x.R to Y.

0190-3918/86/0000/0669 $01.00 © 1986 IEEE

Now we consider the balancing. If a node is balanced and sends an insert instruction to its right child, or if it is right biased and sends an insert instruction to its left child the node simply changes its flag. Otherwise, the tree needs to be balanced. To simplify the description, we assume that if a leaf node w has only one element. then $w.L=w.M$. Also, if a leaf node has two data elements, they are stored in the registers L and R, accordingly.
(i) If node x is balanced before the insertion I[Y] is applied and $Y<x.M$, an insert instruction must be sent to its left child (as in case 1 and 2) above. The following modification is therefore required.

1. x sends I[x.M] to its right child z and sets x.M to max(Y,y.R).

2. If $Y<x.L$, x sends an instruction IR[x.L] to the left child y and sets x.L to Y. (The instruction IR[b] when applied to a node y will delete y.R and insert b at y).

   If $x.L<Y<x.M$ and $Y>y.R$, then no instruction is sent to y (note that x.M is set to Y).

   If $x.L<Y<x.M$ and $Y<y.R$, then x sends IR[Y] to its left child y (note that x.M is set to y.R)

3. x changes its flag to 1.

(ii) If x is right biased before I[Y] is applied and $Y>x.M$, then the following modification is necessary because an insert instruction must be sent to its right child.

1. x sends I[x.M] to its left child y and sets x.M to min(Y,z.L).

2. If $Y>x.R$, x sends an instruction IL[x.R] to its right child z and sets x.R to Y. where an instruction IL[W] applied at node z will delete z.L and insert W at z.

   If $x.M<Y<x.R$ and $Y<z.L$. then no instruction is sent to z (note that x.M is set to Y).

   If $x.M<Y<x.R$ and $Y>z.L$. then x sends IL[Y] to its right child z.

3. x changes its flag to 0.

As shown above, some insert instructions may generate instructions IL and IR in the next stage. Let us consider the process of IL[Y] at node x. IR[Y] can be executed similarly. If node x is a leaf node, IL[Y] simply deletes x.L and inserts Y into node x. Consider an IL[Y] to a nonleaf node x with left child y and right child z.
If $Y<y.L$, x.L is set to be Y and no further processing is necessary. Otherwise, x sets x.L to y.L and does the following process:
(a) If $y.L<Y<x.M$, x sends IL[Y] to y.
(b) If $x.M<Y<z.L$, x sends IL[x.M] to y, sets x.M to Y.
(c) If $z.L<Y<x.R$, x sends IL[x.M] to y, sets x.M to z.L and sends IL[Y] to z.
(d) If $Y>x.R$, x sends IL[x.M] and IL[x.R] to y and z respectively, and sets x.M to z.L and x.R to Y.

Note that neither IL nor IR instruction changes the flag of the node. The case when node x has only one child can be handled in a similar way. Figure 3 shows the data distributions after a sequence of insert operations are done.

A Deletemin instruction at node x with left child y and right child z causes the following actions. First, x sets x.L to y.L. If x is balanced (before Deletemin is applied), x sends Deletemin to its left child y. If x is right biased, x sends IL[x.M] to y, sets x.M to z.L and sends Deletemin to z. Then, x changes its flag.

Similar operations can be derived for Deletemax and Deletemed. [CHA85] Note that each delete operation must be followed by a compress cycle so that when a delete operation is applied at a non-leaf node x, x must have three data elements after the operation.

## 4. Dictionary Machine

The dictionary machine, in addition to the above priority queue operations, permits Delete[Y], which removes the key Y from the dictionary and is denoted by D[Y]. First, we discuss the action taken at each node as a result of each operation under the assumption that no redundant operation is allowed. Later the issue of redundancy is considered. D[Y] applied at a leaf node can be handled in an obvious way. Suppose that D[Y] is applied at node x with left child y and right child z.

(i) If $x.L=Y$, x sets x.L to y.L and sends down Deletemin to its left child y. If node x is balanced (before D[Y] is applied), no further processing is necessary for balancing. If node x is right biased, then x sends I[x.M] together with Deletemin to its left child y. sets x.M to z.L and sends Deletemin to its right child z.

(ii) If $x.L<Y<x.M$. D[Y] must be sent to the left child y. If x is balanced, no further process at node x is necessary for balancing. If x is right biased, x sends I[x.M] together with D[Y] to its left child y, sets x.M to z.L and sends down Deletemin to its right child z.

(iii) If $x.M=Y$ and x is balanced, x sets x.M to y.R and sends Deletemax to its left child y. If $x.M=Y$ and x is right biased, x sets x.M to z.L and sends Deletemin to the right child z.

(iv) If $x.M<Y<x.R$, D[Y] must be sent to the right child z. If x is right biased, no further process is needed at node x for balancing. If x is balanced, x sends I[x.M] together with D[Y] to its right child z, sets x.M to y.R and sends Deletemax to its left child y.

(v) If $x.R=Y$, x sets x.R to z.R and sends Deletemax to its right child z. If x is right biased, no further process is needed at node x for balancing. If x is balanced, x sends I[x.M](together with the Deletemax) to its right child z, sets x.M to y.R and sends Deletemax to its left child y.
In each of the above cases, node x changes its flag.

As described above, a delete instruction at a node may require the node to send a pair of instructions to its child in the next stage. The execution of an instruction pair is very similar to the execution of the instructions IL and IR generated in a priority queue. Also, the processes that take place for an instruction pair arriving at a leaf node or a node having only one child can be described in an obvious way. Figure 4 shows the configurations of a dictionary machine before and after a deletion.

When redundant insert and delete are allowed, we need extra O(log n) time cycles to check the redundancy. Each instruction has three phases: broadcasting phase, verifying phase and execution phase. During the broadcasting phase, the given instruction will be broadcasted down the tree. The verifying phase starts when the instruction arrives at the leaf nodes. During the verifying phase, the instruction arriving at a leaf node moves up to the root by checking data stored in nodes and the instructions which are in the execution phase. Thus, at the root node, the redundancy of the instruction is finally verified. For example, the instruction I[X] which follows I[X]. and D[X] which follows D[X] should be flagged as redundant. Special care must be taken to consider the two cases.
(i) I[X] is in the execution phase and two D[X] instructions are in the verifying phase. The first D[X] should be non-redundant.
(ii) D[X] is in the execution phase and two I[X] are in the verifying phase. The first I[X] is non-redundant.

# A COMPARATIVE STUDY OF TWO SYSTEMATIC DESIGN METHODOLOGIES FOR SYSTOLIC ARRAYS

*M. T. O'Keefe and J. A. B. Fortes* *
School of Electrical Engineering
Purdue University
West Lafayette, IN 47907

## Abstract

This paper identifies equivalences between two systematic methodologies for the design of systolic arrays and illustrates the benefits of understanding these relationships. The methods are the parameter method of Li and Wah and the dependency method of Moldovan and Fortes. After a review of the core ideas, models and parameters of each method, mathematical relations between them are derived. The usefulness of these relationships is illustrated by showing how (1) optimization procedures for the parameter method suggest similar procedures for the dependency method, and (2) new systolic equations for the parameter method result from the knowledge of equivalent equations in the dependency method. Also, systolic designs for convolution, obtained through different methods, can be mathematically proven to be identical [5].

## I - Introduction

In this paper, two proposed methodologies for the systematic design of systolic arrays are comparatively studied. They are the data dependency method of Moldovan and Fortes, [1]-[3], and the parameter method of Li and Wah [4]. We find and expose the recondite relationships and equivalences between the two methodologies and use this information to improve them and verify similar designs.

Section II provides a short description of both methodologies. Section III establishes equivalences between the mathematical expressions used to systematically design systolic arrays in the two methods. The equivalences of section III are used in section IV to propose optimization procedures and improvements for both methodologies.

## II - Introduction to the Parameter and Data Dependency Methods

### 2.1 Parameter Method [4]

This methodology considers the design of optimal pure planar systolic arrays for a class of linear recurrences which take the general form

$$z_{i,j}^{k} = f\left[z_{i,j}^{k+\delta}, x_{\hat{x}(i,k)}, y_{\hat{y}(k,j)}\right], \delta = \pm 1 \qquad (2.1.1)$$

where $f$ is the function to be executed by each cell of the array and $\hat{x}(i,k)$, $\hat{y}(k,j)$ are linear indexing functions for the two-dimensional input variables **X** and **Y**. In the following presentation, the coefficients of i,j, k are either 1 or -1. One-dimensional recurrences have the general form

$$z_{i}^{k} = f\left[z_{i}^{k+\delta}, x_{\hat{x}(i,k)}, a_{\hat{a}(k)}\right], \qquad \delta = \pm 1 \qquad (2.1.2)$$

Three sets of parameters are used to characterize a systolic array: velocities of data flow, data distributions, and periods of computation. The velocity of a datum $x$ is the directional distance passed by that datum in one clock cycle and is denoted by $\vec{x}_d$. The distance between two PEs is defined to be one. Thus, $\vec{x}_d$ must be less than or equal to one because broadcasting is not allowed in pure systolic arrays.

Data distributions are defined using row and column displacements. For two-dimensional input and output matrices, the elements along a row or column are arranged in a straight line and the distance between adjacent elements in a row or column remains constant as the data flows through the array. To define the row displacement of array **X**, suppose that the row and column indices of **X** are $i$ and $j$, respectively. The row displacement of **X** is the directional distance between $x_{\hat{x}(i,j)}$ and $x_{\hat{x}(i+1,j)}$ and is written as $\vec{x}_{is}$. Similarly, the column displacement is the distance between $x_{\hat{x}(i,j)}$ and $x_{\hat{x}(i,j+1)}$ and is written as $\vec{x}_{js}$.

Periods of computation are described using two functions, $\tau_c$ and $\tau_a$. $\tau_c$ is defined as the time at which a computation is performed, whereas $\tau_a$ defines the time at which a variable is accessed. The periods of $i$ and $j$ for two-dimensional outputs are defined as

$$t_i = \tau_c(z_{i+1,j}^{k}) - \tau_c(z_{i,j}^{k}) \qquad (2.1.3)$$

$$t_j = \tau_c(z_{i,j+1}^{k}) - \tau_c(z_{i,j}^{k}) \qquad (2.1.4)$$

$$t_k = \tau_c(z_{i,j}^{k+1}) - \tau_c(z_{i,j}^{k}) \qquad (2.1.5)$$

It will be assumed that $t_k$ is positive. If this is not true for a given recurrence, the recurrence can be rewritten to satisfy this condition. In computing $z_{i,j}^{k}$, $x_{\hat{x}(i,k)}$ and $y_{\hat{y}(k,j)}$ are accessed and two additional periods can be included to describe this interaction. They are

$$t_{kx} = \tau_a(x_{\hat{x}(i,k+1)}) - \tau_a(x_{\hat{x}(i,k)}) \qquad (2.1.6)$$

$$t_{ky} = \tau_a(y_{\hat{y}(k+1,j)}) - \tau_a(y_{\hat{y}(k,j)}) \qquad (2.1.7)$$

Depending on the order of access, $t_{kx}$ and $t_{ky}$ may be negative. Since operands to be used in a computation must arrive at a PE simultaneously, the magnitude of the periods must equal $t_k$, i.e. ,it must be true that

$$t_k = |t_{kx}| = |t_{ky}| \qquad (2.1.8)$$

The periods are independent of the indices $i$, $j$, and $k$, and they must be greater than or equal to one to prevent broadcasting.

These parameters (velocity, data distribution, and periods) can be combined into a set of equations which describe the operations of a systolic array. These equations, for the two-dimensional case, are

$$t_{kx}\vec{x}_d + \vec{x}_{ks} = t_{kx}\vec{z}_d \qquad (2.1.9)$$

$$t_{ky}\vec{y}_d + \vec{y}_{ks} = t_{ky}\vec{z}_d \qquad (2.1.10)$$

$$t_i\vec{x}_d + \vec{x}_{is} = t_i\vec{y}_d \qquad (2.1.11)$$

$$t_i\vec{z}_d + \vec{z}_{is} = t_i\vec{y}_d \qquad (2.1.12)$$

$$t_j\vec{y}_d + \vec{y}_{js} = t_j\vec{x}_d \qquad (2.1.13)$$

$$t_j\vec{z}_d + \vec{z}_{js} = t_j\vec{x}_d \qquad (2.1.14)$$

For the one-dimensional case, the last two equations are removed from the set of systolic equations given above.

0190-3918/86/0000/0672 $01.00 © 1986 IEEE

The optimal systolic array for a given recurrence can be found by systematically enumerating the possible solutions using a search order that guarantees that the first feasible solution found is, in fact, the optimal one. Consider optimizing **T**, the total time needed to complete the computation. First set the magnitudes of the directional distance traversed by the variables equal to 1, i.e., $k_1 = k_2 = k_3 = 1$ [4]. Then, set the magnitudes of the periods $t_i$, $t_j$, and $t_k$ equal to one and determine if a feasible solution exists. If a feasible solution is found it is the optimal solution for **T** because **T** is a linear function of the periods that increases monotonically with increases in the magnitude of these periods. If no feasible solution is found with $t_i = t_j = t_k = 1$, one of the periods is increased by one and the search for a feasible solution repeats. If no feasible solution can be found with $k_1 = k_2 = k_3 = 1$, one of the $k_{i}$, $1 \leq i \leq 3$, is increased by one and the search begins again. A flowchart describing this optimality procedure is shown in [5]. A similar procedure is used to optimize the $\mathbf{AT}^2$ measure [4],[5].

## 2.2 Data Dependency Method [1]-[3]

The essence of the data dependency method is the representation of the dependency structure of an algorithm in concise, matricial form. That is, the dependencies between computations are condensed into an matrix that can be easily understood and manipulated.

Let $Z^n$ denote the nth cartesian power of Z, the set of nonnegative integers. To describe an algorithm **A**, a five tuple $\mathbf{A} = (\mathbf{J}^n, \mathbf{C}, \mathbf{D}, \mathbf{X}, \mathbf{Y})$ is used where $\mathbf{J}^n \subset \mathbf{Z}^n$ is the index set, **C** is the set of computations, **D** is the set of dependence vectors, **X** is the set of input variables, and **Y** is the set of output variables. The data dependencies describe the structure of the algorithm and are given as a set of triples $(\bar{d}, v, \bar{j})$ such that the computation indexed by $\bar{j}$ requires the variable v, generated at index $\bar{j} - \bar{d}$, as an operand.

Linear indexing functions [3] describe how variables are referenced. A linear indexing function $\bar{\mathbf{F}}: \mathbf{J}^n \rightarrow \mathbf{Z}^m$ is defined by an equation of the form $\bar{\mathbf{F}}(\bar{j}) = \bar{\mathbf{C}}_0 + \mathbf{C}\bar{j}$ where $\bar{\mathbf{C}}_0 \in \mathbf{Z}^{(m \times 1)}$ is called the index displacement and $\mathbf{C} \in \mathbf{Z}^{(m \times n)}$ is called the indexing matrix. For example, the variable $a(j_1 - j_2, j_2 + j_3 - 1, j_3 - j_1)$ has a linear indexing function for which

$$\mathbf{C} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & 1 \\ -1 & 0 & 1 \end{bmatrix} \quad \text{and} \quad \bar{\mathbf{C}}_0 = \begin{bmatrix} 0 \\ -1 \\ 0 \end{bmatrix} .$$

A transformation matrix **T** can be used to describe a linear bijection which transforms the dependency matrix and index set of an algorithm so that it can be executed in a VLSI array. **T** can be partitioned into two matrices, $\pi$ and S:

$$\mathbf{T} = \begin{bmatrix} \pi \\ \mathrm{S} \end{bmatrix}$$

The $\pi$ matrix defines the time transformation whereas S defines the space transformation to be applied to the dependence matrix and index set of an algorithm. The time at which a computation indexed by $\bar{j}$ is executed is determined by $\pi\bar{j}$, while $\mathrm{S}\bar{j}$ specifies which processor is to execute this computation. Of course, $\pi$ and S must satisfy certain conditions if they are to be considered valid transformations. Let *m* be the number of columns in the dependency matrix. Time transformations must satisfy $\pi\bar{d}_i > 0$, $i=1,2,\ldots,m$, where $\bar{d}_i$ is a column vector in the dependence matrix. This constraint results from the requirement that a variable must be generated before it is used in a computation.

The space transformation $\underline{\mathbf{S}}$ maps the computation indexed by $\bar{j}$ into processor $\mathrm{S}\bar{j}$. This assumes a processor array model consisting of a grid which has the dimensionality of the array Each point of the grid corresponds to a processor and the coordinates of the point are the index of the processor. Certain restrictions must be placed on possible solutions for **S** due to the limited interconnections available in VLSI arrays. These restrictions can be embodied in the **P** and **K** matrices. The **P** matrix describes the interconnection primitives available within an array, i.e., the vector differences between indices of connected processors. The utilization matrix **K** describes the interconnections used by the transformed algorithm during execution. The relationship between **K**, **P**, **S**, and **D** is

$$\mathbf{SD} = \mathbf{PK} \tag{2.2.1}$$

where the entries of **K** must satisfy the following constraint

$$\sum_{j=1}^{r} k_{ij} \leq \pi\bar{d}_i \ , \ i=1,\ldots,m \quad . \tag{2.2.2}$$

This last constraint requires that the time between the generation and use of a variable must be greater than or equal to the number of interconnection primitives needed by the datum to travel from the PE in which it was generated to the PE in which it will be used. Optimization procedures for the dependency method are given in [2],[3].

## III - Equivalences between the Parameter and Data Dependency Methods

*Lemmas* 1–3 provide equivalences between the different parameters of the two methods, while *Lemma* 4 describes the form of the dependency matrices for algorithms considered in the data dependency method. These lemmas are then applied in *Theorem* 1 to show that the space equations and systolic processing equations are equivalent. The proofs are omitted here but can be found in [5].

The first lemma gives expressions for the data distribution and velocity vectors of the parameter method in terms of the transformations and indexing matrices of the data dependency method.

*Lemma 1*

Let S, $\pi$ be as defined previously in section 2.2, and let *v* be any of the variables *x*, *y*, *z* as given for the parameter method. Also, let $\mathrm{C}^v$ represent the indexing matrix for variable *v*. Then the following relationships hold for the two-dimensional case:

$$\mathrm{S}\begin{bmatrix} \mathrm{C}^v \\ \pi \end{bmatrix}^{-1} \begin{bmatrix} \pm1 \\ 0 \\ 0 \end{bmatrix} = \vec{v}_{is} \ , \ \mathrm{S}\begin{bmatrix} \mathrm{C}^v \\ \pi \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ \pm1 \\ 0 \end{bmatrix} = \vec{v}_{js} \ ,$$

$$\mathrm{S}\begin{bmatrix} \mathrm{C}^v \\ \pi \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 0 \\ \pm1 \end{bmatrix} = \vec{v}_d$$

For the one-dimensional case, the following relationships apply:

$$\mathrm{S}\begin{bmatrix} \mathrm{C}^v \\ \pi \end{bmatrix}^{-1} \begin{bmatrix} \pm1 \\ 0 \end{bmatrix} = \vec{v}_s \ , \ \mathrm{S}\begin{bmatrix} \mathrm{C}^v \\ \pi \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ \pm1 \end{bmatrix} = \vec{v}_d$$

The following lemma describes the relationship between the $\pi$ vector of the data dependency method and the periods $t_i$, $t_j$, $t_k$ of the parameter method. The relationship is remarkably simple.

*Lemma 2*

$$\pi = \begin{bmatrix} t_i & t_j & t_k \end{bmatrix}$$

Thus, the periods of the parameter method are the elements of the $\pi$ matrix. The next lemma relates the elements of the data dependency method's **K** matrix and the constants, $k_i$ $(1 \leq i \leq 3)$, as defined in [4]; i.e., $|t_k| \, |\vec{z}_d| = k_1$ , $|t_i| \, |\vec{y}_d| = k_2$ , $|t_j| \, |\vec{x}_d| = k_3$ . Let $\hat{k}_i$ be the single nonzero entry of the i'th column of **K**.

*Lemma 3*

$$\hat{k}_i = k_i \qquad 1 \leq i \leq 3$$

The next lemma describes the form of the dependency matrices for the class of recurrences considered in the parameter method.

*Lemma 4*

The dependency matrices for the class of recurrences considered in the parameter method have the following structure:

**Two-dimensional Recurrence:**

$$\mathbf{D} = \left[\begin{array}{ccc|c} \pm 1 & 0 & 0 & \\ 0 & \pm 1 & 0 & \bar{d}_1 \ldots \bar{d}_r \\ 0 & 0 & \pm 1 & \end{array}\right]$$

**One-dimensional Recurrence:**

$$\mathbf{D} = \left[\begin{array}{cc|c|c} \pm 1 & 0 & c_1 & \\ 0 & \pm 1 & c_2 & \bar{d}_1 \ldots \bar{d}_r \end{array}\right] , \; | c_1 | = | c_2 | = 1$$

where $\bar{\mathbf{d}}_1, \ldots, \bar{\mathbf{d}}_r$ are dependency vectory which are a function of the recurrence, as is r, the total number of these additional dependencies.

The following theorem states that the equations used in both methods to describe the operation of a systolic array are equivalent.

*Theorem 1*

The constraint equations (2.1.9 - 2.1.14) of the parameter method are equivalent to the space equations, **SD = PK**, of the data dependency method.

## IV - Optimization Procedures and Examples

### 4.1 Optimization Procedures

Optimization procedures for the parameter method were discussed previously in section II. By directly translating the parameters and constraints of this method into the corresponding elements of the dependency method, we can devise a similar procedure which is applicable to the recurrences considered in [4]. However, by using a slightly different approach, it is possible to propose a related optimization procedure applicable to all cases for which disp$\pi$=1 in the dependency method. Note that disp$\pi$ refers to the number of parallel wavefronts in the array. It differs from that proposed for the parameter method in that it checks all possible values of K before considering longer execution times (i.e., different $\pi$'s). The flowchart of Figure 1 describes the new optimization procedure. In words, it starts by finding all transformations $\pi$ which minimize execution time. This is relatively easy, since only the case disp$\pi$=1 is considered and execution time is therefore a monotonic function of the entries of $\pi$. Hence, one can start with all entries of $\pi$ being zero and progressively increase their absolute values considering all possible combinations of signs and magnitudes (while, of course, checking for the validity of each $\pi$). Possible $\pi$'s, which might result from further increases in the absolute value of the entries of a particular $\pi$ for which execution time is larger than the known minimum, need not be considered due to monotonicity property mentioned above. Thus, the search space is finite, and, in fact, rather small for most cases. Once the set of $\pi$'s is known, it is necessary to check if there exists a solution to the equation SD=PK for at least one of the possible values of K. If a solution is found, then the corresponding $\pi$ (as well as the design determined by $\pi$ and S) is optimal with respect to execution time. Otherwise, a new set of $\pi$'s must be found which increase execution time by the least amount and the process is repeated again. The procedure always terminates, since, in the worst case, serial execution is reached as a feasible solution.

A similar reasoning can be used to optimize measures combining area and execution time, e.g., AT or $AT^2$. Figure 2 illustrates such a procedure. It differs from that of figure 2 in that the search space is reduced to the set of $\pi$'s which result in execution time bounded above by a constant factor [4]. In this finite space, all valid values of $\pi$ and S are considered and those which optimize the combined measure of area and time determine the optimal solution. This is exactly the same approach used in the parameter method. The key idea consists of limiting the search space by choosing bounds for $\pi$ and, thus, for the execution time.

### 4.2 New systolic equations

Convolution can be expressed as the following recurrence equation

$$y_i^0 = 0 \quad 1 \leq i \leq n$$

$$y_i^k = y_i^{k-1} + a_k x_{i+k-1} \quad 1 \leq i \leq n,$$

$$1 \leq k \leq m, \; x_j = 0 \text{ for } j > n \tag{4.1}$$

Another possible description with the order of access of the input terms reversed is

$$y_i^k = y_i^{k-1} + a_{m-k+1} x_{m-k+i} \quad 1 \leq i \leq n,$$

$$1 \leq k \leq m, \; n > m \tag{4.2}$$

*Theorem 1* showed that the systolic equations of the parameter method are equivalent to the space equations, **SD = PK**, of the data dependency method. Systolic equations for the one-dimensional case are equivalent to $\mathbf{S\bar{d}_y = P\bar{k}_y}$ and $\mathbf{S\bar{d}_a = P\bar{k}_a}$, respectively. The subscripts on the vectors $\bar{\mathbf{k}}$ and $\bar{\mathbf{d}}$ indicate which variable is associated with a particular vector. Thus, the $\mathbf{S\bar{d}_x = P\bar{k}_x}$ space equation is not contained within the systolic equations of the parameter method for the one-dimensional case.

The systolic equations for the $x$ dependency will take the general form

$$f_a \vec{\mathbf{a}}_d + \vec{\mathbf{a}}_s = f_a \vec{\mathbf{x}}_d \tag{4.3}$$

$$f_y \vec{\mathbf{y}}_d + \vec{\mathbf{y}}_s = f_y \vec{\mathbf{x}}_d \tag{4.4}$$

where $f_a$ and $f_y$ are linear functions of $t_i$ and $t_k$. To determine the functions $f_a$ , $f_y$ , the equivalences defined in *Lemmas* 1 and 2 are applied to (4.3-4.4) resulting in $f_a = -(t_i + t_k)$ , $f_y = (t_i + t_k)$ and these equations become

$$-(t_i + t_k)\vec{\mathbf{a}}_d + \vec{\mathbf{a}}_s = -(t_i + t_k)\vec{\mathbf{x}}_d$$

$$(t_i + t_k)\vec{\mathbf{y}}_d + \vec{\mathbf{y}}_s = (t_k + t_i)\vec{\mathbf{x}}_d$$

The above analysis was applied to the recurrence of equation (4.2). A similar analysis of the recurrence expressed in equation (4.1) results in $f_x = (t_k - t_i)$ and $f_y = -(t_k - t_i)$ in equations (4.3) and (4.4). This new set of systolic equations, derived from the data dependency method through the equivalences described in Section III, can be added to the set of systolic equations. From this new set, only four equations are needed to provide equivalent solutions to those derived from the original four equations.

## ABSTRACT

In this paper we propose several data structures partitioning and transformation schemes, in order to get an efficient execution of various matrix algorithms without any size restriction. The following matrix operations are considered:

- Matrix-Matrix multiplication
- Triangular matrix equations.
- L-U decomposition and
- Inverses of triangular and dense matrices.

All these algorithms are to be executed on a problem-size independent spiral systolic array processor. The array topology is fixed, and a simple feedback and control are needed. For all the algorithms that have been considered, the PE's utilization tends to the maximum possible value.

## 1. INTRODUCTION

With the advent of VLSI, cheap processors can be nowadays designed to solve at very high speed one subset of numerical or symbolic applications. An interesting class of systems are the systolic array processors (SAP) /1/,/2/.

In a strict sense, a SAP allows the hardware implementation of an algorithm which settles the functions to be performed in every PE, the number of PEs and the system topology. Many systolic algorithm implementations have been proposed: /2/, /3/. Nevertheless, a clear trend exists towards the realization of SAP connected to a host, in order to execute several algorithms.

Two important problems arise when this kind of processors is considered: the PEs operation and sometimes the interconnection topology must be programmable, and computations on different sized data structures must be executed in a fixed number of PEs. In order to get the maximum efficiency of the global system, the partitioning algorithms must impose the lower overhead possible with respect to the execution time spent by the complete problem, the extra control needed to modify the PEs functionality, their interconnections, and the access from the boundaries PE to the data structures. To evaluate the system efficiency, the utilization factor of the systolic array, or the number of time units (T) needed to execute the algorithm in the system can be used.

In this paper, some data structures partitioning and transformation schemes are proposed, in order to get an efficient execution of various matrix algorithms, with no size restriction, on a fixed dimension single array processor. All the algorithms are to be executed on a contraflow hexagonal SAP with w-by-w PEs (see fig. 1). The array topology includes connections to recirculate and feedbacking of PEs with partial results (SAP with this interconnection topology has been named spiral SAP, (SSAP) /4/). Some of the boundaring PEs must be able of executing several functions as those to be described in section 2.

The notation to be used in the rest of this paper is explained in the following lines:

- Capital letters A, B, C, D, X, Y,... denote matrices and capital letters N, M, P,... the dimension of those matrices.
- Without any loss of generality, the matrices dimensions are supposed to be multiples of w. When this assumption is not true, we extend the matrix with

a sufficient and minimum number of rows and/or columns formed with zero-valued elements. Accordingly, we define: $\bar{N} = N/w$, $\bar{M} = M/w$, $\bar{P} = P/w$.

- Regarding the partitioning, if A is an $\bar{N}$-by-$\bar{M}$ matrix, we shall consider it as a $\bar{N}$-by-$\bar{M}$ block matrix. And now $A_{i,j}$ is the (i,j) block with w-by-w elements.
- The following submatrices of A are defined:
  - $A^k_{i,*}=(A_{i,1},A_{i,2},\dots A_{i,k})$ for $1 \le k \le \bar{M}$ and $1 \le i \le \bar{N}$. $A^k_{i,*}$ is a block-row matrix with w-by-kw elements.
  - $A^k_{*,j}=(A_{1,j},A_{2,j},\dots A_{k,j})^T$ for $1 \le k \le \bar{N}$ and $1 \le j \le \bar{M}$. $A^k_{*,j}$ is a block-column matrix with kw-by-w elements.
  - $A^k_{*,*}=(A^k_{1,*},A^k_{2,*},\dots,A^k_{k,*})^T= =(A^k_{*,1},A^k_{*,2},\dots A^k_{*,k})$ for $1 \le k \le \min(\bar{N},\bar{M})$. $A^k_{*,*}$ is a k-by-k block matrix.

Every $A_{i,j}$ is, in turn, decomposed into the following matrices:

$$A_{i,j} = A_{Li,j} + A_{Di,j} + A_{Ui,j} = \\ = A_{LDi,j} + A_{Ui,j} = A_{Li,j} + A_{DUi,j}$$

where: $A_L$ ($A_U$) are strictly lower (upper) triangular matrices, $A_D$ is a diagonal matrix, and $A_{LD}$ ($A_{DU}$) are lower (upper) triangular matrices.

The outline of this paper is as follows: in section 2 the concepts of partitioning and transformation of a dense problem into an equivalent band problem is introduced; in section 3 the problem D=A.B+C is solved, and the solution presented there is reused in subsequent sections;insection 4 the methodology to solve triangular matrix equations is applied; in section 5 the LU decomposition without pivoting is solved; and in section 6 operation of inverting triangular matrices and $A^{-1}=U^{-1}.L^{-1}$, is presented. Finally, in section 7 the main conclusions of this work are summarized.

## 2. PARTITIONING AND DATA RESTRUCTURATION

Several partitioning algorithms of matrix problems have been recently proposed. These algorithms are intended to work on SIMD array processors, pipeline vector supercomputers /5/, Modular VLSI arithmetic systems /6/, or systolic array processors /7/, /8/.

It is imperative to attain a good matching between the resulting partitioned submatrices and the array processing system, because the maximum utilization of the SAP PEs is desired. The data restructuration serves to define the sequence to chain the execution of subproblems in a SAP. This function must ensure the correctness of the solution and must allow a simple control and a maximum PEs utilization. Overlapping of a subproblem loading with the unloading of the precedent, is an adequate feature to maximize the system utilization.

In our work a contraflow SAP is used. This SAP constitute a good solution to problems requiring the computation of recurrences (e.g. a linear triangular system solving, LU decomposition... /9/).

A triangular partitioning, and various types of data restructurations to transform dense to band matrices, are proposed in /10/. Those transformations yield to maximum efficiency of the PEs utilization. Such a methodology is applied to matrix-matrix and matrix-vector multiplications.

To achieve this goal, each N-by-M matrix A is partitioned into $\bar{N}$-by-$\bar{M}$ block matrices. Each w-by-w block matrix $A_{i,j}$ is split into two triangular matrices $A_{LDi,j}$ and $A_{Ui,j}$ (or $A_{Li,j}$ and $A_{UDi,j}$). The optimal restructuration is attained by juxtaposing these triangular submatrices, by means of different algorithms, in order to obtain a $\bar{N}\bar{M}$+1-by-$\bar{N}\bar{M}$ ($\bar{N}\bar{M}$-by-$\bar{N}\bar{M}$+1) block lower (or upper) band matrix, $\bar{A}$. Maximal efficiency is achieved because the $\bar{A}$ band contains only elements from the original matrix, A, with no empty positions.

When problems that include inner product operations are appointed, several considerations to obtain $\bar{A}$ must be taken into account.

a) For $1 \le k \le \bar{N}\bar{M}$, if $\bar{A}_{kk}=A_{LDi,j}$, then $\bar{A}_{k+1,k}$ must be equal to $A_{Up,j}$ for any p such that $1 \le p \le \bar{N}$.

b) For $2 \le k \le \bar{N}\bar{M}$, if $\bar{A}_{k,k-1}=A_{Ui,j}$ then $\bar{A}_{k,k}$ must be equal to $A_{LDi,p}$ for any p such that $1 \le p \le \bar{M}$.

c) Obviously, dependencies in the computational sequence needed by some algorithms must be respected.

We shall name this type of transformations as Dense to Band Matrix Transformation by Triangular block Partitioning, (DBT).

The PRT /11/ and PCT /12/ transformations, proposed by R.W. Priester et al., can be regarded as particular cases of the DBT. The transformation of a N-by-N dense matrix into a band matrix with bandwith w=N is proposed in the mentioned papers; they attain a 50% reduction of the number of PEs in the SAP, with no overhead in the algorithm time under certain conditions.

Our DBT method serves to transform all the algorithms mentioned above, and the obtained algorithms are to be executed on a single hexagonal SSAP with w-by-w PEs (fig. 1). The feedbacking needed to recirculate all partial results introduces a delay of w cycles, except in the case of the main diagonal which is 2w cycles. As the SSAP must execute various algorithms, some PEs must be able of executing several operations, according to the precise algorithm and the precise cycle. In figure 2, the elementary processor is shown, as well as the types of operations needed, named OP(A), OP(B)etc.. The PEs(i,j), $2\leq i,j\leq w$, perform only OP(A), which corresponds to the type of inner product step processor /19/. The PEs(1,j), with $2\leq j\leq w$, must perform OP(B) and OP(D). The PEs(i,1), with $2\leq i\leq w$, must perform OP(A) and OP(F). Finally, the PE(1,1) performs all types of operation.

## 3. MATRIX-MATRIX MULTIPLICATION

We consider now the operation:

$$D := A \cdot B + C \qquad (1)$$

to be performed on a w-by-w systolic array. When A,B and C are M-by-N, N-by-P and M-by-P matrices, the problem is partitioned into $\bar{M}\bar{P}$ disjoint subproblems, according to the algorithm:

```
Algorithm 1:
For m:= 1 to $\bar{M}$ do
    For p:= 1 to $\bar{P}$ do
        $D_{m,p} := A^{\bar{N}}_{m,*} B^{\bar{N}}_{*,p} + C_{m,p}$        (2)
```

Each one of the subproblems in (2) is solved sequentially by the SAP. Every subproblem is of the type:

$$D := A \cdot B + C \qquad (3)$$

where A,B and C are, respectively, w-by-N, N-by-w and w-by-w matrices. We focus our attention on the execution of one of these subproblems.

By means of DBT transformations on the dense matrices A and B, the problem (3) is mapped onto a banded problem (see fig. 3)

$$\bar{D} := \bar{A} \cdot \bar{B} + \bar{C} \qquad (4)$$

To define the transformed problem, partitioning of $A=(A_1 A_2 \ldots A_j \ldots A_{\bar{N}})$ and $B=(B_1 B_2 \ldots B_i \ldots B_{\bar{N}})^T$ into w-by-w triangular submatrices is required, as follows:

$A_j = A_{LDj} + A_{Uj} \quad 1\leq j\leq \bar{N}$

$B_i = B_{DUi} + B_{Li} \quad 1\leq i\leq \bar{N}$

Applying one DBT to A, $\bar{A}$ is obtained. $\bar{A}$ is a $(\bar{N}+1)$-by-$\bar{N}$ block lower two-diagonal matrix, with w-by-w blocks $\bar{A}_{i,j}$:

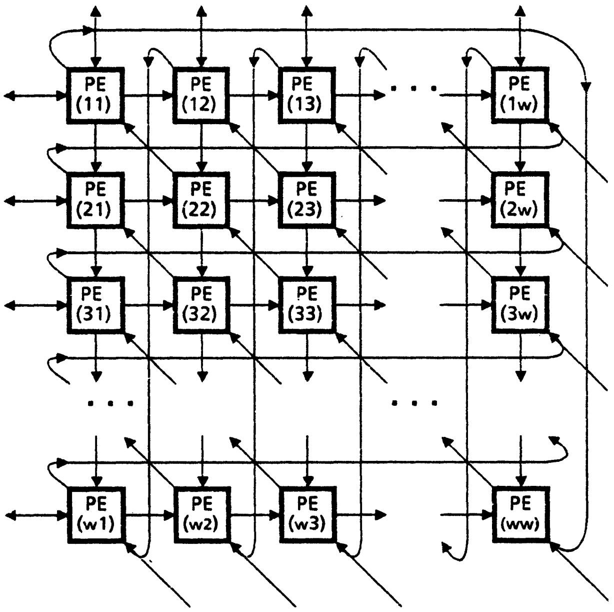

Fig. 1. Spiral Systolic Array Processor.

| OP (C) | OP (D) | OP (E) | OP (F) | OP (G) |
|---|---|---|---|---|
| N←SE/W<br>NW←0<br>S←-SE/W<br>E←1/W | NW←SE-N*W<br>S←-N<br>E←W | N←SE<br>W←1<br>S←1/SE<br>E←1 | NW←0<br>W←SE*N<br>S←N<br>E←SE*N | NW←0<br>W←SE/N<br>S←1/N<br>E←SE/N |

Fig. 2. PE's ports and operations.

for $1 \leq i \leq \bar{N}+1$ and $1 \leq j \leq \bar{N}$

$$\bar{A}_{i,j} = \begin{cases} A_{LDj} & \text{if } i=j \\ A_{Uj} & \text{if } i=j+1 \\ 0 & \text{if } i>j+1 \text{ or } i<j \end{cases}$$

In a similar way, we define another DBT on B, yielding $\bar{B}$ which is a $\bar{N}$-by-$(\bar{N}+1)$ block upper two-diagonal matrix with blocks $\bar{B}_{i,j}$.

for $1 \leq i \leq \bar{N}$ and $1 \leq j \leq \bar{N}+1$

$$\bar{B}_{i,j} = \begin{cases} B_{DUi} & \text{if } j=i \\ B_{Li} & \text{if } j=i+1 \\ 0 & \text{if } j>i+1 \text{ or } i<j \end{cases}$$

We define now $\bar{C}$ as a $(\bar{N}+1)$-by-$(\bar{N}+1)$ block tridiagonal matrix:

$$\bar{C}_{i,j} = \begin{cases} C \text{ if } i=j=1 \\ 0 \text{ otherwise} \end{cases} \quad \text{for } 1 \leq i,j \leq \bar{N}+1$$

Then $\bar{D}$ is a $(\bar{N}+1)$-by-$(\bar{N}+1)$ block tridiagonal matrix.

$\bar{D}_{1,1} := A_{LD1} \cdot B_{DU1} + C$

for $2 \leq k \leq \bar{N}$

$\bar{D}_{k,k} := A_{U(k-1)} \cdot B_{L(k-1)} + A_{LDk} \cdot B_{DUk}$

$\bar{D}_{\bar{N}+1,\bar{N}+1} := A_{U\bar{N}} \cdot B_{L\bar{N}}$

$\bar{D}_{Lk,k+1} := A_{LDk} \cdot B_{Lk}$ for $1 \leq k \leq \bar{N}$

$\bar{D}_{Uk+1,k} := A_{Uk} \cdot B_{DUk}$ for $1 \leq k \leq \bar{N}$

$\bar{D}_{i,j} := 0$ for $j<i-1$ or$j>i+1$

Figure 3.a shows the triangular blocks decomposition for problem (3). Figure 3.b shows the resulting band problem (4). Matrix $\bar{D}$ can be efficiently obtained on a hexagonal array with w-by-w PEs, similar to the one proposed by H.T. Kung in /19/. This can be accomplished in the w-by-w SSAP, by programming all the PEs with OP(A). The D matrix is the result of the original problem, and can be found from $\bar{D}$ by means of the following computation:

$$D = \sum_{k=1}^{\bar{N}} (\bar{D}_{k,k} + \bar{D}_{Lk,k+1} + \bar{D}_{Uk+1,k}) + \bar{D}_{\bar{N}+1,\bar{N}+1}$$

This computation may be performed inside the array by using the spiral systolic array feedbacks, causing no calculation time overhead.

To specify the required feedback, we define two matrices: I (input) and O (output), which are $(\bar{N}+1)$-by-$(\bar{N}+1)$ tridiagonal block matrices. I contains data and partial results which must come in through the SE ports of the South and East PEs. O contains the partial results coming out through the NW ports of the North and West PEs.

We have, consequently, the following inputs to the array:

$I_{1,1} := C$

for $2 \leq i \leq \bar{N}+1$

$$I_{Li,i} := O_{Li-1,i} = \sum_{k=1}^{i-1} \bar{D}_{Lk,k} + \sum_{k=1}^{i-1} \bar{D}_{Lk,k+1}$$

$$I_{Ui,i} := O_{Ui,i-1} = \sum_{k=1}^{i-1} \bar{D}_{Uk,k} + \sum_{k=1}^{i-1} \bar{D}_{Uk+1,k}$$

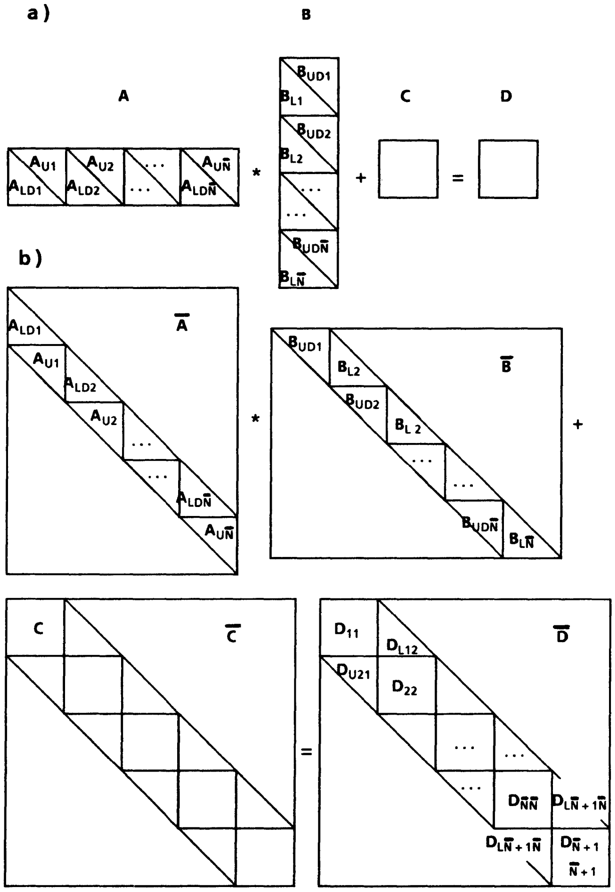

Fig.3. a) Particioning D = A*B + C in triangular submatrices
b) Band problem originated through a DBT transformation

$$I_{Di,i} := O_{Di-1,i-1} = \sum_{k=1}^{i-1} \bar{D}_{Dk,k}$$

for $1 \leq i \leq \bar{N}$

$$I_{Li,i+1} := O_{Li,i} = \sum_{k=1}^{i} \bar{D}_{Lk,k} + \sum_{k=1}^{i-1} \bar{D}_{Lk,k+1}$$

$$I_{Ui+1,i} := O_{Ui,i} = \sum_{k=1}^{i} \bar{D}_{Uk,k} + \sum_{k=1}^{i-1} \bar{D}_{Uk+1,k}$$

And the last output from the array is the desired result for (3):

$$O_{U\bar{N}+1,\bar{N}+1} := \sum_{k=1}^{\bar{N}+1} \bar{D}_{kk} + \sum_{k=1}^{\bar{N}} (\bar{D}_{Lk,k+1} + \bar{D}_{Uk+1,k}) = D$$

Remark that the elements of the output submatrices, $O_U$ or $O_L$, are required in the SE input ports w cycles later than their appearance at the output NW ports. The elements of $O_D$ must be delayed by 2w cycles, instead.

To compute D:=AB+C, when A and B are w-by-N and N-by-w matrices, in the SSAP, the elapsed time is T = 3N+4w. When A and B are M-by-N and N-by-P matrices, respectively, the resulting $\overline{MP}$ subproblems must be chained, originating a computation elapsed time: $T = 3MPN/w^2 +$ $+ 3MP/w+w$. The value of T can be diminished by $3(MP-w^2)/w$ time units if the DBT algorithm presented in /10/ is used, because a total chaining of the $\overline{MP}$ subproblems is attained.

## 4.TRIANGULAR MATRIX EQUATIONS

One of the basic problems in linear Algebra is the solving of a linear system of equations. A matrix equation

$$AX = B \qquad (5)$$

is a multiple set of linear systems, all working with the same matrix, A, and different column-vectors. If the main submatrices of A are all non singular, then there exist a unique lower-triangular matrix L with $l_{kk}=1$, and a unique upper-triangular matrix so that A=LU /24/. As a consequence, (5) is equivalent to LUX=B, yielding to a decomposition into two triangular matrix equations:

$$LY = B \qquad (6)$$
and
$$UX = Y \qquad (7)$$

In this section we consider the solution of the lower triangular matrix equation (6). The solving of equation (7) shall be briefly commented at the end of this section, as it resembles the solution of (6). Let us consider that L is a N-by-N lower triangular matrix, and Y, B are N-by-M matrices. The problem is first partitioned into $\bar{M}$ disjoint subproblems, according to the following algorithm:

**Algorithm 2:**

```
For m:=1 to $\bar{M}$ do
Compute $Y^{\bar{N}}_{*,m}$ from: $B^{\bar{N}}_{*,m} - L\,Y^{\bar{N}}_{*,m} = 0$   (8)
```

Each subproblem (8) is solved by the array in a sequently fashion. We focus our attention, now, in the resolution of one of these subproblems, e.g. the first one (m:=1)

$$B^{\bar{N}}_{*,1} - L\,Y^{\bar{N}}_{*,1} = 0 \qquad (9)$$

The direct solution of (9), by forward substitution, is again decomposed as follows:

**Algorithm 3:**

```
Compute $Y_{1,1}$ from: $B_{1,1} - L_{1,1}\,Y_{1,1} = 0$   (10)
for n:=2 to $\bar{N}$ do
$B_{n,1} := B_{n,1} - L^{n-1}_{n,*}\,Y^{n-1}_{*,1}$   (11)
Compute $Y_{n,1}$ from: $B_{n,1} - L_{n,n}\,Y_{n,1} = 0$   (12)
```

The submatrices, $Y_{n,1}$ with $1 \leq n \leq \bar{N}$, appearing in (10) and (12) must satisfy an equation as:

$$B - LY = 0 \qquad (13)$$

where L, Y and B are w-by-w matrices.

To find the Y matrix satisfying (13) using the SSAP, the problem (13) must be decomposed into subproblems with triangular matrices structures:

$$B_{DU} - (LY_{DU})_{DU} = 0 \qquad (14)$$

$$B_L - (LY_{DU})_L - LY_L = 0 \qquad (15)$$

If the boundary PEs are programmed in a way such that a) PE(1,1) performs OP(C) (see fig. 2), b) PEs (1,j) $2 \leq j \leq w$ perform OP(B) and c) the rest perform OP(A), the SSAP can solve equations of the type

$$\bar{B} - \bar{L}\,\bar{Y} = \bar{C} \qquad (16)$$

where $\bar{L}$ is a w-by-w lower triangular matrix, $\bar{Y}$ is a w-by-2w upper band matrix with bandwidth w, and $\bar{B}$ and $\bar{C}$ are w-by-2w band matrix with bandwidth 2w-1. In order to get the desired solution, $\bar{L}$

must be input through the $\bar{W}$, ports of the west boundary PEs, and $\bar{B}$ through the SE ports of the south and west PEs. The result $\bar{Y}$ is obtained at the ports of the north PEs, and the following equations are satisfied: $\bar{B}_{DU1,1} - (\bar{L}\,\bar{Y}_{1,1})_{DU} = 0$ and $\bar{B}_{L1,2} - \bar{L}\,\bar{Y}_{1,2} = 0$. Besides, matrix $\bar{C}$ is obtained at the NW ports of the North and West PEs, with: $\bar{C}_{DU1,1} = = \bar{C}_{L1,2} = 0$ and $\bar{C}_{L1,1} = \bar{B}_{L1,1} - (\bar{L}\bar{Y}_{1,1})_L$. By making $\bar{L} = L$ and $\bar{B}_{1,1} = \bar{B}$, $Y_{DU}$ can be obtained to satisfy (14), and $\bar{Y}_{1,1}$, $\bar{C}_{L1,1}$ are attained as: $\bar{Y}_{1,1} = Y_{DU}$ and $\bar{C}_{L1,1} = B_L - (L\,Y_{DU})_L$. If, in addition, $\bar{B}_{L1,2} = \bar{C}_{L1,1}$, the $\bar{Y}_{1,2}$ resulting submatrix is equal to the $Y_L$ submatrix that satisfies (15).

To complete the solution of problem (9) according to algorithm 3, the subproblems (11) must be solved. These subproblems consist in a block-row matrix $(L^{n-1}_{n,*})$ by block-column matrix $(-Y^{n-1}_{1,*})$ multiplication with accumulation of $B_{1,n}$. Each one of these subproblems can be solved in the array just like has been described in section 3, except that now the PEs(1,j) $1\leq j\leq w$ must perform OP(D) to change the sign of the previously calculated matrix, $Y^{n-1}_{1,*}$.

The chaining of the subproblems to be executed in the SSAP, according to algorithm 3, is shown in fig. 4. This figure shown the I/O block-data stream at the W, N, SE ports of the West, North, South and East PEs, respectively, for the case $\bar{N}$=3. The blocks labeled as f indicate that the corresponding data come from the feedback links.

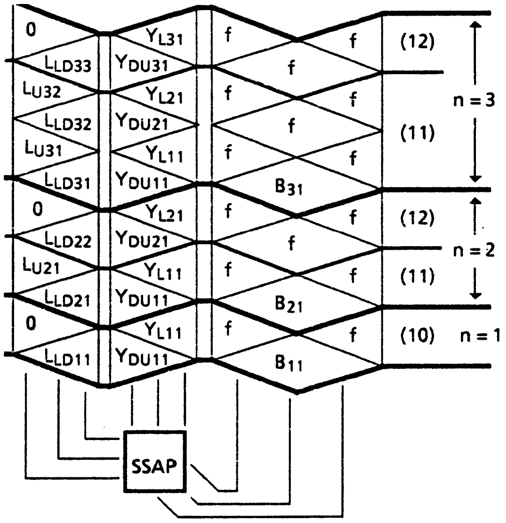

Fig.4. I/O block - data stream to solve matrix equations (with $\bar{N}=3$).

The computational time of one subproblem (8) is

$$T = 3N^2/2w + 3N/2 + w \tag{17}$$

The computational time of the $\bar{M}$ subproblems needed to solve the matrix equation LY=B where L is a N-by-N lower triangular matrix, and Y, B are N-by-M matrices is

$$T = 3MN^2/2w^2 + 3MN/2w + w \tag{18}$$

The problem (7) is solved by back substitution, that is through reordering of matrices and solution by forward substitution of the problem

$$X'\,U' = Y' \tag{19}$$

where X' and Y' are block-row matrices with $x'_i = x_{N-i+1}$ for $1\leq i\leq N$ and $y'_i = = y_{N-i+1}$ for $1\leq i\leq N$; and U' is upper triangular, with $u'_{i,j} = u_{N-j+1,N-i+1}$ for $1\leq i,j\leq N$.

If equation (19) is transposed, we arrive to the problem

$$U'^T\,X'^T = Y'^T \tag{20}$$

which is of type of problem (6), previously analyzed in this same section.

Normally, problem (7) is solved after performing a LU decomposition. In this case, as will be shown in the next section, the final results of matrix U are obtained at the North boundary PEs. Consequently, in the execution of (20) we shall consider that matrix $U'^T$ is available at the North boundary PEs, and $X'^T$ is obtained at the West boundary PEs. In order to get the solution, in those cycles where the PE(1,1) performed OP(C), the OP(G) must be performed now; and in the cycle where PEs (1,j) $2\leq j\leq w$ performed OP(B), now the PEs $(\bar{i},\bar{1})$ $2\leq i\leq w$ must perform the OP(F), instead. The value of T for problem (7) are the same as for (6).

## 5. LU DECOMPOSITION

In this section we consider the LU decomposition

$$A = L\,U \tag{21}$$

for a N-by-N matrix in the w-by-w SSAP. The partitioning method and the execution sequence of the resulting subproblems are specified in the following algorithm:

**Algorithm 4:**

Compute $L_{1,1}$ and $U_{1,1}$ from

$$A_{1,1} = L_{1,1} U_{1,1} \qquad (22)$$

For n:= 2 to N do

Compute $U^{n-1}_{*,n}$ from: $L^{n-1}_{*,*} U^{n-1}_{*,n} = A^{n-1}_{*,n}$ (23)

Compute $L^{n-1}_{n,*}$ from $L^{n-1}_{*,*} U^{n-1}_{*,*} = A^{n-1}_{n,*}$ (24)

$A_{n,n} := A_{n,n} - L^{n-1}_{n,*} U^{n-1}_{*,n}$ (25)

Compute $L_{n,n}$ and $U_{n,n}$ from $A_{n,n}$ =

= $L_{n,n} U_{n,n}$ (26)

The subproblem (22) and (26) involve a LU decomposition of a w-by-w matrix, $A_{n,n}$, $1 \leq n \leq N$. This can be directly accomplished in the w-by-w SSAP (without need of any transformation), by programming the boundary PEs in such a manner that PE(1,1) perform OP(E), The PEs (1,j) $2 \leq j \leq w$ perform OP(B), and the PEs (i,1) $2 \leq i \leq w$ perform OP(F).

Every subproblem (24) implies to find a block-column matrix, $U^{n-1}_{*,n}$, that satisfies the lower triangular matrix equation

$$L^{n-1}_{*,*} U^{n-1}_{*,n} = A^{n-1}_{*,n}$$

Every subproblem (28) implies to find a block-row matrix $L^{n-1}_{n,*}$, that satisfies the upper triangular matrix equation

$$L^{n-1}_{n,*} U^{n-1}_{*,*} = A^{n-1}_{n,*}$$

Both types of subproblems, and their solution in a w-by-w SSAP, have been presented in section 4 of this paper.

The subproblems (25) involve a block-row matrix $(L^{n-1}_{n,*})$ by a block-column matrix $(-U^{n-1}_{*,n})$ multiplication, with accumulation of $A_{n,n}$. This was considered in section 3.

Therefore, all the subproblems present in the partitioning algorithm 4 have been solved. The chained execution of these subproblems can be seen in fig. 5.

The computational time of the LU decomposition of a N-by-N matrix on the w-by-w SSAP is $T=N^3/w^2 + N^2/2w + N/6 + w$

## 6. MATRIX INVERSION

In most cases, the computation of inverse matrices can be avoided. Nevertheless, in some statistical and engineering applications, this calculation is mandatory.

Let us consider the case of obtaining the inverse $A^{-1}$, of a N-by-N matrix, A, which has previously suffered an LU decomposition. We have

$$A^{-1} = U^{-1} L^{-1} \qquad (27)$$

The matrix equation L X = I must be solved, to find $L^{-1}$, where I is the N-by-N identity matrix, and $L^{-1}$ is the unknown matrix, X.

This computation can be performed in a w-by-w SSAP, taking into account that $L^{-1}$ is also a lower triangular matrix; in this case

$$T = N^3/2w^2 + 3N^2/2w + N + w \quad (28)$$

In a similar way, by means of the solution of the matrix equation YU=I we

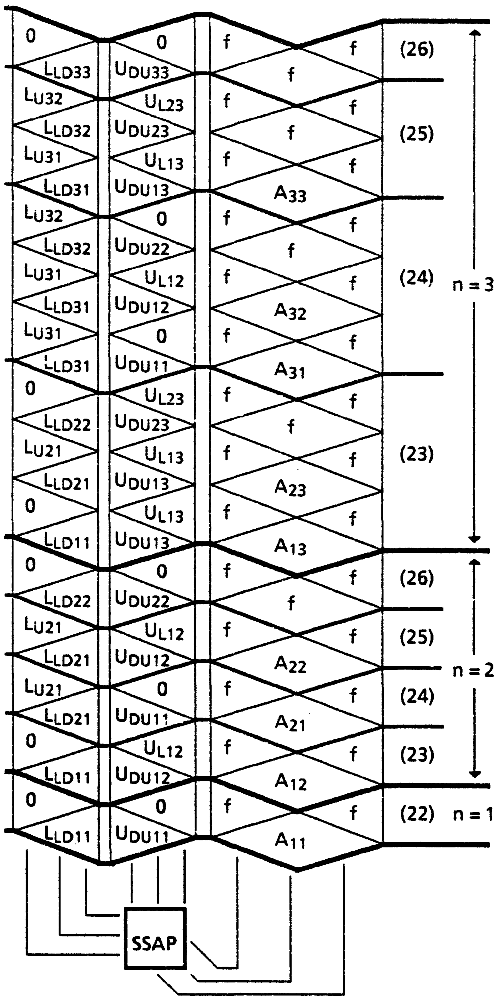

Fig.5. I/O block - data stream for a_LU decomposotion problem (with N = 3).

obtain $Y=U^{-1}$; taking into account that $U^{-1}$ is upper triangular, T is (28).

To find $A^{-1}$ from (27), the algorithm of section 3 may be used eliminating the multiplications by blocks 0. Then, we have $T = N^3/w^2 + 3N^2/2w + N/2 + w$. Therefore, the elapsed computational time to calculate the inverse of a N-by-N matrix, A, by using the LU decomposition, inverting the triangular matrices and multiplying, is:

$$T = 3N^3/w^2 + 5N^3/w + 8N/3 + 4w$$

## 7. CONCLUSIONS

In this paper, an efficient execution of several matrix algorithms with variable dimensions on a single systolic array of fixed size, has been presented. The processor is a SSAP with w-by-w PEs. Each PE is of the hexagonal type, and some of them must be able to perform several different operations. The array topology is fixed, and simple feedback and control are needed.

A partitioning method to divide the problem into subproblems matching the array size and characteristics, has been developed. Further conditions have been defined for the transformation algorithm that maps the original problem onto a different problem, which has been solved. The algorithms that have been described in this paper are: matrix multiplications, matrix equations, LU decomposition and calculation of the inverse matrices.

The array control is very simple and regular, indeed. Every partial result obtained in one boundary PE, that must be reused, is input through that same PE. The ordering of production and reuse of these data, follows a FIFO policy by blocks. No storing of intermediate results outside the systolic array is needed. The feedback networks utilizes storage elements to transmit, in pipelined fashion, the partial results.

For all the algorithms, the PE's utilization tends to the maximum possible value (1/3) and the computing time to the minimum. Nevertheless, with an adequate implementation PE's utilization approaching 1 can be obtained.

# PARSOR: A PARALLEL PROCESSOR FOR SPARSE MATRIX SOLUTION BY SOR ITERATION

David A. Arpin* and Yongmin Kim

Department of Electrical Engineering
University of Washington
Seattle, Washington 98195

Abstract -- The need for fast solutions of a class of linear systems has led to the design of a special purpose parallel processor. The SOR (successive overrelaxation) iterative algorithm allows a high degree of parallelism in computations, and is well suited to certain types of problems. An architecture is described which executes this algorithm efficiently, and achieves parallel operation at several levels. A small scale prototype of this architecture has been constructed. Simulation results for the complete system and test results for the prototype are outlined.

## INTRODUCTION

There are many applications for linear systems which are large (involving thousands or tens of thousands of variables) and sparse, with a symmetric positive definite (SPD) matrix (since its entries represent some physical quantity such as resistivity or elasticity which is isotropic), for which solutions must be computed quickly. For example, Kim et al. [1] devised a finite element model of the human body for use in impedance imaging. In this technique, an iterative process consisting of the solution to Laplace's equation along with several other steps is repeated up to several hundred times. The finite element method [2] converts Laplace's equation to the type of linear system described above. Since hundreds of linear system solutions are required for image reconstruction, each instance of solving Laplace's equation must be done quickly in order to produce images in a reasonable length of time. A parallel processor can potentially provide the required speed.

Gauss-Seidel iteration with successive over-relaxation, known as the SOR method [3], is a good algorithm for this application. In this method, the system Ax = b is solved iteratively. Successive iterations of each component $x_i$ are computed from a combination of the previous value of that component, the corresponding component of vector b, and products of matrix entry $a_{i,j}$ and $x_j$. This algorithm allows for a high degree of parallelism of computation. For example, the computation for a variable can begin with the available values of $x_i$ and $b_i$. As values of $x_j$ become available, products involving them can be computed and added to the summation. With careful node ordering, such computations can be in progress for many nodes simultaneously.

## THE ParSOR ARCHITECTURE

We have devised an architecture which implements the SOR algorithm efficiently. We call this the ParSOR (for Parallel SOR solution) architecture.

Since the SOR algorithm allows computation to proceed for many of the variables at the same time, separate processors for each variable in the system can be utilized efficiently. The value $x_i$ computed in each processor is needed for the computations in several other processors, so the processors must be arranged to allow efficient inter-communication.

The "one processor per variable" assumption requires that each processor be inexpensive, so that the system can be applied to problems of reasonable size. Therefore, the architecture is designed for implementation in VLSI, with each processor requiring a single chip. This limits the number of I/O pins for each processor, as well as the die area which can be dedicated to various functions.

Since matrix A is sparse, most elements ($a_{i,j}$) are zeroes, so corresponding values $x_j$ need not be communicated to compute $x_i$. For example, in the finite element method, $a_{i,j}$ is non-zero only if i and j are node numbers of nodes in a common element. For typical two-dimensional finite element models with triangular or rectangular elements, each node is connected by common elements to 6 - 8 others. In such problems, each processor will almost always need to communicate with its nearest neighbors. In other cases, some longer communication paths will be required, depending on how well the problem can be mapped onto the grid of processors.

Thus, the communication scheme must be capable of routing data to distant processors, but should be optimized for communicating over short distances. To enhance parallelism, it should be possible to communicate with several nodes at the same time. Finally, since data required in a computation can arrive at the processor while another portion of the computation is in progress, it should be possible to perform communications without interfering with the computation. These requirements must be weighed against the limited number of I/O pins and die area available in the single chip processor.

Based on all these considerations, we selected a simple nearest neighbor rectangular grid for communication between PEs, as shown in

*David Arpin is now at the Dept. of Electrical Engineering, US Air Force Academy, CO 80840.

Fig. 1. Data to be sent to more distant PEs is routed through intermediate nodes. This arrangement provides very short data paths for regular finite element grids, and the flexibility to handle longer communications paths. In order to minimize the impact of inter-processor communication on the performance of the system, each processor is partitioned into an Arithmetic Unit (AU) and a Communications Unit (CU) (Fig. 2), which can operate independently.

The Arithmetic Unit at node i receives data consisting of values $x_j$ and associated matrix elements $a_{i,j}$ from the Communications Unit, performs the multiplications and additions necessary to compute the next iterated value of $x_i$, and sends this result back to the CU. To do these tasks, the AU needs a multiplier, an adder, a few registers, and a small amount of logic to keep track of when it has finished an iteration.

When an iteration is finished, the result $(x_i)$ is sent to the nodes which need that value. In order to use this value, the receiving nodes need to know which value it is, i.e., the subscript i, so this value is appended to the message. Some means of routing the message to its destination is also needed. In the SOR algorithm, the structure of matrix A and the mapping of variables onto processors determines where the messages must be sent, so a number of rows (R) and a number of columns (C) of displacement in the network can be precomputed to specify this routing. Thus, a complete message would consist of $x_j$, j, R and C.

For a message arriving at node i, two separate activities are required. The value of the index j must be examined to determine whether the value $x_j$ is needed for the iteration computation at node i. Also, the values of R and C must be examined to determine whether the message should be sent on to other nodes, and updated to reflect the fact that the message has moved one step closer to its ultimate destination. These two determinations are independent of each other, and so can be performed in parallel. To prevent these activities from interfering with the iteration computations, they are performed by the Communications Unit.

The CU is partitioned into four separate Communication Processors (CPs) (Fig. 2), each dedicated to communication with one neighboring node in the network. This allows messages to be sent to or received from several nodes simultaneously. Each CP can determine whether the data is needed by the AU and/or other nodes, and route the data on as required, with no intervention from the AU. Figure 3 shows the basic architecture of one CP. This processor is divided into six autonomous functional units:

External Bus Interface - This unit provides the communication with another processing element. Control lines are used to allow the processors to coordinate their use of the data lines efficiently and prevent conflicts. In order to reduce the number of input/output pins, the data lines are multiplexed.

Associative Memory - This unit examines the value of the index, j, of the incoming message to determine whether the data is needed by the AU. If the value of j, as received by the External Bus Interface, is stored in this memory, it signals that the data $(x_j)$ is needed by the AU for this node, and retrieves matrix entry $a_{i,j}$.

RC Update - This unit examines the values of R and C received in the message. If either of these is nonzero, the message must be sent to another node. This unit signals the fact that the message must be sent on, updates the value of either R or C to reflect the fact that the message has moved to this node, and determines which of the other 3 CPs in this node should send the message out to the next node in its path to the specified destination.

Internal Bus Interface - This unit provides communication with other CPs in the same processing element via a single shared bus. This communication is required when the message received by the External Bus Interface of a CP must be sent on to another node in the network.

AU Interface - This unit receives data consisting of an x value and a matrix entry from the Associative Memory, and sends this data to the Arithmetic Unit. All the CPs share a single data path to the AU, and the AU uses this same path to send results to the CPs. In order to send data over this bus, the CPs must request and be granted access. However, the AU need not be granted access, since it is not possible for the AU and the CPs to send data over this bus at the same time (this is caused by the data requirements for each step in the SOR iteration and the fact that the A matrix is symmetric). When the AU finishes an iteration, it sends the new value to the AU Interface of all four CPs.

Message Generator - When a result is received from the AU, this unit generates new messages to carry that value to the other processing elements which need it.

This architecture achieves parallelism at several levels - e.g., between computations at different nodes, between computation and communication, and between the various aspects of message routing and handling. Thus, it can implement the SOR algorithm with high efficiency.

## SIMULATION and PROTOTYPE

A finely detailed, parameterized model of this architecture was constructed using the SIMULA language. We used this model to measure the number of clock cycles needed to complete each iteration, in order to obtain a performance measure which is independent of the technology used to implement the system.

The performance of the system depends in part on the number of interconnections between variables. More interconnections require more computations at each node, and cause data to be communicated over longer paths. For most of our runs, we simulated a network of 15 nodes, arranged as a 3 x 5 finite element grid with triangular elements, with some additional connections between more distant nodes added. This model provided a reasonable degree of complexity, so the results would not just represent the best possible performance.

System performance also depends on assumptions such as the number of cycles required to send a message over the external bus, and the time required to complete multiplications. Assuming nominal values of such parameters, we determined that this system can complete each iteration in approximately 330 clock cycles. Processors in the interior of the grid achieve efficiencies (i.e., percent of time when the AU is performing computations) of over 70%.

A hardware prototype of the processing element was constructed to validate these results, and further refine the details of the architecture. The complexity of the design, and the size of the data paths, made it impossible to build an entire processing node, so the prototype was scaled down substantially. We eliminated the Arithmetic Unit completely, and constructed two CPs. The AU and neighboring nodes in the grid are simulated by a microprocessor (Motorola 68000). Extensive testing of this prototype verified the operation of the communication processors and supported the conclusions of the simulation programs.

## CONCLUSIONS

Problems in this architecture such as how to load data into the processors, control the stopping of the iteration, and retrieve the results have been addressed [4]. Evaluation of these results suggests that this architecture is capable of solving linear systems involving tens of thousands of variables in less than one second.

Department of Computer Science
Duke University
Durham, NC 27706

**Abstract**

A parallel algorithm to generate optimum test-and-treatment decision trees is presented. Constructing such trees is NP-hard. The algorithm is designed for a machine whose number of connections is $3p/2$, where $p$ is the number of processing elements(PEs), and where the PEs are simple enough such that a machine with $2^{20}$ PEs is currently implementable and a $2^{30}$ PE machine is feasible. A speedup of $O(p/\log p)$ over a sequential dynamic programming algorithm for this task is achieved, by paying careful attention to the communication problem. This algorithm is realized on the Boolean Vector Machine, a cube-connected-cycle system with $2^{20}$ PEs which is currently running in prototype form, with 512 PEs. The algorithm is concrete, in that all processor allocation and other control issues have been solved. The particular NP-hard problem is of independent interest; it generalizes the binary testing problem by introducing treatments on an equal basis with tests. Applications of this test-and-treatment problem are found in medical diagnosis, systematic biology, machine fault location, laboratory analysis and many other fields.

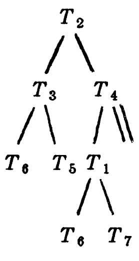
## 1. Introduction

### 1.1. The Test and Treatment Problem

The test-and-treatment(TT) problem originally defined by D.W. Loveland is a generalization of the binary testing problem studied by many researchers(see [1][2][5][6][7]). This problem is of independent interest since it finds applications in numerous real-world applications.

The test and treatment problem requests the selection of a "best" test and treatment procedure under a minimum expected cost criteria. The problem specification consists of a universe $U = \{0,1,...,k-1\}$ of $k$ objects, each with an associated weight $P_i$, and a set of tests and treatments $\{T_i, 1 \leq i \leq N\}$, each with an associated cost. The $T_i$, $1 \leq i \leq m$, denote tests, and the $T_i$, $m < i \leq N$, denote treatments. We assume that only one object is actually faulty, its identity is unknown, and each object $i$ has *a priori* likelihood $P_i$ of being the faulty object. Each test and treatment is specified by a subset of the universe; if the unknown object is in the test or treatment set then the test responds positively, or "is successful", or the treatment is successful. If the test is successful, the objects not in the test set are eliminated from consideration (and if negative, the test set of objects is eliminated), while a successful treatment ends the procedure. A failed treatment means the processing must continue. A successful TT procedure must provide for each object to be treated; a TT problem specification is ***adequate*** if there exists a successful TT procedure. With each test and treatment $T_i$ a cost $t_i$ of executing that test or treatment is given with the problem specification.

From the above description we see that a TT procedure is a binary decision tree, with both test and treatment nodes. A typical TT procedure is given in Fig. 1, where a single-line arc is used for both test outcomes (the positive outcome to the left by convention) and a treatment failure, and a double-line arc denotes a treatment set. (The double-line arc is for emphasis only since every branch of a successful TT procedure must terminate in a treatment set.)



$U=\{0,1,2,3,4,5\}$, $P_i=1/6$ for all $i$,
$T_1=\{2\}$, $T_2=\{0,4\}$, $T_3=\{0,1\}$, $T_4=\{0,1,3\}$,
$T_5=\{4\}$, $T_6=\{0,2\}$, $T_7=\{5\}$, $m=3$
$t_i=1$ for all $i$.

Fig. 1.

The TT procedure tree has an expected cost defined as: $Cost(Tree) = \sum_{i \epsilon U}$ (cost of all tests and treatments encountered if $i$ is the faulty object) $\cdot P_i$. The desired solution is the procedure which minimizes this cost. Thus $Cost = \min_{all\ trees} Cost(Tree)$.

It has been shown[3][5] that finding optimal solution to the binary testing problem is in general NP-hard. Since the test-and-treatment problem generalizes the binary testing problem, the test-and-treatment problem is also NP-hard. A parallel algorithm for this problem is presented which is implemented on the Boolean Vector Machine(BVM). We are able to achieve time complexity $O(ks(k+\log N))$ using $p=O(N2^k)$ processors, where $k$ is the size of the universe of objects containing the malfunctioned one, $s$ is the precision required, and $N$ is the total number of tests and treatments available. This result represents a speedup of $O(p/\log p)$, with regard to the known sequential algorithm which could be obtained by modifying the backward induction algorithm given by Garey[1].

### 1.2. The Boolean Vector Machine

The BVM is a CCC[8] parallel machine. Logically the BVM can be viewed as a bit array. Each row of bits forms a register. Each column forms a PE. The registers are denoted R[0], R[1], R[2],..., and are termed the PE's "memory". Each PE also contains 2 non-memory registers A and B which act like 1-bit accumulator. Let $r$ be a positive integer and $Q=2^r$, there are a total of $2^{r+Q}$ PE's, as required by a complete CCC network. The address of a PE can be represented by $(i, j)$ with the first component being the cycle number and the second the address within the cycle. Within cycle $i$ PE $(i, j)$ is only connected to its predecessor $(i,(j+Q-1)\%Q)$** and its successor $(i,(j+1)\%Q)$. In addition each PE $(i,j)$ is connected to its lateral neighbor $(i \char`^ 2^j, j)$, thus connecting the cycles together.

** As in the C language[4], %, /, &, |, ^ are the modulo, integer division, and, or, and exclusive-or operations respectively.

0190-3918/86/0000/0688 $01.00 © 1986 IEEE

The BVM is a bit-oriented machine. Only Boolean function operations are allowed. Each of its instructions involves possibly register A and B and at most one another register. Its instruction has the form:

{A or R[j]}, B = f, g(F, D, B) {IF or NF} <set>;

Two assignment operations will be simultaneously performed by executing this instruction. The first assigns f(F, D, B) to either A or R[j]; the second assigns g(F, D, B) to B. f and g are any Boolean functions of three arguments. F may be A or R[j]. D may be A.N or R[j].N. N denotes a neighbor PE of PE $(c ,p )$. It can be:

S: successor PE $(c ,(p +1)\%Q )$;

P: predecessor PE $(c ,(p +Q -1)\%Q )$;

L: lateral PE $(c\,\hat{}\,2^p ,p )$;

XS: even successor exchange PE $(c ,p\,\hat{}\,2^0)$;

XP: even predecessor exchange XP=P if $p$ is even; XP=S if $p$ is odd;

I: input one bit to PE (0, 0), PE $(2^Q -1,Q -1)$ outputs one bit at the same time. All other PEs get bits from their predecessors except PEs (., 0), which get bits from PEs $(.-1,\ Q -1)$.

The {IF or NF} <set> denotes the activate/deactivate set. <set> is a subset of $\{0, 1, ..., 2^r -1\}$. IF <set> means all the PE's $(i ,j )$, $0 \leq i < 2^Q$ and $j \epsilon$ <set>, will be activated while the remaining PE's will be deactivated. The meaning of NF <set> is just the opposite. If the part {IF or NF} <set> is not present in the instruction, then all the PE's are activated. There is also a special memory register, E, which is used as an enable/disable register. PE $i$ will be enabled or disabled according to whether its bit of the E register is 1 or 0. The E register itself is always enabled. The value of a PE's memory(except for register E) will not be changed while that PE is disabled. The entire state of a PE will remain unchanged by an instruction which deactivates that PE.

For further details of the BVM, the reader is referred to [9], [10].

### 1.3. ASCEND/DESCEND Algorithms

An algorithm is in the ASCEND(DESCEND)[8] form if it consists of a sequence of basic operations on pairs of data, where the addresses of the pairs differ successively in bit 0, bit 1, ..., bit $p$ -1 (bit $p$ -1, bit $p$ -2, ..., bit 0), here and henceforth bits are counted from the least significant bit.

Preparata and Vuillemin showed in [8] that the ASCEND/DESCEND algorithms can be simulated on a CCC at a slowdown of a factor of 4 to 6, regardless of the network sizes. Thus designing an ASCEND/DESCEND algorithm for a hypercube, and transforming it into a CCC algorithm seems to be a reasonable way of designing an efficient CCC algorithm. The algorithm presented in this paper is in the ASCEND/DESCEND form. The processor control is largely ignored here. We will address this issue in the expanded version of this paper.

## 2. A Parallel BVM Algorithm for the Test-and-Treatment Problem

Rather than enumerate all the possible TT trees and take the minimum cost directly as in section 1.1, we use the approach of dynamic programming and note that the optimal tree must apply the minimum cost action (test or treatment) to already optimal subtrees. The optimal subtrees are obtained by beginning with the empty tree and combining trees as just described. Thus we start with $C(\phi)=0$ and $C(S)=\infty$ for $S \neq \phi$. For an arbitrary nonempty set $S$ of objects we compute the cost $C(S)$ as follows:

$$C(S) = \min[\ \min_{1 \leq i \leq m}(t_i *p(S) + C(S \cap T_i) + C(S-T_i)),\ \min_{m < i \leq N}(t_i *p(S) + C(S-T_i))].$$

where $p(S) = \sum_{j \epsilon S} p_j$.

This definition is from first principles: the value $t_i$ is charged to each object subject to that action and the total weight of those objects to be charged is $p(S)$. For tests, one adds in the cost $C(S \cap T_i)$ of the set $S \cap T_i$ to which the test responds positively (the test set) plus the cost $C(S-T_i)$ of the set $S-T_i$ of objects not responding to the test. Treatments terminate action on the objects of $T_i$, $m < i \leq n$, (i.e., treat them) so the only objects needing further action are the objects in $S-T_i$; we add in the cost $C(S-T_i)$. The essence of an argument by induction that $C(S)$ is correctly computed uses the assumption that $C(S \cap T_i)$ and $C(S-T_i)$ are the correct costs for the subtrees and then we note from the above description that the correct minimum is taken to compute $C(S)$. We see that $C(U)=$ $Cost(tree)$ as desired.

In actual computation we will assign an array $M[S , k]$ to calculate $C(S)$: $M[S ,i]=t_i\, p(S)+C(S \cap T_i)+C(S-T_i)$, $0 \leq i \leq m$, and $M[S ,i]=t_i\, p(S)+C(S-T_i)$, $m < i < N$, therefore

$$C(S)=\min\{M[S ,i] \mid 0 \leq i < N\}.$$

The above observation is expressed in the following algorithm.

```
TT( )
{
  foreach $i$ : $0 \leq i < N$ do {
      $TP[S ,i]=t_i *p(S)$, if $|S| > 0$,
      $M[S ,i] = \begin{cases} 0, \text{ if } |S| =0, \\ \infty, \textit{ otherwise.} \end{cases}$
  }
  for($j$ =1; $j \leq |U|$ ; $j$ ++) {
    foreach $(S, i)$: $U \supseteq S$ and $|S| = j$ and $0 \leq i < N$ do {
        $M[S ,i]=M[S-T_i ,i]$;
        $M[S ,i]$+=$TP[S ,i]$;
        if($i \leq m$) $M[S ,i]$+=$M[S \cap T_i ,i]$;
    }
    foreach $(S ,i)$: $U \supseteq S$ and $|S| = j$ and $0 \leq i < N$ do
        $M[S ,i]=\min(M[S ,x] \mid 0 \leq x < N)$;
    }
  }
}
```

$|S|$ in the algorithm denotes the size of set $S$.

Can our parallel TT algorithm be transformed into the ASCEND/DESCEND form? Observe that if we assign a PE to each $(S ,i)$ pair with $M[S ,i]$ and $TP[S ,i]$ placed in different portion of that PE's memory, the instruction $M[S ,i]$+=$TP[S ,i]$ can be executed in parallel by all PEs at once.(The necessary bit-serial addition algorithm is a subroutine, executed in parallel on all PEs.) The minimization part of the algorithm can be transformed into the following ASCEND form:

```
for($t$ =0; $t < \log N$; $t$ ++)
   foreach$(S ,i)$: $U \supseteq S$ and $|S| = j$ and $0 \leq i < N$ do
      $M[S ,i]=\min(M[S ,i],M[S ,i\#t])$;
```

where $i\#t$ is the binary number obtained by complementing the $t$-th bit (from the right) of $i$.

Now consider the instruction:

foreach $(S ,i)$: $M[S ,i]=M[S-T_i ,i]$.

Can this operation be transformed into the

ASCEND/DESCEND form?

Let us begin by expanding it into its component operations as follows:

```
foreach $(S,i)$ do {
    $R[S,i]=M[S-T_i,i]$;
    $M[S,i]=R[S,i]$;
}
```

Consider now the operation

$$R[S,i]=M[S-T_i,i].$$

For each $S$ and $i$, this operation is well-defined, i.e.: each PE which receives information during this activity receives information from only one PE. However, one PE must send information to several PEs. In general, $M[S-T_i,i]$ must be broadcast to $R[(S-T_i)\bigcup V,i]$, for each $V$ such that $S\bigcap T_i \supseteq V$. The following loop accomplishes the required broadcast, for all $i$, $0\leq i<N$:

```
$R[S,i]=M[S,i]$;
for($e=0$; $e<k$; $e$++)
   foreach $(S,i)$: $U\supseteq S$ and $0\leq i<N$ and $e \epsilon S\bigcap T_i$ do
      $R[S,i]=R[S-\{e\},i]$;
$M[S,i]=R[S,i]$;
```

Let $I_t=\{j \epsilon U \mid j\leq t\}$. Using induction one can show that just before $e$ takes on value $t$, $R[(S-T_i)\bigcup(S\bigcap T_i\bigcap I_{t-1}),i]$ holds $M[S-T_i,i]$. After all iterations of the loop on $e$, $I_t=U$, and $S\bigcap T_i \bigcap I_t=S\bigcap T_i$. Thus, for all $S$ and $i$, $R[S,i]=M[S-T_i,i]$.

Similarly, the operation

$$\text{if } (i\leq m)\ M[S,i]+=M[S\bigcap T_i,i]$$

can be transformed into:

```
$Q[S,i]=M[S,i]$;
for($e=0$; $e<k$; $e$++)
   foreach $(S,i)$: $U\supseteq S$ and $0\leq i<N$ and $e \epsilon S-T_i$ do
      $Q[S,i]=Q[S-\{e\},i]$;
if ($i\leq m$) $M[S,i]+=Q[S,i]$;
```

The complete algorithm now appears as:

```
TT()
{
  foreach $i$: $0\leq i<N$ do {
      if( $|S|>0$) $TP[S,i]=t_i*p(S)$;
      $M[\phi,i]=0$;
      if( $|S|>0$) $M[S,i]=\infty$;
    }

    for($j=1$; $j\leq k$; $j$++) {
      foreach $(S,i)$: $P_1(S,i)$ {
        $Q[S,i]=R[S,i]=M[S,i]$;
      }
      for($e=0$; $e<k$; $e$++) {
        foreach $(S,i)$: $P_1(S,i)$ and $e \epsilon S\bigcap T_i$ {
          $R[S,i]=R[S-\{e\},i]$;
        }
        foreach $(S,i)$: $P_1(S,i)$ and $e \epsilon S-T_i$ {
          $Q[S,i]=Q[S-\{e\},i]$;
        }
      }

            foreach $(S,i)$: $P(S,i,j)$ {
              $M[S,i]=R[S,i]$;
              $M[S,i]+=TP[S,i]$;
              if($i\leq m$) $M[S,i]+=Q[S,i]$;
            }
            for($t=0$; $t<\log N$; $t$++)
              foreach $(S,i)$: $P(S,i,j)$ {
                $M[S,i]=\min(M[S,i],M[S,i\#t])$;
            }
          }
        }
```

Where $P_1(S,i)\equiv U\supseteq S$ and $0\leq i<N$, and $P(S,i.j)\equiv P_1(S,i)$ and $|S|=j$.

On the BVM each PE will stand for a pair $(i,j)$, where $i$ and $j$ are binary numbers and $ij$, the concatenation of $i$ and $j$, is the address of the PE. $|i|$, the number of bits in $i$, is $k$. The component $i$ denotes a subset $S$ of $U$, $a \epsilon S$ iff $a$-th bit of $i$ is 1. $j$ is the index of a test or a treatment.

The predicates $e \epsilon S\bigcap T_i$ and $e \epsilon S-T_i$ can be implemented by using the processor-ID. The Processor-ID is a bit pattern in which the memory of processor $(i, j)$ contains $ij$ [9]. The processor-ID bits will let each PE know the set $S$ it represents. $T_i$ should be input to the BVM. The most interesting part of the algorithm is the loop indexed by the variable $e$. Note that by imposing the conditions $e \epsilon S\bigcap T_i$ and $e \epsilon S-T_i$ the result becomes $R[S,i]=R[S-T_i,i]$ and $Q[S,i]=Q[S\bigcap T_i,i]$.

## 3. Conclusion

Many NP-complete problems can be solved on the BVM fairly efficiently, as we illustrate using the test-and-treatment problem. Indeed, the test-and-treatment problem itself is of real interest as it has many important applications. A parallel algorithm for this problem is presented and implemented on the Boolean Vector Machine. The communication problem and the PE allocation problem have been solved so that a speedup of $O(p/\log p)$ is achieved.

## ABSTRACT

*"Truth maintenance" is an important artificial intelligence technique. Although some recent research has increased the efficiency of the status assignment process, it is still computationally expensive. Fortunately, there is a significant amount of parallelism inherent in the process. We present a distributed computation for status assignment in a Truth Maintenance System (TMS) where each node in the system is implemented as an independent processor.*

## 1 Introduction

Doyle first presented a formal Truth Maintenance System (TMS) in [2]. (This was later renamed a Reason Maintenance System [3], but TMS has come to mean a class of techniques within artificial intelligence and we use this generic term.) One of the major functions of such a system is to properly assign the status of IN or OUT to each node in a network. The nodes correspond to assertions and the statuses to belief in the assertions. We discuss below the structure of the network and the criteria for proper status assignment.

The status assignment process in a network of significant size requires a large amount of computation. This is evident not only from the algorithm but from general experience with systems that include a TMS, such as DUCK [6] and MRS [4]. Recent work has attempted to improve both the efficiency and functionality of the original algorithm [7] and [5]. However, the process is inherently expensive. Fortunately, status assignment in a typical network allows the status of many nodes to be determined based on only that of a relatively few other nodes. This allows a large degree of parallelism in status assignment.

Dijkstra has proposed a distributed computation called "diffusive computation" in [1]. In such a system, a computation proceeds by passing messages in a finite, directed graph of processors. A processor is activated only when it receives a message. It makes a calculation and sends the result in a message to its successor. The end of the computation is signaled by a system of replies. A TMS network of nodes can be implemented as a finite, directed graph of processors which seek to determine their status. We give a diffusive computation which implements status assignment in such a network of processors. In the discussion that follows, we assume that the reader is less familiar with the TMS proposed by Doyle than with Dijkstra's diffusive computation.

## 2 TMS Status Assignment

Each node in a TMS network is to be assigned a status of **IN** or **OUT**. A set of **justifications** is associated with each node. Each justification in the set consist of an ordered pair of sets of nodes. The first element of the pair is called the **Inlist** of the justification, and the second is called the **Outlist**. A justification is **valid** exactly when each element of the Inlist is IN and each element of the Outlist is OUT. An assignment of statuses to a TMS network is **consistent** when each node is assigned a status of IN iff it has at least one valid justification and OUT otherwise. The nodes form a directed graph where the union of the Inlists and Outlists of the justifications for a node are its predecessors, and those nodes which include it in a justification are its successors.

It is convenient to name certain subsets relative to a node. Its successors are also its **consequences**. If a node is IN, the nodes in one valid justification are designated its **supporters**. If a node is OUT, its supporters will include exactly one node from each justification: either an OUT node in the Inlist or an IN node in the Outlist. The **affected consequences** of a node are those consequences for which the node is a supporter. The transitive closure of the affected consequences constitutes the **repercussions** of the node. The **believed consequences** are those affected consequences which are IN. The transitive closure of these is the set of **believed repercussions**. The **ancestors** of a node are those in the transitive closure of its supporters. Any of the sets mentioned so far may be empty. If the set of justifications is empty, then the node has no justification and is OUT. If the Inlist and Outlist of a justification are both empty, the justification is valid and is said to be a **premise**.

We consider the problem of adding a justification to a node in a TMS network in which the status assignments are consistent and **well-founded**. This last means that no node is in its own believed repercussions. The status assignment computation should preserve the conditions of consistency and well-foundedness after the justification is added if it is possible to do so. As an example, consider Figure 1. In this graph and those which follow, each circle corresponds to a

0190-3918/86/0000/0691 $01.00 © 1986 IEEE

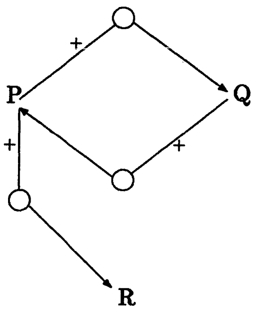

Figure 1: Unique Well-founded Consistent State

justification, with an arrow pointing to the justified node, positive arcs connected to the elements of the Inlist, and negative arcs to elements of the Outlist. The requirement of consistency is met if each node in this graph is assigned a status of IN. However, such a state of assigned statuses would not be well-founded. The only consistent well-founded state has each node labeled OUT.

We will show next how status assignment can be accomplished by a simple diffusive computation that generally follows Doyle's original algorithm. It is important to note that our computation, like that of Doyle's, is incomplete in some respects. A new justification may also introduce an **unsatisfiable circularity** into the system by creating a graph, such as that of Figure 2, for which no consistent assignment of statuses can be found. We improve upon the original algorithm by ensuring termination if a consistent labeling of statuses is not found. However, it may be possible to consistently assign statuses only if the supporters of some of the nodes are examined, and our computation only examines consequences of nodes. Our computation will also assign statuses if it is possible to do so consistently even though there is no assignment which is both consistent and well-founded. Russinoff has solved these problems in [7] with a more complex truth maintenance algorithm.

## 3 The Diffusive Computation

Imagine now that the nodes in a TMS network are processors connected to each other via two-way channels that carry messages in one direction and replies in the other. Each processor stores a set of justifications and its status. It is connected to other processors by channels which carry messages to its consequences and replies to the processors named in any of its justifications. We will describe below programs for the processors that implement the diffusive computation of status assignment.

Given a "root" processor which is initially OUT and which acquires a valid justification, we begin as Doyle does: the status of the processor and every element of its repercussions is set to NIL. This status assignment is special and only occurs during updating. The diffusive computation for this is quite simple. Each processor sends a message giving its status as NIL to each of its consequences. If a processor receives such a message from a processor which is not a supporter, or if the processor has already received a message from a supporter, it replies immediately. Otherwise, it sets its status to NIL, and sends the same message to each of its consequences. The originator of the first message is known to the processor as its "engager". When each one of the consequences of the processor, if any, has replied, then it replies to the engager. The root processor recognizes the termination of the NIL sweep when all of its consequences have replied because it marks itself as its own engager. At this point, we can attempt an assignment of IN or OUT to the designated processors.

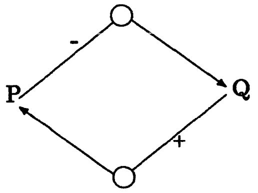

Figure 2: Unsatisfiable Dependencies

The basic idea of the diffusive computation for status assignment is that upon receiving a message for the first time, a processor records the sender as the engager and checks to see if if its own status is changed by the new information. This is determined by whether or not there is now a valid justification for the processor based on the new status of the engager. If the status of the receiving processor is unchanged, it replies immediately. If the processor's status is changed, then it sends a message containing its new status to each of its consequences. A processor also replies to any sender if it has already received another message to which it has not replied or if it has no consequences. It replies to the engager when it receives replies from all of its consequences.

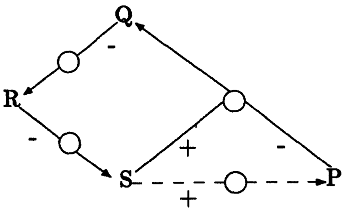

Figure 3: New Justification

We illustrate the use of such a diffusive computation with Figure 3. Suppose that initially P had no justification and was thus OUT. The justification being added is shown in the dotted lines. Processors Q and S were IN and R was OUT. Thus P is an OUT processor which acquires an initially valid justification and so becomes the root node in a diffusive computation to determine status assignments.

After the NIL sweep, both P and Q will each determine its status to be OUT because of the NIL status of S. Q will make its determination when it receives a message from P that it is OUT. Q then sends a message to R who is able to determine that its status is IN. R's message to S confirms the assumption that the NIL status of S would eventually result in an OUT status. S sends a message to Q and P. Since they are already engaged, they take note of the new status and reply immediately. Each node in the graph then replies to its engager after determining that its status is unchanged since it first received a message. In the final state, only R is IN and the other processors are OUT.

The above descriptions of diffusive computations would suffice for status assignment were it not for unsatisfiable circularities. Obviously, some graphs may not admit a consistent assignment of statuses. In such a case, the diffusive computation described above would not terminate. The simple fix for this problem proposed here is to pass a message which contains a string of processor names as well as a status. The string contains the ancestors of the engager. Thus a processor can determine if its current status depends on itself. If an engaged processor switches status twice as a result of being its own ancestor, then it is involved in an unsatisfiable circularity. (In [2], Doyle claims that an unsatisfiable circularity can be detected if a node is its own ancestor after finding a valid justification with a NIL status in the Outlist. Unfortunately, this is not the case.) We propose that a processor signals a special "trouble" reply to its engager when an unsatisfiable circularity is so detected.

Detection of an unsatisfiable circularity, given a particular state of assignments, is by itself insufficient. It may be that the diffusive computation has not yet terminated for some possible supporters of processors involved in the apparent circularity. We must specify what action is to be taken by a processor when it receives a trouble reply. Our solution is for the processor to wait until all replies have been received and then resend its status to its consequences if it has received the trouble report for the first time from a particular consequence. If a trouble reply is received twice from the same consequence, then the processor replies trouble to its engager.

For example, in Figure 4, only S is IN before P acquires its premise justification. After the NIL sweep, P determines that it is IN and sends its new status to Q and T with the message $< P, IN >$. Suppose that T is much slower than the other processors. While T is very slowly determining its status, Q determines that its own status is OUT since the status of S is NIL. R then receives the message $< QP, OUT >$. R then sends $< RQP, OUT >$ to S which then sends $< SRQP, IN >$ to Q. The latter records R's new status and replies immediately since it is already engaged. Eventually, Q receives its outstanding reply from R.

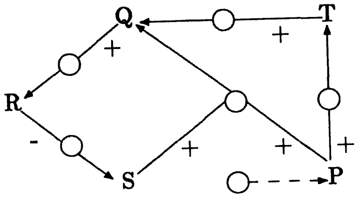

Figure 4: Apparent Circularity

Now Q finds that its status has changed to IN. Also, one of its supporters includes Q in its ancestors: S is recorded as having the status of IN due to the message $< SRQP, IN >$. Since Q is its own ancestor, it sets a circularity flag before it resends its status. It is easy to see that its status will change again due to its being its own ancestor if it does not receive a message from T before it receives its next reply from R. If T is so slow, then, since the circularity flag has been set, Q replies trouble to P.

Processor P does nothing until it hears from T. At that point, P rebroadcasts its status regardless of the fact that it has not changed. This time, T will be IN and Q will have a valid justification regardless of the status of S. Thus, the final determination of status assignments in this example will be the inverse of the state before P received a justification: only S will be OUT.

In the next section, we give the algorithm for a processor to carry out the diffusive computation described above. We omit the NIL sweep as trivial and assume that we start with all of the affected consequences of the root processor NIL and all of their consequences notified of their new status. We also assume that the root processor has already made itself its own engager and has initiated the message sending.

## 4 Algorithm for Processor $i$

Each processor $P_i$ has the following stores:

**Status:** IN, OUT, or NIL.

**Justification Set:** This is is the set of justifications for $P_i$ and will be abbreviated $\mathcal{J}$. Each Justification consists of a pair of sets of processor ids. For a particular justification $J_k$, we denote the first element of the pair as *Inlist*($J_k$) and the second element *Outlist*($J_k$). Both $\mathcal{J}$ or either element of any justification may be empty.

**Supporter-Status:** This is a vector of pairs indexed over the union of the processor ids in any set in $\mathcal{J}$. For any element $j$ of the vector, the first element of its pair is a set of processors called *Contributors(j)*. The second is *Update(j)*: the last known Status of $j$. Thus, each element of this vector has the same format as a message.

**Deficit:** The obvious integer required for a diffusive computation.

**New-Status:** IN or OUT.

**Circularity:** A boolean flag indicating a possible unsatisfiable circularity.

**Ancestors:** The set of processors upon which the current value of Status depends as determined by the procedure Status(i).

**Consequences:** The set of processors which mention $P_i$ in their justifications.

**Trouble:** The set of processors which have reported an unsatisfiable circularity with a trouble reply to $P_i$.

```
Define Processor(i):
begin
If receive message $< P_j\omega, T >$ then
  begin
  Supporter-Status(j) := $< P_j\omega, T >$
  If Engager = 0 then
    begin
    Engager := $P_j$
    New-Status := Det-Status(i)
    Circularity := false
    Trouble := {}
    If New-Status=Status then
      Send-Reply(i,'N')
      else Resend-Status(i)
    end
    else Send-Reply(i,'N')
  end
If receive normal reply from $P_j$ then
  begin
  Deficit := Deficit -1
  If Deficit= 0 then
    begin
      New-Status := Det-Status(i)
      If Trouble= {} then***No unsatisfiable circularities reported
        If New-Status = Status then *** No status change
          Send-Reply(i,'N') *** Send normal reply
          else If $i \in$Ancestors then***Possible unsatisfiable circularity
                If Circularity then***Definite unsatisfiable circularity
                  Send-Reply(i,'T') *** Trouble Reply
                  else
                  begin
                  Circularity := true
                  Resend-Status(i) *** Try to resolve possible problem
                  end
                else Resend-Status(i) *** $P_i$ is not its own ancestor
        else *** Trouble set is not empty
        If Circularity then Send-Reply(i,'T') *** Trouble Reply
          else Resend-Status(i) *** Problem may be resolvable
    end
  end
If receive trouble reply from $P_j$ then
  If $P_j \ni$ Trouble then
    Trouble := Trouble $\bigcup\{P_j\}$
    else Circularity := true *** Trouble Reply
end.
```

```
Define Send-Reply(i,b):
begin
if Engager = $P_i$ then halt
  else
  begin
  Engager := 0
  If b = 'N' then send normal reply
    else send trouble reply
  end
end.
```

```
Define Resend-Status(i):
begin
Status := New-Status
Deficit := size of Consequences
If Deficit = 0 then Send-Reply(i,'N')
  else send message $< \omega, S >$ to each consequence
    where $\omega := \{P_i\} \bigcup$ Ancestors
end.
```

```
Define Status(i):
If $\exists J_k \in \mathcal{J} \mid \forall n \in Inlist(J_k), Update(n)$ =IN
  and $\neg\exists o \in Outlist(J_k) \mid Update(o)$ =IN, then
  begin
  Ancestors := $\{j\} \bigcup Contributors(j) \forall j \in Inlist(J_k) \bigcup Outlist(J_k)$
  Return IN
  end
  else
  begin
  Ancestors := $\bigcup \forall J_k \in \mathcal{J} \bigcup Contributors(j)$
      for some $j$ | either $j \in Inlist(J_k)$ and $Update(j) \neq IN$
        or $j \in Outlist(J_k)$ and $Update(j) = IN$
  Return OUT
  end.
```

## 5 Conclusion

The amount of computation required and parallelism inherent in the truth maintenance process makes it a good candidate for a distributed computation. Dijkstra's diffusive computation is a good fit to at least Doyle's original algorithm for truth maintenance. In fact, if, like Doyle, we do not provide for termination given a graph which cannot be labeled consistently, the diffusive computations required are very simple.

Providing for such termination has the effect of complicating the final computation and significantly increasing the length of the necessary messages, as well as their number in some cases. And our algorithm does not properly identify just when it is possible to give a consistent and well-founded labeling of statuses to a graph.

However, the diffusive computation presented here is still relatively straight-forward and accomplishes as much or more than all but the most recent previous algorithms for this task. Furthermore, the remaining problems seem likely to be resolved by extensions of the current algorithm. For example, when the root processor halts with a trouble reply, it seems likely that a diffusive computation could be devised to examine its supporters as does Russinoff's algorithm. We conclude that diffusive computations are a good model for distributed implementations of truth maintenance.

# POTENTIALS FOR PARALLEL EXECUTION OF COMMON LISP PROGRAMS

*Patrick F. McGehearty and Edward J. Krall**

Parallel Processing Architecture
Microelectronics and Computer Technology Corporation
Austin, Texas 78759

*ABSTRACT*

Several Lisp application kernels were modified for parallel execution. Their simulated behavior showed speed-ups ranging from one to 850 times faster, suggesting that the technique is of no value to a few programs, of great value to a few programs, and of moderate value to most programs. The modifications were minimal and could be done mechanically.

## OVERVIEW

To assess how much faster Lisp programs would run on large multiprocessor systems, we modified several application kernels for parallel execution and simulated their behavior. We obtained speed-ups ranging from one to 850 times faster, suggesting that the technique is of no value to a few programs, of great value to a few programs, and of moderate value to most programs. The modifications were minimal and could be done mechanically.

An approximation of this technique is used to modify several application kernels by hand to run in parallel. The effective parallelism obtained is measured by means of simulation. These results are combined with results previously published [6] to identify areas of research needed for parallel execution of Lisp programs with minimal programmer intervention.

## REQUIREMENTS FOR "SAFE" PARALLEL EXECUTION

Unlike many languages, Lisp contains a viable "pure function" subset. Moreover, applications written in Lisp are typically composed of many functions which are "pure." Such functions can be rendered into parallel routines without fear of destroying the meaning of the program.

Unlike the functional languages, however, Lisp also supports applications which are not pure, which make use of "blackboards," global data structures, and side-effects in order to be useful. These side-effects must be carefully handled to insure correct parallel program execution.

### The Detection of Side-effects

Much of the effort in converting a program in Lisp (or any other language) to run in parallel comes in determining which parts may execute simultaneously without interference. We propose to study the restricted case of executing side-effect-free functions in parallel. Given a "black box" model of computation, a side-effect-free function may be viewed as a computational entity which accepts certain values as input parameters, and returns one or more values through the well-isolated interface of the function call. As such, the black box operates independently of its implementation -- it is behavior not structure that is important. Whether the function is implemented as software, firmware or hardware, nothing in the calling environment is altered, save the values returned through the function call interface.

A side-effect is therefore a change to the calling environment not associated with the function call interface. Note that this definition is usually weakened somewhat to exclude changes in internal addresses, memory allocation, timers, etc., which are beyond the access of the program.

There are two types of side-effect phenomena in Lisp: (1) functions which by their nature cause side-effects, and (2) functions which make use of global or free variables. Functions which use free variables have the potential for their computation being affected from any other part of the computation that uses those variables. Side-effecting functions include *rplaca, rplacd, set,* and the Input/Output functions. Moreover, any function which calls a side-effecting function may be considered side-effecting. In addition, any function which touches the property list of symbols (such as *get, putprop*) implicitly references globally available data.

*On Assignment to MCC from NCR Corporation

0190-3918/86/0000/0696 $01.00 © 1986 IEEE

Three answers may occur when performing side-effect analysis on a function: (1) no side-effects exist, (2) side-effects exist, and (3) don't know. We assume that only functions in the first category may be executed in parallel. We recognize that some algorithms exist which correctly use overlapping execution with side-effects, but we will not consider such cases here.

Static syntactic analysis should approach 100% accuracy in identifying the presence of global variables and side-effecting functions if they exist, but will be less accurate in establishing the absence of global variables or the lack of side-effecting functions.

In this determination, however, "don't know" may be the most common answer. Certain constructs are so suspicious (*(setq x (format ...))* or *(eval ...)* ) that we will flag them as side-effecting without further analysis. Others, such as *setq* will require further consideration. If a global variable is used as the assignee, then *setq* will cause side-effects. The use of a local variable as the assignee of a *setq* encapsulates the side-effect to the scope of the local variable. Hence the function itself acts as a black box, and can be executed in an applicative and parallel fashion.

### Obtaining Parallelism

After functions have been identified as safe candidates for parallel execution, some mechanism must be supplied for creating a separate task for their execution and observing the degree of parallelism obtained. We selected the *future* construct from Multilisp [5] as our primary construct for specifying parallel execution. The *future* is a form which spawns a new task for the evaluation of a given Lisp form. For example,

```
(setq x (future (add1 y))
(setq z x)
```

spawns a task to evaluate *(add1 y)*, assigns to *x* a pointer to the future of *(add1 y)*, and continues execution in line. When *(add1 y)* completes, the value of *x* becomes a pointer to the value of *(add1 y)*. If the value of *x* is needed before the future is completed, that task will suspend itself. However, if only *x* as a whole is needed (as in the subsequent assignment), the task is NOT blocked; instead *z* is set to point to the future also.

Note that the word *future* is used in two senses: as the name of the function which spawns the tasks, and as the (uncompleted) value of the task spawning. When it is necessary to distingush between the two, we will refer to the value of the task spawning as the *-future-* data-structure. In the example above, if *x* were inspected before the value was available, then something like the following might be seen:

```
*-FUTURE-*: (future (add1 y))
```

Two other forms are used in our study: *touch* and *pmapcar*. The function *touch* will return the value of its argument, blocking if necessary on an as-yet undetermined *future*. The function *pmapcar* is also built from futures. It is the analog of *mapcar*:

```
(pmapcar fn '(1 2 3 4 5))
```

will spawn tasks to evaluate (fn 1), (fn 2), ..., (fn 5) simultaneously, and return the list of values (or their futures).

It is important to note that a *future* does not automatically allow parallel execution. Consider the following:

```
(plus 10 (future (sin x)))
```

No useful parallelism is obtained. While (future (sin x)) does create a parallel task, the main line task tries to execute the plus instruction, and immediately blocks until the computation of (sin x) is completed. If *future* has any overhead, it would take less time to execute:

```
(plus 10 (sin x))
```

Therefore, a *future* should only be inserted when both paths of computation can be expected to have more computation to perform than the overhead of invoking a *future* before the invoker requires the value of the *future*.

### The Insertion Process

Because the *future* is a data structuring concept, and because it behaves like a function call, it is not only easy for the programmer to use, but it is also easy for a pre-processor to insert *futures* in a program to be parallelized. Since we do not currently have a program which detects side-effects or estimates computation requirements of code fragments, we inserted *futures* in the application kernels where we judged such programs would make those insertions.

As an example, consider the following:

```
(defun rewrite-args (lst)
  (cond ((null lst) nil)
        (t (cons (FUTURE (rewrite (car lst)))
                 (rewrite-args (cdr lst))))))
```

It is known that rewrite is side-effect-free; hence, the *future* can be inserted on the first argument of cons.

However, guaranteeing freedom from side effects is only a *sine qua non* for insertion of *futures.* The candidate function must also satisfy two other criteria:

1. The work being done by the spawned task must be sufficient in the light of the process scheduling overheads.
2. The work remaining in the spawning task until the future value is needed must also exceed the scheduling overhead.

For example, consider the following function:

```
(defun test (x) (+ (sin x) (cos x)))
```

One may insert futures indiscrimately as follows:

```
(defun test1 (x) (+    (future (sin x))
                       (future (cos x))))
```

Such insertion on the second argument of the addition is pointless -- the mainline task must block while it waits for the completion of computation of both arguments.

A better insertion is

```
(defun test2 (x) (+    (future (sin x))
                       (cos x)))
```

Now, after spawning the (sin x), the mainline will compute the (cos x) coincidentally with the computation of (sin x). The parallelism is now useful provided that (sin x) and (cos x) take longer to compute than a task takes to be spawned.

We note that Sharon Gray at MIT has developed a program for inserting *futures* in code that is alreadv known to be side-effect-free [4].

## MEASUREMENT TOOLS

Several tools were developed to allow measurement of the parallel execution of Lisp programs. Since a multiprocessor was not readily available to the authors, a simulator was developed to approximate the behavior of parallel Lisp programs on a multiprocessor. It generates a trace of events related to task scheduling and timing, such as task start, task end, and task blocking, using a value generated by another task. These trace events are used by a post-processing program to determine a running average degree of parallel execution and the overall average number of processors in use.

### The "Pure-Lisp" Simulator

The "pure-Lisp" simulator extends Common Lisp by implementing two interrelated primitives, *future* and *touch* to support parallel execution. As mentioned before, the *future* primitive returns a *-future-* data-structure. However, Common Lisp primitives do not support the *-future-* data type. This support is provided by means of a preprocessor for Common Lisp source code. The arguments to each system primitive such as *car* which requires access to their contents are enclosed in a *touch* primitive. The *touch* primitive treats normal Lisp values like the identify function. When its argument is a *-future-* data-structure, it simulates the appropriate delay, if necessary, and returns the value computed by the associated *-future-*. Thus, no changes are needed to the underlying Lisp system primitives.

During program execution, the various tasks are executed in a depth-first order, with the most recently created task being executed until it completes or starts another task. When it completes, then the task that started it is resumed. A simulated time is maintained throughout this execution. Whenever a *future* primitive is encountered, the current simulated time is recorded as the start-time for that *future.* Then the argument of that *future* is evaluated as a normal Lisp expression. The new simulated time is recorded as the end-time for that *future.* Then the simulated time is reset to the start-time of the *future.* Thus, the next instruction in the task that executed the *future* appears to occur during the time that the *future's* argument is being evaluated. When a task executes a *touch* of a *-future-* data structure, the simulated time is set to the greater of the current simulated time and the simulated completion time for that *-future-*. This adjustment represents waiting for a *future* to complete if necessary.

The "pure-Lisp" simulator described above has the advantage of relatively straightforward implementation. Further, so long as the arguments to the *future* primitive have no side-effects, the results computed will be correct and the estimated degree of parallelism and simulated timing will also be correct. However, if the arguments to the *future* primitive have side-effects, the simulator can be arbitrarily optimistic or pessimistic.

Suppose that a single computation is needed in several places in a parallel program. Further, suppose whatever portion of the parallel program needs that computation first sets a flag and computes the value while other portions of the program just use the result of the computation when they find the flag set. The *future* construct supports this kind of parallel programming, but the "pure-Lisp" simulator does not. If the shared computation first occurs inside of a *future*, then it could end up being used by another portion of the program at a simulated time earlier than it was computed. Or, if it is the value of a *future* which also includes a longer computation, another task could be delayed longer than necessary. Therefore, the "pure-Lisp" simulator used in these experiments is only appropriate for studying *futures* with no side-effects. Since the current study is only concerned with mutually independent sub-tasks, this limitation is not harmful.

### The Trace and Post-Processing Facility

The following events are traced: task start, task end, task block waiting on a *future*, and task unblock when a future is ready. Each trace event records the simulated event time and the event type. The first two events surround the *future* primitive, and the second two events surround the *touch* primitive. The act of recording the event data is hidden from the simulated timer. This series of events can readily be transformed into a time-weighted average of the number of active tasks and the number of blocked tasks. A small program computes the average number of active tasks and the maximum number of tasks that a parallel program uses. Also computed are the total computation for all tasks and the linear time required to execute the parallel program. These times represent the results that would be obtained if the program were executed on a ideal parallel processor that has as many processors as were needed, with no interference between the processors.

## SAMPLE APPLICATION KERNELS

This report examines four sample programs to assess the potentials of obtaining automatic parallel execution. Two of these, Mandelbrot and TAK are small programs, intended to exercise the primitives essential to parallel execution. The other two, EMY and REWRITE are kernels of major AI programs, intended to represent the computation of those programs.

### Mandelbrot

The Mandelbrot program determines, for each of a set of points on a square grid in the complex plane, whether the point is in the Mandelbrot set [2]. Thus, Mandelbrot can be considered a representative kernel of a class of numerical algorithms. The determination for a single point is iterative, but independent of all other points. In the sequential version of the program, the determination for each point done inside of a double loop. The outer loop controls which row in the grid is being evaluated, and the inner loop controls which column within the row is being evaluated. Given an assumption that at least five instructions should be performed by a parallel task to justify its creation overhead, the smallest computation that is suitable for execution as a separate task is the determination of whether a single point is or is not in the Mandelbrot set. Since each such determination is independent of the others, this unit of computation could be surrounded by a *future*.

To obtain experimental results, a grid of 50 by 50 points was selected, with an iteration limit of 100. Without *futures*, the program takes 27.8 seconds. Figure 4-1 shows the parallel execution profile with a single *future*. The y-axis is simulated time, and the x-axis is average number of executing tasks during a time window. With a total run length of 1.17 seconds, the speed-up is approximately 24.

| Time (ms.) | Active PE's | Each * = 2 Active Processors |
|---:|---:|:---|
| 0 | 23 | ************ |
| 100 | 19 | ********** |
| 200 | 19 | ********** |
| 300 | 26 | ************* |
| 400 | 31 | **************** |
| 500 | 31 | **************** |
| 600 | 34 | ***************** |
| 700 | 34 | ***************** |
| 800 | 28 | ************** |
| 900 | 25 | ************ |
| 1000 | 9 | **** |
| 1100 | 4 | ** |

Figure 4-1: Mandelbrot - One Future Case.

Since 2500 tasks were created and executed, this speed-up is disappointing. Careful consideration of program behavior shows that the problem is the rate at which tasks are created. On average, a delay of 360 microseconds occurs between each task startup, mostly due to loop overhead. Since each task takes an average of 11,000 microseconds, only 30 tasks can be started before some tasks complete. Variation in the length of each task causes the variation in the number of active tasks.

As the program is operating on a square grid, the iteration can easily be setup as a loop computing each point on a row, within a loop computing each row. Since there will now be a task for each row, 50 tasks will be starting tasks in parallel, and the average number of running tasks should rise to 1500. Figure 4-2 shows the parallel execution profile of the Mandelbrot program with two *futures.*

| Time | Active | Each * = 50 |
|---|---|---|
| (ms.) | PE's | Active Processors |
| 0 | 39 | * |
| 2 | 249 | ***** |
| 4 | 666 | ************* |
| 6 | 1281 | ************************** |
| 8 | 1581 | ******************************** |
| 10 | 1587 | ******************************** |
| 12 | 1476 | ****************************** |
| 14 | 1413 | ***************************** |
| 16 | 1386 | **************************** |
| 18 | 1376 | **************************** |
| 20 | 1317 | *************************** |
| 22 | 963 | ******************** |
| 24 | 485 | ********** |
| 26 | 147 | *** |
| 28 | 21 | . |
| 30 | 2 | . |
| 32 | 1 | . |

Figure 4-2: Mandelbrot - 50x50 Two Futures Case.

While 1500 tasks do execute simultaneously, the average speedup is approximately 850. The remaining sequential startup time for the 50 rows and 50 points in each column is responsible for average speedup being lower than the peak number of tasks.

A fairly simple program for obtaining automatic parallelism would find the two locations for inserting futures that were used here. A more advanced program might even use three or four levels of futures to speed the startup further. As very substantial amounts of speedup were obtained with minimal overhead, we conclude that programs similar to the Mandelbrot program can be automatically converted to effective parallel execution.

## TAK

TAK is a six line program used in the Gabriel benchmarks [3] intended to test the efficiency of Lisp implementations in calling recursive functions. For the purposes of this report, TAK provides opportunity for rapidly increasing parallelism provided that efficient primitives for fine grain task computation are available. Each recursive call to TAK spawns four more calls to TAK, three of which can execute in parallel. Thus, the potential parallelism of TAK grows exponentially with the call depth. Since the benchmark requires a call depth of 18 to complete, massive parallelism is available. However, a typical recursive call has fewer than ten instructions not counting those required by the deeper levels of recursion. If the overhead of creating a separate task is great, then the effective speedup will be poor. Therefore, TAK requires an efficient implementation of the parallelism primitives. TAK requires 3.05 seconds of sequential time to execute without *futures.* Figure 4-3 shows the results of *futures* on each of the three arguments to the recursive call to TAK.

The total processing time increases to 5.95 seconds in the parallel execution of TAK, almost doubling. The overhead of creating tasks is almost as much as that of executing. However, most of these task creations occur in parallel, so an effective speedup of approximately 85 is obtained. Indeed, if it were not for the long tail of low processor count, the speedup would have been greater. This tail is caused by tasks which block on their futures resuming and continuing the recursive computation. Therefore, even with very fine grain parallelism, significant speedup is possible.

## EMY

| Time | Active | Each * = 50 |
|---|---|---|
| (ms.) | PE's | Active Processors |
| 0 | 1060 | ******************** |
| 2 | 1414 | *************************** |

| 14 | 10 | . |
| 16 | 6 | . |
| 18 | 3 | . |
| 20 | 3 | . |
| 22 | 2 | . |
| 24 | 6 | . |
| 26 | 7 | . |
| 28 | 2 | . |
| 30 | 4 | . |
| 32 | 5 | . |
| 34 | 4 | . |
| 36 | 1 | . |

Figure 4-3: Tak with three *futures.*

EMY is an implementation of the inference kernel of the EMYCIN expert system [1]. It represents approximately 600 lines of Lisp code. It was discussed in detail in [6]. Briefly, it uses backward chaining reasoning to answer queries against its database. During the process of making deductions, it updates a global database, to save conclusions for use by other rules. These frequent operations on a shared database or "blackboard" prevent much parallel operation without use of synchronization primitives. Note that the "blackboard" model of execution is used in other AI programs such as Hearsay.

Nine locations were found for inserting *futures* in the EMY program. The effective speedup obtained was negligible. The lack of speedup reflects the small granularity of parallel tasks between operations on the shared database. These results are particularly noteworthy, as the EMY program has been shown to allow significant speedup (by factors of ten to twenty) when synchronized operations are allowed on the global database. At the current time, it is not well understood how to insert automatically synchronization around the access to a shared data structure.

## REWRITE

REWRITE is a simple theorem prover developed by Boyer and Moore to evaluate Lisp implementations. It is also included in the Gabriel benchmarks. It represents approximately 100 lines of Lisp code and 350 lines of data consisting of 104 lemmas. It was written with the intent of providing behavior that was representative of the much larger Boyer and Moore Theorem Prover. Theorem proving is an important part of the planning section of many AI programs. While the authors (Boyer and Moore) now have some doubts about the representative nature of REWRITE, it is the best available sample theorem prover. As it is shown in the Gabriel benchmarks, there are two places in the code which use global variables to pass extra values back from a function. To allow parallel execution, the code was changed to pass the extra values back as part of the function. After this change, most of the program is without side-effects, allowing automatic parallel execution.

The following theorem was selected for our measurement experiment:

```
(IMPLIES
   (AND (AND P1 Q1)
        (AND (IMPLIES P1 P)
           (IMPLIES Q1 Q)))
   (OR P Q))
```

| Time | Active | Each * = 5 |
|---|---|---|
| (ms.) | PE's | Active Processors |
| 0 | 10 | ** |
| 5 | 9 | ** |
| 10 | 17 | *** |
| 15 | 27 | ***** |
| 20 | 30 | ****** |
| 25 | 37 | ******* |
| 30 | 36 | ******* |
| 35 | 42 | ******** |
| 40 | 56 | *********** |
| 45 | 75 | *************** |
| 50 | 84 | ***************** |
| 55 | 85 | ***************** |
| 60 | 99 | ******************** |
| 65 | 136 | *************************** |
| 70 | 150 | ****************************** |
| 75 | 134 | *************************** |
| 80 | 143 | ***************************** |
| 85 | 139 | **************************** |

| 100 | 72 | ************** |
| 105 | 76 | *************** |
| 110 | 34 | ******* |
| 115 | 26 | ***** |
| 120 | 15 | *** |
| 125 | 11 | ** |
| 130 | 2 | . |
| 135 | 2 | . |
| 140 | 1 | . |
| 145 | 1 | . |
| 150 | 1 | . |

Figure 4-4: REWRITE with three *futures.*

Figure 4-4 shows the results of hand-insertion of three *futures* on the selected theorem. Sequential execution requires 7.1 seconds. A speedup on the selected test case of approximately 48 was obtained. More complex theorems would yield more opportunities for parallel execution, so we would expect greater speedups. We expect that similar results could be obtained from programs similar to theorem provers.

## Summary of Results

Table 4-1 summarizes the results of each experiment. The Mandelbrot program is listed in both the 1-*future* and 2-*future* form. We have observed speedups based on automatic syntactic insertion of parallel constructs ranging from 1 to 850. We draw the obvious inference that the amount of parallelism to be obtained is strongly dependent on the application selected.

| Program | Parallel Time (secs.) | Sequential Time (secs.) | Parallel Factor |
|---|---|---|---|
| Mandelbrot-1 | 1.168 | 27.8 | 24 |
| Mandelbrot-2 | 0.032 | 27.8 | 850 |
| TAK-3 | 0.036 | 3.1 | 85 |
| EMY | 0.500 | 0.5 | 1 |
| REWRITE | 0.150 | 7.1 | 48 |

Table 4-1: Summary

## CONCLUSIONS

### Style

Programming style is a major determinate of the effectiveness of these mechanical parallelizing techniques. The EMY program achieved no gain in performance due to frequent reading and writing of global data structures. The Mandelbrot program achieved massive parallelism because a well-defined separable unit of computation was incapsulated in a function. TAK and REWRITE achieved their parallel execution by having recursive functions with several arguments, each requiring substantial computation. Other programming styles may be expected to aid or hinder automatic parallel execution in similar ways.

### Implications

The approach adopted here — (simulated) automatic syntactic insertion of parallel constructs — has potential both for research into parallel execution of some Lisp programs, and also for "real" Lisp application programming. We expect to continue investigation of Lisp applications to broaden our understanding of the relationship between programming style and achievable parallelism.

Software engineering theorists have stressed that an applicative, non-side-effecting style of programming produces clearer and safer code. It can also be run in parallel with the same clarity and safety.

The requirements of many applications force a "blackboard" model for efficient operation. To the degree that the blackboard permeates the program design, to that degree will automatic syntactic insertion of parallel constructs be hindered. This style of programming shows that the automatic parallelization by syntactic pre-processors is not panacea for all programs, but just a part of a total solution.

### Approach to a Solution

A more complete solution would include: (1) syntactic pre-processors for modifying existing programs, (2) interactive analyzers to guide programmers in modifying existing programs for parallel execution, and to guide them in the initial construction of new applications, and (3) research into semantic analyzers to allow automation of the parallel execution of a broader class of programming styles.

In addition, it is imperative that a "cost analyzer" be incorporated into the pre-processor. The purpose of the analyzer is to predict the processing cost (time, memory references, bus delays, etc.) in order to estimate the benefits of simultaneous execution.

# REPRESENTING S-EXPRESSIONS FOR THE EFFICIENT EVALUATION OF LISP ON PARALLEL PROCESSORS

W. Ludwell Harrison, III
David A. Padua

Center for Supercomputing Research and Development
University of Illinois
Urbana, Illinois 61801

Abstract -- Present methods for exploiting parallelism in Lisp programs perform poorly upon lists (long, flat s-expressions), as such structures must be both created and traversed sequentially. While such a serial operation may be masked by overlapping it with other computation (by virtue of process spawning, or by the use of a mechanism such as *futures*), it represents a lost (and potentially large) source of parallelism. In this paper we describe the representation of s-expressions employed in PARCEL (Project for the Automatic Restructuring and Concurrent Evaluation of Lisp), which faciliates the creation and access of lists, without compromising the performance of functions which manipulate s-expressions of a more general shape. Using this representation, the PARCEL compiler translates Lisp programs written in a subset of the Scheme dialect (which allows for global variables and atom properties) into code for a large, tightly coupled shared memory multiprocessor.

## Introduction

Conventional methods of evaluating Lisp programs on parallel architectures are heavily skewed in favor of s-expressions which assume the shape of (relatively balanced) trees. In particular, it is frequently pointed out that much parallelism may exist in a program, written in an applicative subset of Lisp, which makes a symmetrical traversal of such an s-expression. By the use of a construct such as the *future* (see [6]) the time to traverse and operate upon a long, flat s-expresssion may be masked to a degree (if several processes are traversing the list, their operations upon it may be pipelined), but the essentially serial nature of such operations cannot be overcome by such a mechanism. In this paper we present the details of the storage scheme employed by PARCEL (Project for the Automatic Restructuring and Concurrent Evaluation of Lisp). This representation is intended to allow the fast creation and access of s-expressions which have the shape of lists, while not detracting from the performance of code which traverses s-expressions of other shapes (such as the trees mentioned above). The representation has some properties which make it interesting apart from its implications for parallelism in Lisp.

PARCEL is an investigation of the problem of compiling Lisp for evaluation on a large, tightly coupled shared memory multiprocessor. The project consists of a restructuring compiler, which produces from a program written in a subset of the Scheme dialect of Lisp an object code containing various directives for parallelism, and a run-time system, including parallel algorithms invoked by the compiled code, and a parallel garbage collection mechanism. The subset treated by PARCEL includes the side-effect causing mechanisms of free variables, atom properties, etc., as well as downward and upward funargs.

The PARCEL compiler employs novel algorithms for the compile-time transformation of Lisp programs. Some of these are extensions of ideas developed in the PARAFRASE project (see [8], [12]), while others are specific to the problem of compiling Lisp. For instance, an algorithm for creating loops from a recursive function is employed, which requires neither that the function be tail-recursive, nor that it be side-effect free (the algorithm is described briefly in this paper). A complete description of the design of the compiler is presented in [7].

The machine for which we are compiling is assumed to have a large number of identical processors connected to an interleaved memory via a fast interconnection network. Examples of such machines are the NYU Ultracomputer (see [4]), and the CEDAR machine (see [5]). We assume that the processors operate asynchronously, but at nearly identical rates of processing. Delays due to memory read conflicts will be ignored, in estimations of the performance of algorithms presented in this paper.

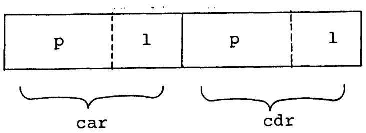

Figure 1. The Cons Cell Employed in PARCEL

## Pointers and Cons Cells

The PARCEL compiler employs an unusual cons cell, illustrated in Figure 1.[a] This cell consists, of course, of two pointers, the `car` and the `cdr`. The `p` field within each is an address in memory; for simplicity, let's assume that the fundamental unit of memory (machine word) is a single cons cell. The `l` field is an integer whose use will be explained shortly.

Throughout this paper, the word ***pointer*** will indicate a pair `[p, l]` such as the `car` and `cdr` in the illustrated cell. (Brackets will be used when treating a pointer explicitly as an ordered pair.) When we mean the location in memory of a data object, we will use the word ***address***; an address is but one of the two components of a pointer. If `z` is a pointer, then we will use `z.p` to mean the `p` component of `z`, and `z.l` to mean its `l` component. If `z` points to a cons cell, then we will use `z.p->car` to indicate the `car` pointer within the cell, and `z.p->cdr` to mean its `cdr` field. Accordingly, the components of the `car` pointer would be `z.p->car.p`, and `z.p->car.l`, and likewise for the `cdr` pointer. (This is meant to mimic the conventions of a language such as C or pascal.)

Consider Figure 2. The list `x = (a b c d e f)` is illustrated. Beside each arc (`p` component) in the figure is shown the value of the corresponding `l` component. For "variable" pointers (such as `x`) and `car` pointers, the `l` component indicates the length of the pointed-to s-expression. The list `x` has length six; beside the arc leaving `x` is shown a 6. A length of zero is associated with pointers to atoms. The `l` component of a `cdr` pointer has a very different meaning. Suppose that we take a double vertical line separating a pair of adjacent cons cells to indicate that the cells occupy adjacent locations in memory. In this example, the sublist `(a b c d)` consists of a block of four cons cells in contiguous memory locations (`x.p` through `x.p + 3`), and the sublist `(e f)` occupies two consecutive memory locations. If `y` is

[a] For the purposes of illustration, we have omitted other tag bits used to indicate, for example, a numeric atom (integer), etc.

[b] We will see shortly that it is also possible for a list to terminate "within" a contiguous block, i.e., at a cell `y` such that `y.cdr.l` ≠ 0.

0190-3918/86/0000/0703 $01.00 © 1986 IEEE

a cons cell, then y.cdr.l indicates the number of cons cells "to the right" of y in the contiguous block of cells containing y. In other words, if one is traversing a list beginning at y, y.cdr.l is the number of adjacent locations following y that will be visited before a cdr pointer leads to a non-adjacent memory location, or the end of the list is reached.[b] This is very similar to the *cdr-coding* scheme for list storage; see [1], [10]. Cdr-coding is a technique for reducing the average space consumed by a cons cell, and is based on the observation that the cells in the top level of a list frequently occupy contiguous memory locations. The storage scheme presented here has properties not available from cdr-coding; the motivation for its development is to facilitate the parallel creation and access of lists, although we will see that it allows a more flexible sharing of sublists than conventional list representations, which may result in greater than usual efficiency of storage. For the moment we will assume that, unlike in the cdr-coding scheme, all cdr pointers are present and properly assigned, even within contiguous blocks of cells.[c]

## The Primitive Operations car, cdr, cons and length

Figure 3 shows our definitions of four primitive operations upon s-expressions: car, cdr, cons, and length.

Let's consider these definitions in turn. car(x) simply returns the value of the cons cell to which x points. cdr(x) is a bit more complex. Notice first that we do ***not*** use the reading of a null pointer as an indication of list termination; if the length of x is one, then cdr(x) returns nil, under the assumption, which we will make throughout this paper, that all lists are nil-terminated.[d] nil is, like all pointers, an ordered pair consisting of the address of the atom nil and an l field of zero. If x.l > l, then cdr(x) returns a list whose length is one less than that of x.

Now consider the function cons(y, x). If the newly allocated cell happens to immediately precede x in memory, then the l component of the cdr pointer of this new cell is set to indicate that it is part of the same contiguous block of cons cells as the first cell in x; otherwise, this l component is set to zero, indicating that the new cell is the rightmost in a new contiguous block of cells. This is an unsatisfactory method of creating large contiguous blocks, as it depends upon only one list at a time being created by calls to cons. In other words, if calls made to cons for the allocation of cells to be used in building a list x are interspersed with calls for cells to be used in building y, then neither x nor y will contain long contiguous blocks. We will return to this matter shortly.

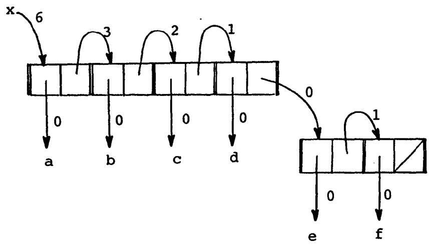

Figure 2. The List (a b c d e f)

Finally, consider the trivial definition of length(x). It goes without saying that if we associate the length of an s-expression with every variable and car pointer, that we may find the length of a list in constant time.

## Some More Primitive List Operations

Now let's consider some slightly more complex list operations as they might be defined to take advantage of our storage scheme. Consider the operation nthcdr, as defined in Figure 4. nthcdr(x, n) is equivalent to cddd ... dr(x) (n d's). It works by first deciding if the cell for which it is searching is among those in the contiguous block containing the first cell in x; if so, it jumps immediately to that cell, and returns a list n cells shorter than x. Otherwise, it skips directly to the end of this contiguous block, and follows the last cdr pointer to the next contiguous block, repeating the process. The important point is that any cell within x may be reached within time proportional to the number of contiguous blocks comprising x, and not proportional to the length of x. A great deal of effort is spent by the PARCEL compiler and run-time system in assuring that the contiguous portions of a list are as long as possible; that is, that each list is comprised of as few contiguous segments as possible. We will return to a discussion of some of the means of doing so.

The operation firstn(x, n) reveals an essential characteristic of our list representation. As its name indicates, firstn returns a list consisting of the first n cells of x. Given a conventional representation for lists, there are two ways of achieving this effect. The first (the usual definition of firstn) is simply to copy the first n cells of x, and return a pointer to this new list. This has no ill-effect upon the storage system as a whole, but necessitates the expenditure of n cells and O(n) time to copy them. The second means is to march out to the nth cell in x, and rplacd the value nil into the cell's cdr field. This has the virtue of requiring no additional storage, but the disadvantage that the original list, along with every other list sharing the cell, is altered, and that it, too, takes O(n) time.

Notice how easily this operation may be performed given our representation. This is entirely due to the fact that the end of a list is located, not by finding a null cdr pointer, but rather by successively decrementing the list's length as it is traversed. In particular, notice that we may remove the last element of a list in constant time, with the operation firstn(length(x) - 1), which makes no examination of the list x at all. This allows us to replace a destructive, side-effect causing operation (rplacding the next-to-last cell of a list) with a functional one, and to reduce the computation time by a factor of n at the same time.

Finally, consider the definition of lastn(x, n) which takes, like nthcdr, time proportional to (at most) the number of contiguous blocks of which x is comprised.

The operations illustrated in this section are very useful when performing traversals (especially parallel access) of an s-expression which is essentially list-like; that is, one that is long in the "cdr" direction. But notice that the speed of a non-linear traversal (one which follows, say, car and cdr pointers in a symmetrical way) has not been compromised; the functions car and cdr have remained quite inexpensive. This is important, for, just as it is not always the case that s-expressions describe balanced trees, so it is not always the case that they describe long and flat lists; we wish to use a representation which does not provide fast access for the one shape at the expense of the other.

[c] As the reader may have guessed, this is unnecessary, but the details of conditionally omitting these fields are not treated in this paper. This system is being implemented experimentally for the CEDAR machine [5], which has a 64 bit word; each of our pointers will occupy one machine word.

[d] It is a simple matter to extend the representation to accomodate improper lists; see [7].

```
nthcdr(x, n) ≡
  if n = 0 then return(x)
  else
     dist := x.p->cdr.l;
     if dist ≥ n
        then return([x.p + n, x.l - n]);
        else return(nthcdr(
                          cdr([x.p + dist,
                               x.l - dist]),
                          n - dist - 1));

firstn(x, n) ≡ return([x.p, x.l - n]);

lastn(x, n) ≡ return(nthcdr(x, x.l - n));
```

Figure 4. Definitions of nthcdr, firstn, and lastn

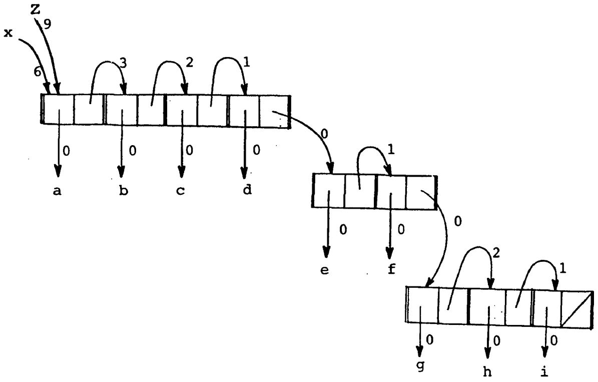

Figure 5. After Performing append(x, y)

## rplaca, rplacd, append, and nconc

The operations rplaca and rplacd are forbidden in PARCEL. While the operation rplaca is no different to perform using our representation than when using a conventional one, the increased level of sublist sharing causes a concomitant increase in the likelihood of rplacaing a shared cell, and makes it practically impossible to give a precise semantic definition of the construct. This combines with the fact that rplaca may be used to violate the call-by-value mechanism in Lisp to make for a very sticky problem. The operation rplacd is far more difficult to perform using this representation. The reason is that the usual semantics of rplacd cause it to affect the length of every list sharing the altered cell. Even if we could determine the location of every variable and car pointer to a list sharing each cell (a very expensive affair), we would have to know the exact position within the list of the cell to determine its effect on the list's length. The philosophy of PARCEL is to forbid the rplac constructs until (unless) they can be incorporated without a crippling effect on the parallelism of the resulting code.

Two of the most important uses of rplacd are to remove elements from the end of a list (delete a suffix) and to add elements to the end of a list, in both cases without causing any of the unaltered portion of the list to be copied. We have already seen that our representation provides a much faster means of doing the former (via firstn); let us now turn to the latter. Consider Figure 2 again, and notice that the cdr pointer of the last cell of the list is never used; non of the primitives we have defined so far examine or alter its contents.

Suppose that we wish to form the list z = append(x, y),, where x is as shown in Figure 2 and y = (g h i). We may perform this operation by rplacding the last cell in x;[e] the p component of this cdr pointer is set to the address of the first cell in y, and its l component is set to zero. We return a pointer to the first cell in x, with an l component equal to x.l + y.l. Figure 5 shows the state of affairs after this operation. Notice that this operation has the semantics of append, and not of nconc; this is, as we have said, because the extent of x is determined using its length and not by searching for a null cdr pointer. The reader may wish to verify that the primitives defined to this point still apply to the list x.

Figure 6 shows a definition of the operation append(x, y). It works as follows. First we find the last cell in x. If the cdr pointer of this cell is nil, then we simply place the address of y in the p component of this cdr pointer, and a zero in its l component, indicating that y is not part of the contiguous block containing the last cell in x. In this case, the entire operation takes only time proportional to the number of contiguous blocks of which x is composed. If the cdr pointer of the last cell in x is non-null, then we must use the old (conventional) definition of append (called old-append here), which copies x to a new location. If, for instance, after performing z = append(x, y) as above, we attempt to form q = append(x, y), we will find that the cdr pointer of the last cell in x is non-null, forcing us to perform the old version of append. Notice that if x is represented in a small (constant) number of blocks,[f] that it may be copied in parallel with linear speedup, to a new (contiguous) block of cons cells. Even if this is done sequentially, by copying it to a contiguous block, we guarantee that later accesses to x will be made faster. (It is easy to allocate a contiguous block, since we know x's length.)

```
append(x, y) ≡
    lastcell := last(x);
    /* lastcell is a pointer */
    if lastcell.p->cdr := nil then
        lastcell.p->cdr := [y.p, 0];
        return([x.p, x.l + y.l]);
    else return(old-append(x, y));
```

Figure 6. A Definition of append

This definition of append affords many of the advantages of nconc, without the side-effects to other lists for which that operation is well-known. Of course, there are occasions for wishing to alter several lists, using "back-door" side-effects, via such constructs as rplacd and nconc; but, as we have said, our primary

[e] Ironically, forbidding the use of rplacd has allowed us to make use of it in a way that is impossible when it is permitted.

[f] A possibility worth exploring is to add to each car and cdr pointer a field indicating the number of contiguous blocks of which the referenced s-expression is composed. The ratio of the length of the list to this value is an estimate of the potential speedup (number of useful processors) of a traversal of the list, such as that done during copying. It is easy to incorporate this information into the return value from cons, append, etc. One difficulty comes when using firstn as we have defined it (there is no way to see the resulting number of blocks without examining the list), but if the number of blocks in a list is used for purposes of estimation, then we may assume that the ratio of length to number of blocks for a particular list remains constant, and adjust the latter accordingly. Such a number might also be used to determine when garbage collection should be applied (our garbage collection algorithm puts every list in the system into contiguous form, space permitting). But we digress.

motivation in developing this representation of s-expressions is to facilitate the parallel reading and writing of lists. It is hoped that the advantage of being easily able to do so will outweigh the advantage of permitting such aliased side-effects.

The definition (of append) is not yet satisfactory however; as given in Figure 6, it decides dynamically whether its operation can be done using "nconc", or must be done by copying its first argument. If, however, there is a sufficient number of processors at hand, it may be best to copy ***both*** arguments to a single contiguous block, than to copy only one or none. In the extreme case, suppose we have two lists of length n/2 (which are, say, in fully contiguous form), and n processors with nothing to do. Clearly it would be best to put these to use by copying these lists (in one time step) to form a single contiguous list.[g] Experimentation is needed in designing a well-behaved heuristic for deciding when such copying should be done; for the moment, let us say that if the number of available processors P is greater than n/k, where k is some small constant and n is the sum of the lengths of the arguments to append, then both arguments will be copied; otherwise the definition of Figure 6 will be applied. (This seems an ideal application for information concerning the number of blocks composing a list - see footnote (f) above.)

## Parallel Creation and Access of Lists

In this section we will show, in an abstract setting, how some recurrences involving list operations may be solved in parallel; the examples will seem, no doubt, removed from the realities of Lisp programming. Afterwards, we will suggest briefly the way our compiler arranges for the detection and solution of such recurrences in the context of real Lisp programs. The example of Figure 5 suggests the possibilities for sublist sharing allowed by this representation. Notice that we have done something impossible with ordinary representations: two lists may share a cell without sharing the entire subexpression rooted at that cell. It is this important property which will allow us to solve some (ordinarily very costly) recurrences involving list operations with greater than linear speedup (when compared to conventional representations and solutions).

Figure 7 shows a simple recurrence, consisting of a loop in which x is traversed, cell by cell. When f(i) is true, x is advanced to the next cell, otherwise it is unaltered. Let us suppose that we wish to know the value of x after every iteration of this loop (say, for input to another parallel loop). We may treat x as an array x[] of length n (a technique called ***scalar expansion*** - see [12], [7]). x[0] will be synonymous with the starting value of x, and x[i] will be the value of x after iteration i of the loop in Figure 7. In this case the code of Figure 8 will suffice. (A doall loop is one in which all iterations may be executed simultaneously; that is, given n processors, where n is the number of iterations of the doall loop, the loop will complete in the time required by its longest running iteration. See [2]). After loop (2), d[i] will indicate the number of times cdr has been applied to x in producing x[i]. This computation of the vector d[] embodies a familiar technique called ***parallel prefix*** - see [8]. Assuming that x is contained in a small (constant) number of contiguous blocks, the speedup obtained is O(n/*lg* n). We can do much better than this if n is large relative to the number of processors (P) allocated to this loop; in fact, if n > P·*lg* P, then we can achieve constant efficiency (a running time of O(n/P)) by operating on the vector d[] in subsequences of length n/P on each processor, before and after the "recursive doubling". Figure 9 shows the improved version of the algorithm in loop (2), which will now have a running time of $T_P$ = O(n/P + *lg* P). The vector D[] has length P + 1; the algorithm works in the following way.

```
do i = 1 to n
    if f(i) then x := cdr(x);
```

Figure 7. A Simple Recurrence Involving cdr

```
(1) doall i = 1 to n
       if f(i) then d[i] = 1;
               else d[i] = 0;
    dist = 1;
(2) do j = 1 to ⌈lg n⌉
      doall i = 1 to n
         if i > dist then
            d[i] := d[i] + d[i-dist];
      dist := dist * 2;
(3) doall i = 1 to n
      x[i] := nthcdr(x[0], d[i]);
```

Figure 8. A Parallel Version of Figure 7

```
doall i = 1 to P
   do j = (i-1) ·⌈n/P⌉ + 2 to i·⌈n/P⌉
      d[j] := d[j] + d[j-1];
   D[i] := d[i·⌈n/P⌉];
do j = 1 to ⌈lg P⌉
    doall i = 1 to P
       if i > dist then
          D[i] := D[i] + D[i-dist];
    dist := dist * 2;
D[0] := 0;
doall i = 1 to P
    do j = (i-1)·⌈n/P⌉+1 to i·⌈n/P⌉
       d[j] := d[j] + D[i-1];
```

Figure 9. An Efficient Algorithm for Parallel Prefix

Processor i, 1 ≤ i ≤ P, forms the sum d[(i-1)·⌈n/P⌉+1] + d[(i-1)·⌈n/P⌉+2] + ... + d[i·⌈n/P⌉]. Then, in the middle loop in the figure, we form the partial sums D[i] = d[1] + d[2] + ... + d[i·⌈n/P⌉]. Finally, we add the value D[i-1] into each of d[(i-1)·⌈n/P⌉+1] through d[i·⌈n/P⌉], in the final doall loop. This is a well-known method for folding the parallel prefix solution onto limited processor; see [8].

Now consider the example in Figure 10. Here, we are adding the list x[i] to the end of y, during each iteration of the the loop. (x[i] might, for example, be a value such as f(car(nthcdr(z, i-1))), for some other list z, as computed by a loop such as that in Figure 8. Notice how the computation has been broken into a series of parallel steps; this is the result of ***loop distribution*** - see [8], [12], [7]. Figure 11 shows the parallel version of this code, in which the value of y after every iteration of the original loop (y[i] is the value after the ith iteration) is produced. In loops (1) and (2), we compute d[i], 1 ≤ i ≤ n, which equals the number of cells added to (the original) y after iteration i of the original loop. Next, we allocate a contiguous block of cons cells of length d[n], i.e., of length equal to the total number of cells added to y. This block is pointed to by z. In loop (3), we copy each appended sublist to its destination within z. The function copy_to takes as arguments a list (pointer) and a destination address; it copies each cell in the top level of the list into contiguous locations beginning at the destination address. In addition, it causes the cdr pointer of the last cell in the duplicate sublist to point to the next location in memory (the destination address of the next sublist to be copied.) After explicitly setting the cdr pointer of the last cell in z to nil, we append z to y (see discussion of append above). Finally, we compute the value of y[i], for 1 ≤ i ≤ n; this is simply a pointer to y (recall

[g] This has no effect upon the semantics of append; however, it (once again) affects the amount of sublists sharing (this time, by decreasing it) which, in turn, affects the use of rplaca.

```
do i = 1 to n
    y := append(y, x[i]);
```

Figure 10. A Simple Recurrence Involving append

```
(1) doall i = 1 to n
        d[i] := x[i].l
    dist := 1;
(2) do j = 1 to ⌈lg n⌉
        doall i = 1 to n
            if i > dist then
                d[i] := d[i] + d[i-dist];
        dist := dist * 2;
    z := allocate(d[n]);
    d[0] := 0;
(3) doall i = 1 to n
        copy_to(x[i], z.p + d[i-1]);
    (z.p + d[n] - 1)->cdr = nil;
    y := append(y[0], z);
(4) doall i = 1 to n
        y[i] = [y.p, y[0].l + d[i]];
```

Figure 11. A Parallel Version of Figure 10

that we are adding cells to the end of y), with length equal to the sum of the lengths of (the original) y, and the number of cells added during iterations 1 through i of the original loop.

To make this procedure more tangible, let's suppose that n = 4, that y (initially) equals (a b c), and that x[0] = (d e), x[1] = (f g h), x[2] = nil, and x[3] = (i j). The initial state of affairs in shown in Figure 12, and the state after execution of the code in Figure 11 is shown in Figure 13.

In the general case, let us assume that each of the x[i]'s to be appended, along with the original y, has length of approximately m, and that (the original) y is represented using a small (relative to n) number of contiguous blocks. Then the time to perform the operation of Figure 11 using P processors is $T_P = O\left(\frac{n \cdot lg\, n}{P}\right) + O\left(\frac{m \cdot n}{P}\right)$. With the improved version of parallel prefix described above, it is $T_P = O\left(\frac{n}{P} + lg\, P\right) + O\left(\frac{m \cdot n}{P}\right)$. The number of cells used in representing the resulting lists is O(nm).

Using a conventional representation and means of evaluation, this operation would take $T_1 = O(mn^2)$.[h] Apparently in this (arguably anomalous) case, we have achieved a speedup of O(nP), suggesting that considerable improvement could be made in the usual (sequential) means of evaluating such a recurrence.

It is straightforward to extend this type of parallel list operation to the operator cons, or to the case of appending onto the front of a list; in these cases, we must be satisfied with (at best) linear speedup. Notice that if, within a loop such as that in Figure 7 or 10, we decrease the length of a list by a constant number of cells per iteration (via the operation cdr) or increase its length by a constant number of cells per iteration (with cons or append), that there is no need to use parallel prefix to compute the lengths of the intermediate values; in such a case, the length of the list behaves as an induction variable (i.e, it describes an arithmetic sequence).

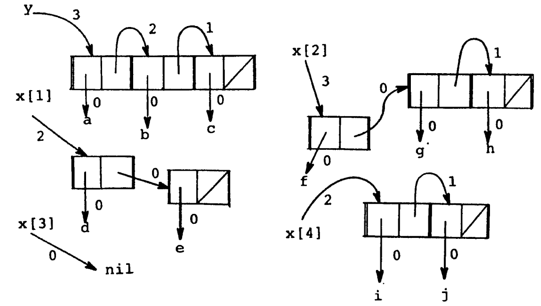

Figure 12. Some Lists to Be Appended as per Figure 11

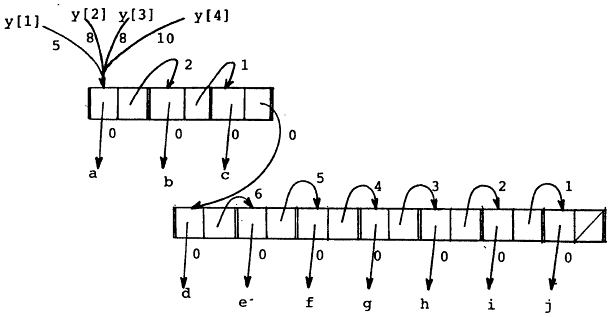

Figure 13. The State After Performing Figure 11

It is an important property of the code generated by the PARCEL compiler that every parallel list-creating operation results in a single, contiguous block of cells, such as z in the above example. This is because such operations make a single call to the function allocate. As mentioned, the performance of code in which the elements of a list must be accessed in parallel depends upon the existence of large, contiguous blocks; consequently, it may be useful to apply techniques which increase the contiguity of lists created sequentially, by repeated calls to cons. See [1], [7].

### The Use of the Storage Scheme in Compiled Lisp Code

Consider the definition of union in Figure 14. The function is recursive, but not (strictly) tail-recursive, as cons may be called after returning from a recursive invocation. The first step taken by our compiler is to build a representation of the function, which is, for the most part, a standard flow-of-control graph. See Figure 15. The variable r is a local temporary variable, used to hold the return value of an invocation of the function. The first optimization to be performed by the compiler in this case is called *recursion splitting*. Recursion splitting is a very general technique for forming loops from recursive functions. It does not require that the function be tail recursive, nor that it be side-effect free. The basic idea is to select a set of *recursive nodes* of the function (nodes in which there is a recursive call to the function) such that there is at most one member of the set along any path through the graph of the function. Then the graph is "split" into two loops (called the forward and backward loops), using these nodes as the points of separation. See Figure Figure 16, in which an abstract function graph is shown. The recursive nodes are shown as double circles, labeled 1, 2, 3, and 4. Suppose that we choose to split using nodes 1 and 2;[i] the result would look something like Figure 17. The first loop in this figure performs the operations of the function as recursive calls are made from members of the selected set of recursive nodes (that is, the portion of the computation of the original function which occurs as the stack becomes deeper due to these calls); the second loop performs the operations of the function as those calls unwind. Recursion splitting works hand-in-hand with our techniques for recurrence recognition and solu-

[h] Note that this is true even if nconc were used; however, as nconc is destructive, only the final value of y could be constructed in this manner. It is arguably rare to repeatedly append to the end of a list; yet it may be that this is because it is ordinarily so expensive (for it seems a natural enough thing to do).

```
(def union (lambda (a b)
   (cond [(null a) b]
         [(member (car a) b)
             (union (cdr a) b)]
         [t (cons (car a)
             (union (cdr a) b))])))
```

Figure 14. The Function union

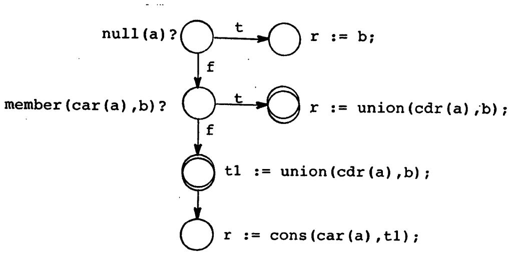

Figure 15. The Graph of union

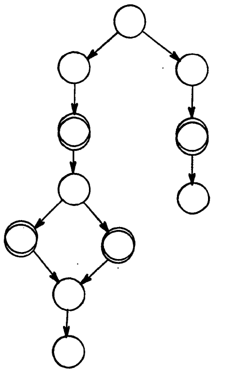

Figure 16. A Function Graph, with Recursive Nodes Indicated

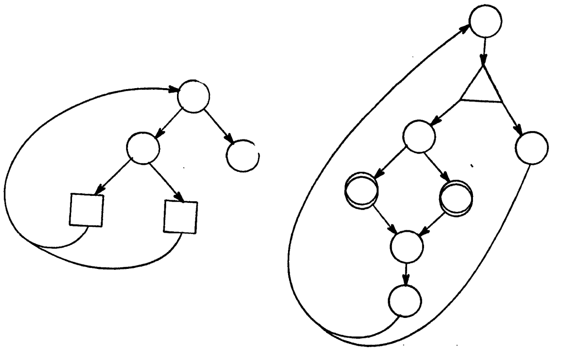

Figure 17. The Graph of Figure 16, After Recursion Splitting

tion. For the transformation to be successful, we must be able to form a recurrence which is used to determine, prior to entering the loops we have created, the number of iterations of each (they have the same number of iterations, just as, in the original function, we must have as many returns from, as we have calls to, the function). This number is equal to the number of consecutive calls made from the nodes used to split the graph. Expanded variables (in the case of Lisp, single pointer variables turned into vectors of pointers) simulate the action of the stack upon the local variables of the function; that is, instead of using a stack to record the state of variables before and after those recursive calls made from those nodes used to split the graph, we represent each variable as a vector, and write the value of the variable before the ith such recursive call into the ith position of the vector. As a consequence, it is much easier to access and manipulate these values in parallel, than if they were dispersed across the run-time stack.

Note that, in this abstract example, the recursive calls in nodes 3 and 4 remain in the modified graph of the function. They become recursive calls to the transformed function, which means that there will be dynamically nested parallel loops if the forward and backward loops are amenable to further optimization. If not, that is, if the bulk of the computation in these loops remains sequential, then we would probably be better off with a more direct translation of the original function definition. The purpose of recursion splitting is to introduce parallelism, and not to remove recursion per se.

Figure 18 shows what union might look like after recursion splitting. Each of a, b, and r is turned into a vector of pointers (in the subsequent transformations, we will turn around and restore b and r to single pointers). The vector e[] is used to record, for each iteration of the forward loop, which of the recursive nodes is reached. This information is used by the corresponding iteration of the backward loop to allow the computation to resume at the correct point. In terms of the original function, this corresponds to the fact that, before a recursive call, a record is made on the stack of the point from which the call is being made, so that execution may proceed from that point when the stack frame is restored. Notice that, intuitively, the backward loop runs "in the opposite direction" of the forward loop; that is, increasing the iteration number of the forward loop corresponds to moving deeper on the run-time stack, while the opposite holds true for the backward loop.

The code finally produced for union, after performing

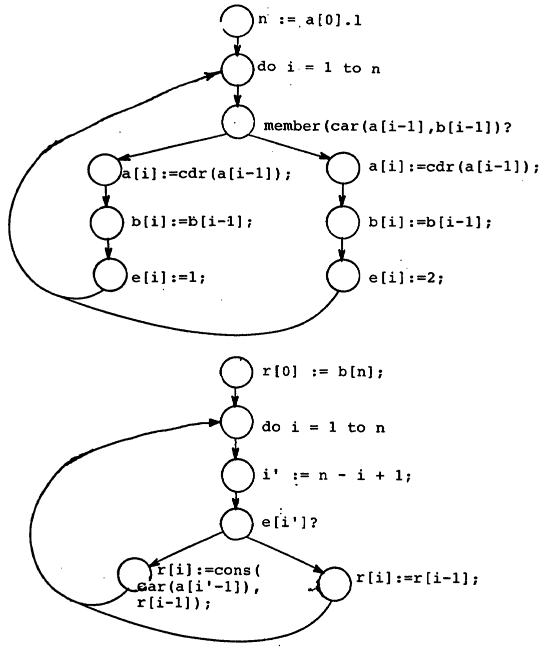

Figure 18. The Graph of union, After Recursion Splitting

(j) The choice of nodes with which to split a function depends upon the recurrences which will result among the variables in the created loops. We wish to find a set of nodes such that the resulting recurrences may be solved in parallel. (We speak of recurrences, but it may be that the variables describe a very simple pattern, such as an arithmetic sequence, or that their values from one iteration to the next are entirely independent; recurrences are the most general case treated by the technique.)

many other manipulations of its graph would look something like that shown in Figure 19. We will describe each of the `doall` loops in turn, assuming that we have $P \leq n$ processors with which to perform the function, where n is the length of (the starting value of) a. (As is frequently the case, no recurrence solution is needed to compute the number of iterations of these loops, as it is simply the length of a list; and because this length is recorded within the pointer to the list, the time to "compute" the loops' upper bound is constant.) Loop (1) assigns all of the intermediate values of a in the loop. As we saw, if a is represented in a constant number of blocks, this will take $T_P = O(n/P)$. The compiler recognizes that the length of a behaves as an induction variable, and knows therefore that its intermediate values may be computed without the use of a recurrence solution technique. Loop (2) assigns the value of `e[i]`, which records the number of the recursive node reached during iteration i of the forward loop. This is also very striaghtforward for the compiler, as it sees that the value of the variable e (which we have "expanded" into a vector) during each iteration is independent of its value in all others. Loops (1) and (2) were created by "loop distribution" from the forward loop (see [12], [7]). (In reality, these loops would be "fused" into a single `doall` loop; see [11].) Loops (3), (4), and (5) were created by distributing the backward loop. Loop (3) places an integer (1 or 0) into each location in the vector `d[]`, indicating whether a cons cell is added to r during a particular iteration of the backward loop. The compiler actually translates this in a more general way, as the length of the sublist appended to the front of r during each iteration. This allows the process of recurrence recognition to made quite formal, as the compiler maps all associative recurrences involving list operations onto arithmetic recurrences involving the intermediate values of the length of the recurrence variable. Loop (4) is the familiar and inefficient version of parallel prefix used to form the values `d[1], d[1] + d[2]`, etc. In the code generated by the compiler, this would be a function call and not written explicitly into the code. Before entering loop (5), space is allocated for the cons cells added by `union` to the front of b. In loop (5), each added cell is copied into its final resting place within this contiguous block of cells. Again, the compiler translates this in a more general way; a `doall` loop is generated, in which every sublist appended to the front of the return value of the function is placed at its destination position within z; a sublist of length zero causes no such placement to occur. We append the block z to the front of b, and return the result. Using an efficient algorithm for parallel prefix, the whole process will take $T_P = O\left(\frac{n \cdot T(\text{member})}{P}\right) + O(lg\, p)$, where T(member) is the time for a call to `member`. Now, `member` is also quite easily made parallel; it, in turn, calls `equal`, which is as well. However, in reality a function such as `union` is likely to appear near the "bottom" of the calling graph of a program, meaning that unless we have either a very large machine, or only procedures which we cannot make parallel "above" `union` in the calling graph, `union` is unlikely to receive a large number of processors. If it is always evaluated sequentially, a translation closer to the original would be better, as (for one thing) the code produced will be smaller than for the transformed version.

Finally, let's examine the definitions of `quicksort` and `split` and given in Figure 20. First consider the driving routine, quicksort. Recursion splitting fails here, as the recurrence defined by the operation `split` cannot be solved in parallel by our methods. (In effect, the compiler sees a recurrence such as `l[i+1] := car(split(cdr(l[i]), car(l[i]), nil, nil))` which must be solved sequentially.) That attempt failing, the compiler inserts a forking directive, causing the two recursive calls to quicksort to be executed simultaneously, resulting in a process tree.

```
     n := a[0].l;
(1)  doall i = 1 to n
         a[i] = nthcdr(a[0], i);
(2)  doall i = 1 to n
        if member(a[i], b) then e[i] := 1;
                                else e[i] := 2;
(3)  doall i = 1 to n
         i' := n - i + 1;
         if e[i'] = 1 then d[i] := 1;
                           else d[i] := 0;
     dist := 1;
(4)  do j = 1 to ⌈lg n⌉
        doall i = 1 to n
           if i > dist then
              d[i] := d[i] + d[i-dist];
        dist := dist * 2;
     z := allocate(d[n]);
     d[0] := 0;
(5)  doall i = 1 to n
         i' := n - i + 1;
         if e[i'] = 1 then
             (z.p + d[i'] - 1)->car :=
                 car(a[i'-1]);
             (z.p + d[i'] - 1)->cdr :=
                 [z.p + d[i'], z.l - d[i']];
     r := append(z, b);
     return(r);
```

Figure 19. A Parallel Translation of `union`

```
(def quicksort (lambda (l)
 (cond
   [(null l) nil]
   [t (let ((l_and_r (split (cdr l) (car l)
                               nil nil)))
        (append (quicksort (car l_and_r))
                (list (car l))
                (quicksort (cadr l_and_r)))
      )]))))

(def split (lambda (l)
 (cond [(null l) (list left right)]
       [(lessp (car l) partition)
          (split (cdr l) partition
                 (cons (car l) left) right)]
       [t (split (cdr l) partition
                 left (cons (car l) right))]
    )))
```

Figure 20. The Function `quicksort`

Now consider the definition of `split`. Recursion splitting succeeds here (trivially), resulting in a function which takes $T_P = O\left(\frac{n}{P} + lg\, P\right)$, on P processors, where n is the length of the first argument to `split`. The fact that `split` is tail recursive means that the backward loop will be empty (non-existent).

Now let's consider how the transformed versions of the functions would work together. Assume that n processors are available to quicksort, where n is the length of the list to be sorted; all n participate in the operation `split`, which thus takes $T_P = O(lg\, n)$, given an input list represented in a constant number of blocks. In the recursive calls to quicksort, assume that the processors are again divided according to the lengths of the sublists to be recursively sorted. Upon the return (join) of these two recursive calls, all n processors are available to perform the append operation; hence the two sorted sublists, along with the list consisting of the single partitioning element, are copied to a single contiguous block of storage (see the discussion above, concerning parallel copying during append operations). Assuming that we have input lists in random order, it can be shown that the average time to perform the entire sort will be $T_P = O(lg^2 n)$. In the case in which there are $P < n$ processors available, the average running time is $T_P = O\left(\frac{n\,lg\,n}{P}\right) + O(lg\,P \cdot lg\,n) - O(lg^2 n)$.

There is an interesting point here, concerning append. Each recursive call to quicksort returns a list which is in a single contiguous block. Because the complexity of split is $O(n/P + lg\,P)$, the time to copy the two results returned by recursive calls into a single contiguous block ($O(n/P)$) will always be less than the time to split the original list which was passed to those calls, meaning that the complexity of the algorithm is not affected adversely by the use of the "copying" version of append. On the contrary, it is only possible to achieve this running time when the copying version of append is used, for otherwise the recursive calls will return lists consisting of (within a constant factor) the same number of blocks as elements, causing append to require linear time.

## Conclusion

We have presented a storage scheme for s-expressions which facilitates the parallel creation and use of lists. The representation may be inexpensively used to represent s-expressions of more general shape, and allows a more flexible sharing of sublists than conventional representations. The PARCEL compiler, assuming this representation, produces code for a shared memory multiprocessor from programs written in a subset of the Scheme dialect of Lisp.

# The Classifier System: A Computational Model That Supports Machine Intelligence

Stephanie Forrest

Teknowledge Inc.
1850 Embarcadero Road
P.O. Box 10119
Palo Alto, California 94303

Abstract -- The Classifier System is a parallel computational model that supports two important aspects of machine intelligence: machine learning algorithms and operations on high-level "knowledge" structures such as those frequently used in artificial intelligence research. The Classifier System formalism is presented and previous research using the Classifier System in conjunction with two learning algorithms is reviewed. A Classifier System implementation of the knowledge representation language KL-ONE is described, and analytical results are described that show that the implementation exploits the parallelism of the Classifier System.

## Introduction

Researchers in artificial intelligence (AI) are exploring various models of parallelism, both for the purpose of improving performance of AI programs and to express models of intelligent behavior. The possibility that parallel architectures could implement AI models directly has encouraged the development of parallel models that might have both efficient hardware implementations and plausibility as intelligent systems.

Performance improvements can be obtained by using parallelism to improve the execution speed of current languages in which most AI programs are implemented. Projects to construct parallel implementations of Lisp [12], [10] and Prolog [4] fall into this category. Parallel hardware is also being designed to help traditional AI programs execute more efficiently. The Butterfly machine under development at Bolt Beranek and Newman, and the FAIM [6] and NON-VON [19] machines are three examples of such hardware projects.

A second approach is to consider new intermediate representations out of which intelligent systems can be built. Projects such as ABE [7] provide computational units that can be readily composed into large knowledge systems and are amenable to implementation on many different multi-processing systems.

Yet another approach is to build machines that implement parallel models of intelligent behavior more or less directly. The most prominent example of this is the Connection Machine architecture [13] being developed by Thinking Machines Inc. However, there are several other proposed computational models for which hardware implementations do not yet exist that claim to express some aspect of intelligence. These include the Classifier System [18], the Boltzmann machine [14], and the NETL machine [8]. These models all have some features in common, such as massive parallelism, processors with limited computational power, and a high degree of connectivity between processors. The Classifier System and the Boltzmann machine are notable in that the models have been designed expressly to support learning; however, it has not been clear how well these two "fine-grained" models will be able to represent and process high-level symbolic structures.

The research described in this paper explores the question of how well the Classifier System can represent and process high-level symbolic knowledge structures. To explore this issue, I selected a high-level knowledge representation language (KL-ONE) that has well-defined algorithms for accessing and manipulating information stored in knowledge structures, and studied how well the Classifier System could support its facilities. The remainder of the paper is divided into four sections: The Classifier System, Methodology, Results, Discussion, and Conclusions.

## The Classifier System

The Classifier System [18] is a massively parallel model developed by John Holland in which each computational unit (classifier) has very limited processing power, and in which there is no global supervisor. Every processor can communicate with every other processor, and, as will be shown, the extent of this communication can be controlled easily. Each processing element is highly standard, which makes the Classifier System a promising candidate for implementation in hardware. The Classifier System is well suited for problems in artificial intelligence because (1) it possesses a high degree of parallelism, (2) it allows processors to communicate with one another flexibly, (3) learning mechanisms can be applied at several levels within the system, and (4) high-level symbolic representations can be expressed within the formalism.

The Classifier System is modeled on the idea of production systems [5]. It contains a data base of production rules, called classifiers. Each classifier can perform one action, that of adding messages (bit strings) to the short term memory (called the message list). At any instant the state of the message list determines which classifiers are eligible to write information to the message list at the next time step.

Each classifier, or production rule, consists of a condition part and an action part. The action part specifies exactly one action, while the condition part may contain many conditions (pre-conditions of activation). Rules with more than one condition are referred to as "multiple-condition classifiers." A multiple-condition classifier must have each of its pre-conditions matched in a single time step for it to be activated (although it is not necessary that the same message match each condition). The conditions and actions are fixed-length strings over the alphabet (1,0,#) where # denotes "don't care" and 1 and 0 are literals. The determination of whether or not a specific message matches a condition is a

0190-3918/86/0000/0711 $01.00 © 1986 IEEE

logical bit comparison on the defined (1 or 0) bits. If a "not" condition is used, the condition is fulfilled just in the case that no message on the message list matches it. The #'s in the condition part designate "don't care" positions in the sense that they match either 1 or 0. The action part of the classifier determines the message to be posted to the message list: if the i-th symbol, $A_i$, of an action is 0 or 1, the i-th symbol of the posted message will be $A_i$. Otherwise, $A_i$ is #, and the i-th message bit will equal the bit matched by the i-th bit of the distinguished condition.[a]

Each classifier may be regarded (functionally) as a separate processor that takes messages as input and produces messages as output. The configuration of the individual classifier determines which messages are accepted as input and how accepted messages are transformed into output messages. A classifier is activated at a given time step if its pre-conditions are satisfied by at least one message which appeared on the message list at the previous time step. The message list is completely rewritten once per time step so that each message has a duration of exactly one time step. Thus, the primary action of the system is a loop in which all of the classifiers access the current message list, each determining if its pre-conditions have been met, and if so, posting its own output message(s) at the next time step. This process continues until the system has iterated a fixed number of times or, in some systems, until the message list remains unchanged (quiescent) for two successive time steps. All external communication (input and output) is via the message list. As a result, all internal control information and external communication reside in one data structure.

As a simple example, consider the following four bit (n = 4) classifier system:

```
#00# => 1101

#101
###1 => ##1#

~1111 => 1111.
```

This classifier system has three classifiers. The second classifier illustrates multiple-conditions, and the third contains a negative condition. If an initial message, "0000" is placed on the message list at time T0, the pattern of activity shown in Figure 1 will be observed on the message list:

| Time Step | Message List | Activating Classifier |
|---|---|---|
| T0: | 0000 | external |
| T1: | 1101 | first |
| | 1111 | third |
| T2: | 1111 | second |
| T3: | | |
| T4: | 1111 | third |

**Figure 1:** Example Classifier System Behavior

The final two message lists (<empty> and 1111) will continue alternating until the system is turned off. At T1, one message (1101) matches the first (distinguished) condition and both messages match the second condition. Pass through is performed on the first condition, producing one output message for time T2. If the conditions had been reversed (###1) distinguished), the message list at time T2 would have contained two identical messages (1111).

One apparent drawback of the Classifier System is that each classifier reads (examines in its entirety) a potentially large message list on which most of the messages may not be relevant. Having each classifier read the entire message list introduces a time consuming search. However, it is possible to arrange the system in such a way that the messages are routed directly to the classifiers that they will activate. Because the format for expressing the condition parts of a classifier is so constrained, it is possible to sort the conditions of any given list of classifiers so that messages are routed efficiently. If this were done, each classifier would only have to read the relevant messages. Messages that were relevant to many classifiers would still be effectively global, but messages that were only relevant to one classifier would only be read by that classifier. This data-flow approach would not change the overall behavior of the system although it would affect the system's efficiency. Since in most applications, the size of the message list remains small with respect to the total number of classifiers, the actual speedups might not be significant.

In large scale parallel systems such as the Classifier System, the issue of design is central. Design issues arise in two ways for the Classifier System: in deciding which external classifiers are to be generated, and in deciding which external messages are to be placed on the message list and when. As the number of classifiers increases, it quickly becomes impossible to do this by hand. Two automatic approaches have been explored: "learning" and "compiling." The process of compiling can be viewed as mapping high-level structures onto lower-level operations ("top down"). Likewise, some kinds of learning (for example, genetic algorithms) can be viewed as the gradual emergence of higher-level structures from a random assortment of low-level processes; systems using these kinds of learning organize themselves from the "bottom up."

[a] For multiple-condition classifiers, this interpretation of an action is ambiguous since it is not clear what it means to simultaneously perform "pass through" on more than one condition. The ambiguity is resolved by distinguishing one condition to be used for pass through. By convention, this will always be the first condition. Another ambiguity arises if more than one message matches the distinguished condition in one time step. Again by convention, in my system I process all the messages that match this condition. The example illustrates this procedure.

Learning algorithms have been used with Classifier Systems by Holland [18], Smith [20], [21], Booker [1], Wilson [22], and Goldberg [11]. Each of these systems has been designed for a specific purpose and relies on adaptive algorithms to control system behavior. In each case, the researcher was able to demonstrate learning for a complex task: Holland's system learned control routines for operating in a two-dimensional environment, Smith's system learned poker-playing strategies, Booker's and Wilson's systems simulated a hypothetical organism that learned to locate resources and avoid noxious stimuli in an uncertain environment, and Goldberg's system learned to control gas pipeline operations.

Access to the message list can be limited by choosing an upper bound for the number of active messages at any one time. In current systems this is typically a small number (for example, thirty-two). The classifiers that are potentially active (those whose conditions are matched by messages on the current message list) then bid to put their messages on the list, and those with the highest bids are allowed to do so. The bid of a classifier is dependent on at least two components: (1) the specificity of the classifier's conditions and (2) the strength of the classifier.[b] There are two principal ways in which learning is used to control a Classifier System whose message list is of limited size. (1) by controlling write access to the message list and (2) by controlling which classifiers are in the data base of rules. Two different algorithms are used for each of these functions.

The first, the "bucket brigade" [16], adjusts the strengths of the classifiers over time, rewarding those classifiers that have contributed to good solutions and punishing those that do not prove useful. Classifier strength is increased when the system produces a "good" external response. Thus, reward is ultimately dependent on the system's performance in its external environment.

The choice of which classifiers are in the data base is controlled by the Genetic Algorithm [15]. The algorithm is used periodically throughout the operation of the Classifier System to evaluate which classifiers are doing well (contributing to useful solutions) and which ones are not doing well. The evaluation is based on the current strengths of each classifier. Based on this evaluation, weak classifiers are eliminated from the data base, strong classifiers are retained, and new classifiers are generated by applying "genetic operators" to previously successful classifiers in the hopes of generating even more successful recombinations.

## Methodology

In order to study the relation between the bit-level operations of the Classifier System and higher-level symbolic operations, I selected one knowledge representation language, KL-ONE [3], and showed how both its data structures and accessing algorithms can be implemented using the Classifier System.

A knowledge representation system consists of data structures (facts known to the system and the relations between the facts) and interpretive procedures used to access them in an orderly fashion. KL-ONE is a knowledge representation system in which information is represented as a directed graph (called a semantic network).

The implementation takes the form of a compiler, mapping "high-level" semantic network definitions onto the Classifier System. In this context, the Classifier System is properly viewed either as a lower-level target language or as a specification for an abstract parallel machine. An external command processor runs the Classifier System, providing input (and reading output) from the "classifier program." The parallel algorithms are formulated as a sequence of queries to the Classifier System representation of a KL-ONE network. The queries are initiated by placing a set of messages on the message list, allowing the system to iterate for a fixed number of cycles, and then reading the new set of messages from the final message list. Figure 2 illustrates the organization of the implemented system.

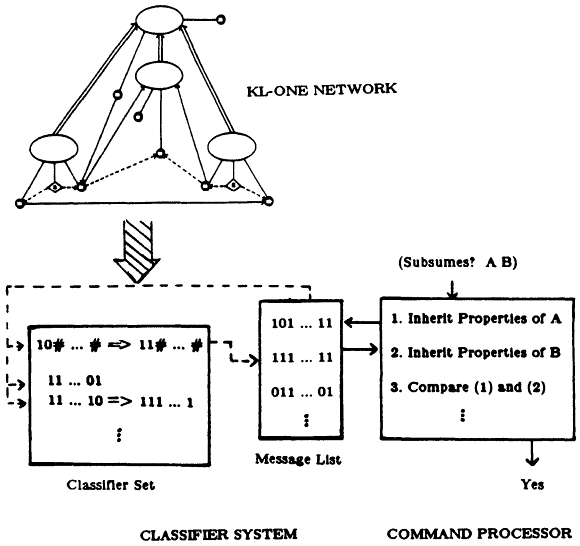

**Figure 2:** Classifier System Implementation of KL-ONE

KL-ONE is one of the few knowledge representation systems for which both the data structures and the operations are well-defined. The central operation in KL-ONE is that of "classification." In its most general formulation, classification is the problem of how to relate new information to an existing knowledge base. In network-based systems, this becomes the problem of deciding which links to add between new and old nodes when incorporating new structures into the network. Of the various knowledge representation paradigms in use today, the KL-ONE family has focused on the issue of classification most precisely.

[b] Recently, a third component has been added. This is called "support," and it corresponds roughly to the number of previously active classifiers that thinks the bidding classifier should be active now.

KL-ONE organizes descriptive terms into a multi-level structure which allows properties of a general concept, such as "mammal," to be inherited by more specific concepts, such as "zebra." This allows the system to store properties that pertain to all mammals (such as "warm-blooded") in one place but to retain the capability of associating those properties with all concepts that are more specific than mammal (such as zebra). In KL-ONE, the multi-level structure is easily represented as a graph, where the nodes of the graph correspond to concepts and properties, and the links correspond to relations between nodes.

In KL-ONE, classification is the process of deciding where a new term (a subgraph) should be located in an existing network. The term may be a single concept, or more likely, a complex description built out of many concepts. The classification procedure can be expressed as the procedure of deciding which concepts are "above" (more general than) and "below" (more specific than) an incoming concept. If a concept A is more general than another concept B (based its definitions), then A is said to *subsume* B. The procedure for deciding whether one concept subsumes another is computationally expensive; the procedure has been shown to be NP-Complete for a related knowledge representation formalism [2].

## Results

The development of the system was divided into several phases: (1) implementing the Classifier System in software, (2) designing and implementing a program that translates KL-ONE networks into production rules for the Classifier System, (3) developing the parallel algorithms to determine subsumption, (4) validating the algorithms, and (5) analyzing the complexity of the system. The Classifier System simulation program, the compiler, and the command processor are all implemented in Franz Lisp, and run on a Vax 11-780 using the Unix Operating System.

The algorithms that have been developed can be divided into two classes: high-level (with respect to the Classifier System) constructs that should be of general utility to other users of the Classifier System, and special-purpose algorithms for classification in KL-ONE. The first class provides a set of general-purpose operations that proved useful for developing KL-ONE-specific algorithms. The general-purpose operations include boolean operations on sets of messages (intersection, complementation, etc.), stack operations (push and pop), and some numerical operations (find the maximum or minimum of a set of numbers, compare two numbers, and addition). For KL-ONE, algorithms for two major operations were developed: (1) a decision procedure for subsumption, and (2) a search procedure that finds the set of *Most Specific Subsumers*[c] (MSS). The sequential version of these algorithms is described in [17] and the parallel version in [9].

The successful implementation of KL-ONE using the Classifier System demonstrates that the Classifier System is capable of representing complex data structures and that complex computations can be performed within the Classifier System formalism. However, this alone does not demonstrate that the implementation is "reasonable." The reasonableness of the implementation has been evaluated using formal complexity measures.

Four measures of complexity were considered: length of computation (in simulated time steps), the size of each processor, the number of processors, and the amount of inter-processor communication. For the Classifier System, these four measures are interpreted as the number of time steps required to complete a computation, the number and length of conditions for each classifier, the number of classifiers used to represent a KL-ONE network, and the maximum size of the global message list. A reasonable implementation is one in which data are not stored redundantly (the number of classifiers and the number and length of conditions grow linearly with the size of the network), the size of the global message list remains small with respect to the total number of classifiers (inter-processor communication should not increase disproportionately to the size of the network), and the parallel algorithms are computationally more efficient than their sequential counterparts (the speed-ups are expected to be related to the fan-out of the underlying structure).

A detailed analysis of the parallel algorithms using these four measures of complexity appears in [9]; in summary, the analysis shows that the implementation meets the above criteria. The number of classifiers required to represent each KL-ONE network is directly proportional to the size of the network definition. The size of each classifier grows as the log of the number of nodes in the network. The maximum size of the message list is related to the topology of the KL-ONE network being processed; for networks in which the fan-out is greater than the fan-in (the expected case), the maximum size of the message list grows with the depth of the network. The Subsumption algorithm and the search for Most Specific Subsumers each run in time proportional to the depth of the network.[d] Because the search for Most Specific Subsumers invokes the Subsumption test, the overall complexity for the algorithms taken together is proportional to the $(\text{depth})^2$.

[c] A is a Most Specific Subsumer of B iff
A SUBSUMES B, and
there does not exist a C, such that
A SUBSUMES C AND C SUBSUMES B.

[d] The implemented version of the search for Most Specific Subsumers may run somewhat slower than this for some networks. However, it would be straightforward to add one field (a small number of bits) to each classifier and guarantee that the algorithm always ran in time proportional to the depth of the network (with a larger message list size). Since the performance of the algorithms is highly dependent on the conformation of the networks it processes and there is very little data available about the conformation of typical networks, it was not clear at the time of implementation whether this was a worthwhile optimization.

## Discussion

In the current implementation, the algorithms rely to some extent on the host language (Lisp) in which the command processor is implemented. That is, some of the algorithms take advantage of the control structures and data management facilities of Lisp beyond using it to formulate queries to the Classifier System. This is an important issue as it would be easy to hide significant amounts of complexity in the processing of the host language and make it appear that the parallelism was accomplishing more than it really was. On the other hand, it seems unreasonable to force intrinsically sequential operations into the parallel formulation when there is an adequate sequential language immediately available. In the extreme, it would be possible to generate a set of classifiers that could answer the subsumption question with one query (with no interference from the host language)[e], but the number and length of classifiers and the time to translate KL-ONE networks into the classifier representation would be unreasonably large.

The parts of the algorithm that have been implemented in Lisp are either natural components of the host language (such as invoking the Classifier System) or they are operations that could be made parallel by adding a constant number of bits (to be used as tags) to each classifier. In particular, the embedding language (Lisp) is used in four ways: (1) to translate symbolic queries such as "(Subsumes? A B)" into binary messages and translate them back after the query, (2) to invoke the Classifier System, (3) to store the results of queries (for example, a list of messages) that will be needed again later, and (4) to control the highest-level sequences of queries through the use of conditional and iterative constructs. The first two of these are appropriate for the command processing role that is played by the embedding programs. The second two are only a matter of convenience for the current simulation and could be implemented in the Classifier System.

The implementation revealed a set of techniques that are useful for controlling the Classifier System. These are tagging, the use of negative conditions as triggers, computations that process one bit position at a time, and synchronization.

Tagging, in which one field of the classifier is used as a selector, is used to maintain groups of messages on the message list that are in distinct states. Tagging allows the use of specific operators that are defined for particular states. This specificity also allows additional "layers" of parallelism to be added by processing more than one operation simultaneously. In these situations, the messages for each operation are kept distinct on the global message list by the unique values of their tags.

Negative conditions activate and deactivate various subsystems of the Classifier System. Negative conditions are used to terminate computations and to explicitly change the state of a group of messages when a "trigger" message is added to the list. When the trigger message appears, it violates the negative condition and that classifier is effectively turned off.

Computations that proceed one bit at a time illustrate two techniques: (1) using control messages to sequence the processing of a computation, and (2) how to collect and combine information from multiple independent messages into one message. Sequencing will always be useful when a computation is distributed over multiple time steps instead of being performed in one step. Collection is important because in the Classifier System it is easy to "parallelize" information from one message into many messages that can be operated on independently. This is most easily accomplished by having many classifiers that match the same message and operate on various fields within the message. The division of one message into its components takes one time step. However, the recombination of the new components back into one message (for example, an answer) is more difficult. The collection process must either be conducted serially (one bit position at a time) or one classifier must be allocated for each possible message combination (a potentially huge number). Intermediate solutions are also possible.

Synchronization techniques allow one operation to be delayed until another has finished. Synchronization can be achieved by combining tagging with negative conditions.

## Conclusions

The implementation of KL-ONE demonstrates that the Classifier System formalism is a powerful and flexible representation system. This result combined with previous work that demonstrates how the Classifier System can learn suggests that the Classifier System is a promising low-level organization from which intelligent systems can be constructed.

In particular, the implementation is one in which reasonable computation time improvements can be obtained without an unreasonable increase in the number and size of processing units or in the degree of inter-processor communication. The approach that was demonstrated for KL-ONE could easily be extended to other similar inheritance networks.

This particular implementation does not include those features that are specific to the use of adaptive algorithms, such as bidding, support, etc. However, previous experiments that combined learning algorithms with the Classifier System worked with rather small sets of classifiers (usually less than two hundred and often less than one hundred). Further, it is very difficult to "decompile" these systems after significant learning has occurred to determine what role is played by individual classifiers. Using a compilation technique allows the construction of much larger sets of classifiers and it allows complex behavior (such as synchronization) to be identified and studied. One promising direction for further research is to try combining the two approaches to see if the kind of complex behavior demonstrated by the KL-ONE implementation can be learned by the bucket brigade and genetic algorithms.

[e] It is straightforward to show that for any finite function, a Classifier System can be constructed that computes it.

Acknowledgements

The inspiration and the original designs of the Classifier System, the Bucket Brigade, and the Genetic algorithm are John Holland's. In addition, he made many helpful suggestions about the KL-ONE implementation and its significance for which I am very grateful. # CONTINUOUS SPEECH RECOGNITION ON A BUTTERFLY ™ PARALLEL PROCESSOR

Lynn Cosell, Owen Kimball, Richard Schwartz, Michael Krasner

BBN Laboratories
10 Moulton St.
Cambridge, MA 02238

## ABSTRACT

This paper describes the implementation of a continuous speech recognition algorithm on the BBN Butterfly$^{TM}$ Parallel Processor. The implementation exploited the parallelism inherent in the recognition algorithm to achieve good performance, as indicated by execution time and processor utilization. The implementation process was simplified by a programming methodology that complements the Butterfly architecture. The paper describes the architecture and methodology used and explains the speech recognition algorithm, detailing the computationally demanding area critical to an efficient parallel realization. The steps taken to first develop and then refine the parallel implementation are discussed, and the appropriateness of the architecture and programming methodology for such speech recognition applications is evaluated.[1]

## INTRODUCTION

This paper describes research to investigate the uses of parallel computation for continuous speech word recognition. Our goal in this work is to determine the extent to which continuous speech recognition algorithms can make use of parallel processing to achieve real time speeds. Our approach has been to develop parallel versions of an existing recognition algorithm on BBN's Butterfly Parallel Processor.

## BUTTERFLY

The Butterfly Parallel Processor [1] is composed of multiple (up to 256) identical nodes interconnected by a high-performance switch. Each node contains a processor and memory. The switch allows each processor to access the memory on all other nodes. Collectively, these memories form the shared memory of the machine, a single address space accessible to every processor. All interprocessor communication is performed using shared memory. Typical memory referencing instructions accessing local memory take about 2 microseconds to complete, whereas those accessing remote memory take about 5 or 6 microseconds.

The Butterfly Parallel Processor is a multiple instruction multiple data stream (MIMD) machine in which each processor node executes its own sequence of instructions, referencing data as specified by the instructions. Processor Nodes are tightly coupled by the Butterfly switch. Tight coupling permits efficient interprocessor communication and allows each processor to access all system memory efficiently. The Butterfly Parallel Processor is expandable to 256 Processor Nodes. Each Processor Node contains a Motorola MC68000 microprocessor, an optional floating-point coprocessor, from 1 to 4 MBytes of main memory, a co-processor called the Processor Node Controller, memory management hardware, an I-O bus, and an interface to the Butterfly switch. The particular machine that was used for development in this project was a 16 processor machine with 1 Mbyte of memory on each Processor Node. It did not have hardware support for floating point arithmetic.

## WORD RECOGNITION ALGORITHM

The problem of speech recognition requires that we map an analog signal onto a sequence of words that comprise sentences. However, the identification of particular speech sounds (phonemes) from this signal is made difficult due to the variability that occurs in speech production. This variability is due to the effect of neighboring speech sounds (coarticulation), and a variety of other effects that all combine to make the same speech unit appear differently each time it occurs.

Our recognition algorithm is based on the explicit modeling of variability in speech through the use of probabilistic Hidden-Markov Models (HMMs) of speech sounds (phonemes) in various phonetic contexts [2]. Each phoneme consists of three states, which are associated with acoustic events corresponding roughly to the beginning, middle and end of the phoneme. There is, associated with each pair of states, a transition probability $a(j|i)$ which is the probability of going to state $j$ given that the process is in state $i$. Unlike a Markov chain, in which each state has associated with it a single output, each HMM state has an output probability density function (pdf) $P(x|i)$ that gives the probability of each possible output symbol $x$, given that the process is in state $i$.

Rather than use actual segments of the speech signal as output symbols, we can represent the speech signal as a sequence of spectra that occur at discrete

[1] This work was sponsored by the Defense Advanced Research Projects Agency and was monitored by the Naval Electronics System Command under Contract No. N00039-85-C-0313.

time intervals. Furthermore, each of these spectra can be approximately characterized as one of a small number of spectral types (256 in our system), which are determined using a clustering procedure. The spectral characterizations, each a single number, then become the possible output symbols. Words can be modeled as concatenations of phoneme HMMs that have been modified to take into account the contextual effects of the word.

One approach to understanding HMMs is to imagine them in a synthesis role, where they are used to produce spectral sequences. Starting from the initial state of the model, we randomly choose the next state according to the transition probabilities on the arcs leaving the initial state. Whenever the process is in an acoustic state, we randomly pick an output symbol according to the state's output pdf. As the process moves from state to state in this manner, it produces a sequence of symbols (speech spectra) as output.

The recognition problem can be viewed as the inverse of the synthesis problem: given a sequence of input spectra and a set of models of all possible words, we wish to find the sequence of models that is most likely to have produced the spectral sequence. An adaptation of the Viterbi algorithm solves just this problem, and is the basis for our recognizer.

The basic recognition algorithm finds the path through the states that is most likely to have produced the spectral sequence to be recognized. The algorithm does this by finding the best path to every state at every time given that the path to the previous state was also "best". Each step along these paths has associated with it a "score", which reflects the probability of the step given the spectral sequence and the transition probabilities of the model. The scores are accumulated along the paths, so that, at every time, the best path to any state has a single score. The best path to a particular state, S, at time t, is determined by considering all possible predecessor states (states which have transitions to S) at time t−1 and the best path to each of these. The score for a path to S is then the combination of the path score to the best predecessor state and the score for the step from that predecessor state to S.

The central computation in the algorithm is: for each time interval, update the scores for all states. Figure 1 schematically illustrates the scoring procedure for a single state in a word. In this figure, the score for state n at time t (the $\alpha_n(t)$ in the lower right corner) is being computed based on the scores for three states computed at time t−1 (the three circles on the left of the figure) each multiplied by the corresponding transition probability of going to state n. The new score for state n is just the maximum of the entering scores multiplied by the probability of the spectrum $x_t$ at time t, at state n, $p(x|n)$.

This scoring procedure is applied to all states in each word for all time frames in the utterance. The scores computed for terminal states (ends of words) are special. They are compared and only the maximum terminal score is saved, as are the word that produced it and the start time for the word. The largest terminal score for a time frame is used as the score for all word-initial states in the next time frame. In addition, the current state score, $\alpha_n(t)$ is compared against the largest state score, $\alpha_{Best}(t)$, encountered so far for the current time frame, and replaces it, if appropriate. This is used to derive a normalization factor ($NF = 1/\alpha_{Best}(t)$), which is used to prevent arithmetic underflow.

When all the time frames in the utterance have been processed in this way, the best sequence of words is determined. The maximum terminal score at the end of the utterance specifies the last word of the utterance. The start time of this last word is the end time for the previous word, so the maximum terminal score at this time indicates which word should be selected as the second-last word in the theory, and so on, back to the beginning of the utterance.

## SINGLE PROCESSOR IMPLEMENTATION

The first step toward a parallel implementation was to bring up the speech recognition program on a single processor of the Butterfly Parallel Processor. The existing VAX implementation depended on the file system to store the large amounts of data which included the transition probabilities and the pdfs for the word models. This data totaled 1.5 Mbytes. Storing this amount of data on the Butterfly required using some parallel memory management techniques to allocate shared memory on multiple nodes.

The VAX (and the first Butterfly implementation) used floating-point arithmetic. Because floating-point arithmetic is performed in software in our Butterfly Parallel Processor, it seemed likely that the time required for the floating-point arithmetic would hide any overhead and task granularity problems we encountered. We decided to investigate using fixed-point arithmetic.

For storage efficiency, most of the data had been represented as indices into a table of probabilities. This table contained 256 entries, ranging between zero and unity, quantized logarithmically. Therefore, the indices themselves were scaled log probabilities. Multiplication of probabilities in the original program could, of course, easily be converted to addition of corresponding log probabilities. The Viterbi algorithm finds the maximum of the path probabilities to a node, which is equivalent in both log and linear domains. We converted the program to use the indices directly as log probabilities, and obtained the same results as before, but the execution time remained disappointingly long. Measurement tools allowed us to discover that most of the time was being squandered in two ways. First, using double indexing into two-dimensional arrays was quite slow because the 68000 compiler available at the time used double precision multiplies for this kind of address calculation. We converted to register pointers to avoid this situation. Secondly, much time was being spent in the call to the subroutine that performed the word scoring. We simplified the calling sequence by defining many of the arguments globally. These modifications caused the execution time to drop to about two minutes for a 3.5 second utterance, (about the same speed as our optimized VAX program). This execution time seemed low enough for reasonable parallelization measurements.

## UNIFORM SYSTEM

We used the Uniform System approach to obtain a parallel implementation. The Uniform System is a programming methodology supported by a library of high-level functions [3]. It exploits the uniform environment provided by the architecture of the Butterfly Parallel Processor to simplify the problem of load balancing for the memory as well as for the processors. Memory accesses must be organized to avoid memory contention. The load on the processors is balanced when all processors are equally busy and no processor is waiting for another to finish.

Balancing the load on memory is accomplished by spreading out the data evenly across the different physical memories in the machine, under the assumption that this will also spread the accesses fairly evenly, reducing the inefficiency that results when many processors attempt to access the same memory simultaneously. Functions for allocating storage in the shared memory are included in the Uniform System, as are functions that perform block transfers between shared memory and local memory.

The philosophy behind the Uniform System processor management methodology views the processors as a uniform pool of workers, all of which know how to execute the same tasks. Using this methodology, the programmer is only required to supply code that operates correctly when multiple processors execute it at the same time. The processor management is accomplished by first copying the program to each of the processors. In most cases, the program will begin with a section of serial code that is executed on a single processor. To begin executing a section of code on multiple processors -- a FOR loop, for example -- the programmer can use a "task generator" to replace the FOR statement and a "worker routine" to replace the body of the FOR loop. The task generator makes a task descriptor available to all processors, which use it, as they become free, to generate calls to the worker routine. Processors, using this descriptor, execute the routine repeatedly for different index values, until the index has run its range. When all processors have finished, the program, once again serial, continues executing on a single processor.

We decided to use the Uniform System for several reasons. First, the speech recognition algorithm is essentially a single task, executed many times. This fits the Uniform System paradigm very well. Second, being novices, we were attracted by the simplicity of use of the Uniform System. Third, functions in the Uniform System allow automatic timing of the same program run on various numbers of processors, and this provided an easy way of evaluating the performance of the parallel implementation. Finally, because the same program can be run on one or many processors, we believed that debugging the parallel implementation would be simplified.

## PARALLEL IMPLEMENTATION AND RESULTS

In our system, both the training and spectral analysis tasks are performed "off-line" and the results are stored. The recognition system begins by reading in the word models for a speaker. Then, for each utterance, the spectral parameters for the utterance are read and stored. At this point in the program, the actual recognition search task begins. This was the only portion considered for parallel implementation. Our execution time measurements began here and continued until the input utterance had been recognized, that is, a theory for the complete utterance had been obtained. The pertinent portion of the speech recognition program can be abstracted as follows:

```
a. FOR all frames
b.     initialize frame
c.     FOR all words
d.         initialize word
e.         FOR all states
f.             compute state score
g.             IF (new max score)
h.                 replace max score
i.         IF (new max terminal)
j.             replace max terminal
k.     determine normalization
l.     FOR all words
m.         get terminal score
n. determine theory
```

The first parallel version combined lines d) through f) and parts of g) and h) into a single task and used the generator GenOnIndex, which includes a prologue task and an epilogue task in addition to the main task. The prologue task is executed only once by each processor before that processor executes the main task for the first time. In this version, the prologue included line b). Similarly, the epilogue task is executed once by each processor after all main tasks have been completed by that processor. For this program, the central task determined the maximum state score and the maximum terminal score seen by each processor. The epilogue task compared these local maxima against global maxima, replacing the global maxima if necessary. The remainder of the program (lines k-m), including the second FOR loop was executed sequentially, on a single processor. Approximately 9 seconds was spent in the sequential portion of the program when it was run for a 3.5 second utterance. When run on 15 processors, this resulted in less than 50% utilization of the processors.

The next step was to attempt to reduce the sequential portion of the program. We noticed that the second FOR loop (lines l and m), which propagates the best word's score in the current frame to word-initial states for the next frame, could be incorporated into the first FOR loop, effectively changing the program to:

```
a. FOR all frames
b.     initialize frame
c.     FOR all words
d.         get previous frame terminal score
e.         initialize word
f.         FOR all states
g.             compute state score
h.             IF (new max score)
i.                 replace max score
j.         IF (new max terminal)
k.             replace terminal
l.     determine normalization
m. determine utterance.
```

This revision substantially reduced the time spent executing serial code. For 15 processors, the execution time dropped from 15 seconds to 11 seconds for a 3.5 second utterance, and the effective number of processors rose from 6.9 to 11.2, or approximately 75% utilization. The processor utilization is shown in Figure 2.

## CONCLUSIONS AND FUTURE RESEARCH

Our work on this project has shown that the Butterfly architecture is suitable for continuous speech word recognition. The decomposition of the algorithm into tasks that match one word to one frame of input speech provided a granularity that made efficient use of the processors. The memory and processor management functions of the Uniform System made parallelization of the algorithm surprisingly easy and rapid.

In the near future, we hope to extend the current research to include a grammar and larger vocabulary tasks. The grammar will require search of a much larger space that is too large to search exhaustively. The search will have to be pruned, thus presenting a more challenging parallel implementation task.

# A Hyperconcentrator Switch for Routing Bit-Serial Messages
(Extended Abstract)

Thomas H. Cormen
Charles E. Leiserson

Laboratory for Computer Science
Massachusetts Institute of Technology
Cambridge, Massachusetts 02139

## Abstract

In highly parallel message routing networks, it is sometimes desirable to concentrate relatively few messages on many wires onto fewer wires. We have designed a VLSI chip for this purpose which is capable of concentrating bit-serial messages quickly. This hyperconcentrator switch has a highly regular layout using ratioed nMOS and takes advantage of the relatively fast performance of large fan-in NOR gates in this technology. A signal incurs exactly $2\log_2 n$ gate delays through the switch, where $n$ is the number of inputs to the circuit. The architecture generalizes to domino CMOS as well.

## 1 Introduction

The problem of concentrating relatively few communications on many input lines onto a lesser number of output lines must be solved in communication networks of all kinds. In many parallel computing systems, communications are packaged into messages which are routed among the processors. This paper presents a design for a VLSI implementation of a fast concentrator switch suitable for routing bit-serial messages in a parallel supercomputer.

An *n-by-m concentrator switch* has $n$ input wires $X_1, X_2, \ldots, X_n$ and $m < n$ output wires $Y_1, Y_2, \ldots, Y_m$. The switch can establish $m$ disjoint electrical paths from any set of $m$ input wires to the $m$ output wires. A concentrator switch always routes as many messages as possible. Specifically, whenever $k$ out of the $n$ input wires of an $n$-by-$m$ concentrator switch carry messages, one of the following is true:

- If $k \leq m$, then an electrical path is established from each input wire which contains a message to an output wire.
- If $k > m$, then each output wire has an electrical path established from an input wire which contains a message.

When $k > m$, some messages cannot be successfully routed, in which case we say the switch is *congested.* Typical ways of handling unsuccessfully routed messages in a routing network are to buffer them, to misroute them, or to simply drop them and rely on a higher-level acknowledgment protocol to detect this situation and resend them. The switch design in this paper is compatible with any of these congestion control methods.

One way to create a concentrator switch is with a hyperconcentrator switch. An *n-by-n hyperconcentrator switch*[1] has $n$ input wires $X_1, X_2, \ldots, X_n$ and $n$ output wires $Y_1, Y_2, \ldots, Y_n$. The switch can establish disjoint electrical paths from any set of $k$ input wires, for any $1 \leq k \leq n$, to the first $k$ output wires $Y_1, Y_2, \ldots, Y_k$. In other words, we route the $k$ messages to the first $k$ output wires. We can make any $n$-by-$m$ concentrator switch from an $n$-by-$n$ hyperconcentrator switch by simply choosing the first $m$ output wires of the hyperconcentrator switch, $Y_1, Y_2, \ldots, Y_m$, as the $m$ output wires of the concentrator switch.

We can use a sorting network to implement a hyperconcentrator switch. The inputs to the sorting network are 1's and 0's, representing the presence or absence of messages on the input wires to the switch. The sorting of the 1's and 0's, with 1's before 0's, causes the $k$ input messages to occupy the first $k$ outputs.

Many sorting networks, such as Batcher's bitonic sort [6], employ the technique of recursive merging.

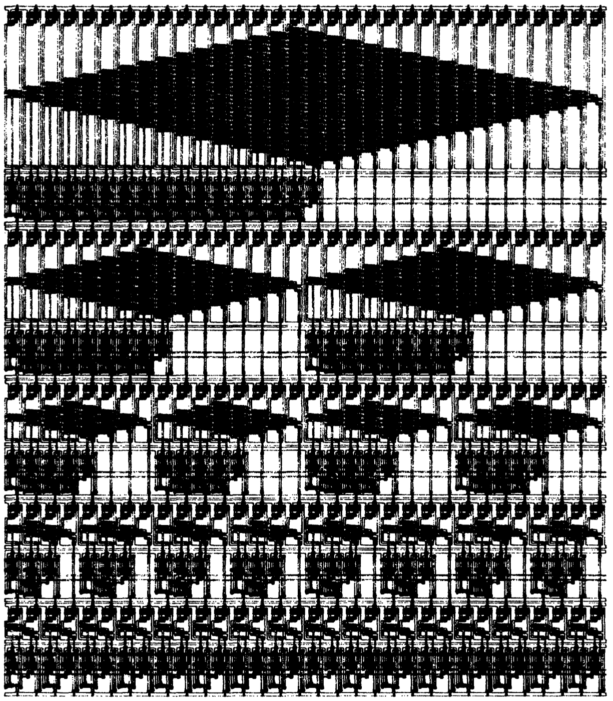

**Figure 1:** An nMOS layout of a 32-by-32 hyperconcentrator switch. The recursive nature of the switch can easily be seen. This implementation includes superbuffers where needed to provide enough drive for high fan-out signals.

A problem of size $n$ is divided into two problems of size $n/2$, which are recursively solved in parallel. The two sorted sets are then merged to produce the solution to the original problem. The recursion requires $\lceil \log_2 n \rceil$ levels, and since each merge step can be performed in $O(\log n)$ time in parallel, the total time to sort $n$ values is $O(\log^2 n)$. Sorting networks of depth $O(\log n)$ are known [1], but they are impractical to use as hyperconcentrator switches because of the large associated constant.

The $n$-by-$n$ hyperconcentrator switch presented in this paper also uses recursive merging, but by taking advantage of the relatively fast performance of high fan-in NOR gates in nMOS technology, each merge takes only 2 gate delays. A signal therefore incurs exactly $2\lceil \log_2 n \rceil$ gate delays in passing through the switch. The switch has a simple design and a regular layout in both ratioed nMOS and domino CMOS technologies. Unlike many concentrator switches in the literature [8,9,10], our switch sets itself up "on-line" when messages are presented to it.

The remainder of this paper is organized as follows. Section 2 covers some basic terminology and describes the message format and timing model upon which the switch is based. Section 3 discusses the merge box, how to use merge boxes to implement the hyperconcentrator switch and describes an nMOS implementation. Section 5 covers some applications which benefit from the switch. Finally, Section 6 contains further remarks about the switch.

## 2 Preliminaries

In this section, we define some basic terminology and notational conventions and present the message format and timing model assumed by the hyperconcentrator switch design.

Bit and boolean values are denoted by "1" and "0", or by "high" and "low", for TRUE and FALSE respectively.

We assume that the hyperconcentrator switch routes *bit-serial messages*. Each message is formed by a stream of bits arriving at a wire at the rate of one bit per clock cycle. The first bit of each message that arrives at an input wire is the *valid bit*, indicating whether subsequent bits arriving on that wire form a valid message or an invalid message. The bit sequence following a valid bit of 1 forms a *valid message*, which we would like to be routed from an input wire to an output wire of the switch. From there it may pass through the remainder of the routing network. A valid bit of 0 indicates an *invalid message*, which does not need to be routed to an output wire. We assume that in an invalid message, not only is the valid bit 0, but so are all the remaining bits in the message.[2]

The valid bits all arrive at the input wires of the hyperconcentrator switch during the same clock cycle, which we call *setup*. An external control line signals setup. Message bits entering through input wires at cycles after setup follow the electrical paths in the switch which are established during setup.

We shall adopt some notational conventions to ease the exposition in the following sections. Uppercase symbols denote wire names and lowercase symbols denote integer values. We shall also use uppercase symbols to denote bit values on the wires they name when the usage is unambiguous. Wire names will usually have subscripts.

## 3 The Merge Box

This section presents the design of the merge box, the key portion of the hyperconcentrator switch architec-

[2] This assumption is easy to enforce — just AND the valid bit into each subsequent bit of the message.

ture. The hyperconcentrator switch consists of many merge boxes, of various sizes, connected as shown in the next section. The design exploits the fast performance of large fan-in NOR gates in nMOS technology, much the same as does a PLA, to merge two sets of messages of any size with two gate delays. The merge box design presented in this section uses ratioed nMOS technology and no pass transistors.

A merge box merges two sets of messages, each set sorted by their valid bits, into one sorted set of messages. A *merge box of size* $2m$, where $m$ is a power of 2, has two sets of input wires $A_1, A_2, \ldots, A_m$ and $B_1, B_2, \ldots, B_m$ and one set of output wires $C_1, C_2, \ldots, C_{2m}$. We require that the lower-numbered wires of both the $A$ and $B$ input sets carry valid messages and that the higher-numbered wires of both the $A$ and $B$ input sets carry invalid messages. That is, if we let $p$ and $q$ be the number of valid messages entering the $A$ and $B$ wire sets respectively, we require that the valid bits appear on the input wires during setup as follows:

$$\begin{aligned} A_1, A_2, \ldots, A_p &= 1 \\ A_{p+1}, A_{p+2}, \ldots, A_m &= 0 \\ B_1, B_2, \ldots, B_q &= 1 \\ B_{q+1}, B_{q+2}, \ldots, B_m &= 0 \end{aligned}$$

During setup, the merge box establishes disjoint electrical connections between the $p + q$ input wires with valid messages and the $p+q$ lower-numbered output wires $C_1, C_2, \ldots, C_{p+q}$ in a combinational fashion, as shown in Figure 2. The connections $C_1 = A_1, C_2 = A_2, \ldots, C_p = A_p, C_{p+1} = B_1, C_{p+2} = B_2, \ldots, C_{p+q} = B_q$ are established, and valid bits appear on the output wires as follows:

$$\begin{aligned} C_1, C_2, \ldots, C_{p+q} &= 1 \\ C_{p+q+1}, C_{p+q+2}, \ldots, C_{2m} &= 0 \end{aligned}$$

These connections are maintained during subsequent cycles for the remaining bits in the message streams to follow.

Figure 3 is a schematic diagram of a merge box for which $m = 4$. This merge box includes eight NOR gates, with diagonal output wires labeled $\overline{C}_1, \overline{C}_2, \ldots, \overline{C}_8$. Each of these NOR gate outputs is inverted to produce the merge box outputs $C_1, C_2, \ldots, C_8$, so we may view the pulling down of a diagonal wire $\overline{C}_i$ to be equivalent to the corresponding output $C_i$ being 1. The NOR gates have fan-ins ranging from just one pulldown circuit (e.g. the gate with output $\overline{C}_8$) to 5 pulldown circuits (e.g. the gate with output $\overline{C}_4$). In general, the NOR gates have fan-ins of up to $m + 1$ pulldown circuits. Each pulldown circuit consists of just one or two transistors, regardless of the size of the merge box, making for fast NOR gates and low-area pulldowns, even with minimum-sized pullups. As can be verified from Figure 3, a merge box of size $2m$ implements the following function:

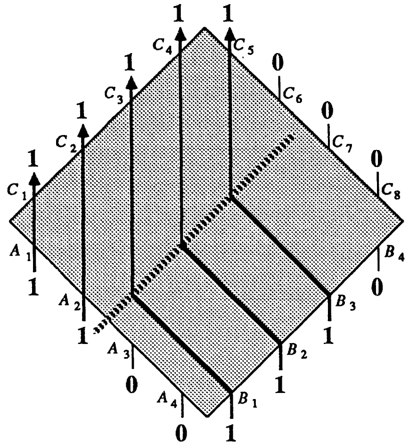

**Figure 2**: The paths taken by valid messages in a merge box. Valid bits are shown as they enter and leave the merge box. The $p$ valid messages arriving at input wires $A_1, A_2, \ldots, A_p$ are routed to output wires $C_1, C_2, \ldots, C_p$ respectively. Here, the only $A$ wires with valid messages are $A_1$ and $A_2$. These valid messages are routed to $C_1$ and $C_2$ respectively. The $q$ valid messages arriving at input wires $B_1, B_2, \ldots, B_q$ head toward $C_1, C_2, \ldots, C_q$ but are steered to $C_{p+1}, C_{p+2}, \ldots, C_{p+q}$. Here, the valid messages entering through $B_1$, $B_2$, and $B_3$ are steered to output wires $C_3$, $C_4$, and $C_5$ respectively.

$$C_i = \begin{cases} A_i \vee \left( \bigvee_{j=1}^{i} (B_j \wedge S_{i+1-j}) \right) & \text{if } 1 \leq i \leq m \\ \bigvee_{j=1}^{2m+1-i} (B_{m+1-j} \wedge S_{i+j-m}) & \text{if } m < i \leq 2m \end{cases}$$

The *switch settings* $S_1, S_2, S_3, S_4, S_5$ are computed and stored in registers during setup, based on the valid bits appearing at the $A$ and $B$ input wires. In general, a merge box of size $2m$ has switch settings $S_1, S_2, \ldots, S_{m+1}$. These stored settings continue to be used during subsequent cycles. These switch settings establish the electrical connections throughout the entire hyperconcentrator switch. Other than the storing of the switch settings, the operation of the merge box is purely combinational.

Let us look at the operation of the merge box during setup. The lower-numbered $A$ and $B$ input wires have valid bit values of 1, and the higher-numbered $A$ and $B$ input wires have valid bit values of 0. If

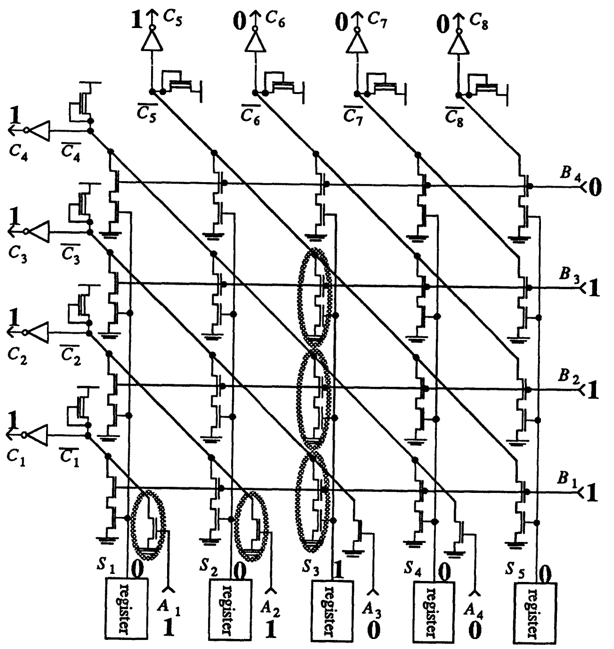

**Figure 3:** A merge box of size 8. The input wires are $A_1, A_2, A_3, A_4$ and $B_1, B_2, B_3, B_4$. The output wires are $C_1, C_2, \ldots, C_8$. The switch settings are stored during setup in registers $S_1, S_2, S_3, S_4, S_5$. Here we have $p = 2$ and $q = 3$ during setup. The valid bit values on each $A$, $B$, and $C$ wire are shown, as are the $S$ switch settings. All conducting paths to ground are circled.

input $A_i$ is 1, then the NOR gate output $\overline{C}_i$ is pulled down by the single transistor whose gate is $A_i$. The inverter causes output $C_i$ to be 1. Having input values $A_1, A_2, \ldots, A_p = 1$ thus causes the outputs $C_1, C_2, \ldots, C_p$ to be 1.

The switch settings $S$ act as steering signals, sending the $B$ values $B_1, B_2, \ldots, B_m$ to the output wires $C_{p+1}, C_{p+2}, \ldots, C_{p+m}$. The $S$ values are computed and stored during setup so that only the setting $S_{p+1}$ is 1, corresponding to input $A_{p+1}$ being the lowest-numbered $A$ with a valid bit of 0. (If no input wire $A_i$ is 0, then we have $p = m$, and only switch $S_{n+1}$ is set to 1.) The $S$ values are defined by the valid bits on the $A$ wires as follows:

$$\begin{aligned} S_1 &= \overline{A}_1 \\ S_i &= A_{i-1} \wedge \overline{A}_i \quad \text{for } 1 < i \leq m \\ S_{m+1} &= A_m \end{aligned}$$

Of the two-transistor pulldown circuits, only column $p+1$ may possibly pull a diagonal wire down to 0, since only switch setting $S_{p+1}$ is high. Similarly, a diagonal wire $\overline{C}_i$ may be pulled down only by input wire $A_i$ or the conjunction $B_{i-p} \wedge S_{p+1}$. The only NOR gate which may be pulled down by input $B_1$ has output wire $\overline{C}_{p+1}$, and in general the only NOR gate which may be pulled down by input $B_i$ has output wire $\overline{C}_{p+i}$.

For example, suppose that, as in Figure 3, the input wires have the following valid bits during setup:

$$\begin{aligned} A_1, A_2 &= 1 \\ A_3, A_4 &= 0 \\ B_1, B_2, B_3 &= 1 \\ B_4 &= 0 \end{aligned}$$

Then we have $p = 2$, $q = 3$, $S_3 = 1$, and all other $S_i = 0$. There are five valid messages passing through the merge box, and there are exactly five conducting paths to ground, circled in Figure 3, one for each of the first five diagonal wires, $\overline{C}_1, \overline{C}_2, \overline{C}_3, \overline{C}_4, \overline{C}_5$. These paths to ground cause output values of 1 on the corresponding output wires $C_1, C_2, C_3, C_4, C_5$. The remaining three diagonal wires, $\overline{C}_6, \overline{C}_7, \overline{C}_8$, are not pulled down to ground by these input values, and the output wires $C_6, C_7, C_8$ all have the value 0.

Now we look at the message bits that arrive after setup. The switch settings $S$ were computed and stored during setup, and they remain unchanged in their registers. Just as during setup, a bit with the value 1 which enters through input wire $A_i$ directly pulls down the diagonal wire $\overline{C}_i$, regardless of the $S$ values. A bit with the value 1 which enters through input wire $B_i$ may pull down only the diagonal wire $\overline{C}_{p+i}$ because the only switch setting which is 1 is $S_{p+1}$. The only difference in the merge box operation between setup and later cycles is that the $S$ values, which are always used to steer the $B$ values to the appropriate $C$ outputs, are computed and stored only during setup. In the cycles following setup, the merge box is a combinational circuit, reading the registers holding the switch settings $S$.

Recall that in Section 2 we required that all bits in an invalid message must be 0. We now can see the reason for this restriction. Suppose that in our above example, in which we had $A_3 = 0$ and $S_3 = 1$ during setup, we had that at some cycle following setup $A_3 = 1$ and $B_1 = 0$. We would expect $C_3$ to be 0 in this case, since $B_1$, which is routed to $C_3$, is 0. Since $A_3$ is 1, however, $\overline{C}_3$ is pulled down, and $C_3$ becomes 1. The requirement that $A_3$ and $A_4$ be 0 after setup eliminates spurious pulldowns.

## 4 The Hyperconcentrator Switch

In this section, we give the recursive construction for assembling merge boxes into a hyperconcentrator switch. We also show that a signal incurs exactly $2\lceil \log_2 n \rceil$ gate delays through the switch.

A hyperconcentrator switch with input wires $X_1, X_2, \ldots, X_n$, of which $k$ contain messages, and output wires $Y_1, Y_2, \ldots, Y_n$ routes the $k$ valid messages to the first $k$ output wires $Y_1, Y_2, \ldots, Y_k$. Since valid messages are identified by a valid bit of 1 during setup, a hyperconcentrator switch may be viewed as a network that sorts 1's and 0's, with 1's before 0's in the output. The switch is set during setup, with subsequent bits following these established electrical paths.

We use recursive merging to sort the messages, solving the subproblems at each level of the recursion in parallel. By knowing in advance the size of the problem, we know in advance exactly how sets will be divided and merged. We can thus build the division process into the hardware and successively merge larger sets of bits through cascades of parallel merge boxes.

Figure 4 shows the organization of a 16-by-16 hyperconcentrator switch. There are four stages through which the bits cascade, from bottom to top in the figure. By this construction, an $n$-by-$n$ hyperconcentrator switch, composed of $\lceil \log_2 n \rceil$ stages of combinational merge boxes, is itself a combinational circuit. Signals incur exactly $2\lceil \log_2 n \rceil$ gate delays in an $n$-by-$n$ hyperconcentrator switch. During setup, the $S$ switches in each merge box are computed and stored in registers. These switches establish electrical paths for messages in each merge box. Since there are no other switches between merge boxes, the $S$ switches actually establish the paths through the entire hyperconcentrator switch. As in the individual merge boxes, message bits that enter after the valid bit follow the established paths through the hyperconcentrator switch.

Figure 1 shows the layout of a 32-by-32 hyperconcentrator switch, using 4$\mu$m nMOS MOSIS design rules. In order to provide enough drive for the pulldown transistors of the next stage, the inverters following the NOR gates in each merge box are actually inverting superbuffers. Timing simulations have shown that the propagation delay through this circuit is under 70 nanoseconds in the worst case.

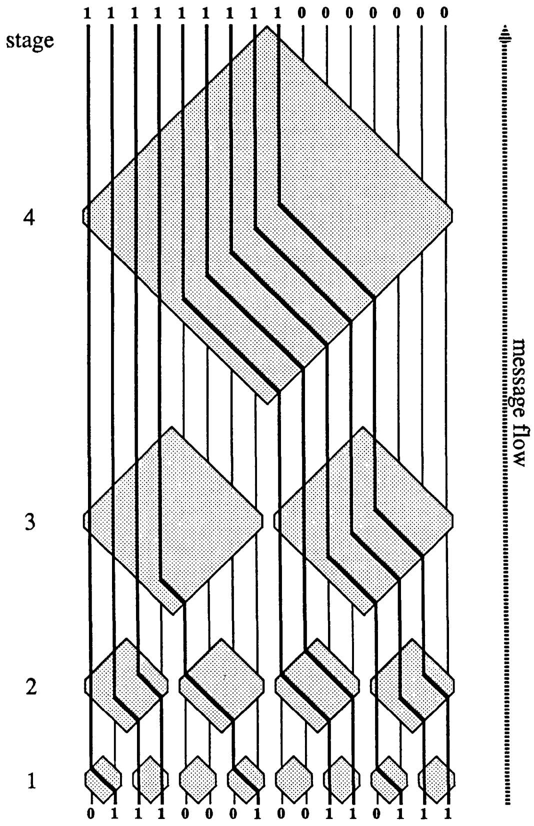

**Figure 4**: A 16-by-16 hyperconcentrator switch with four stages of merge boxes. Individual merge boxes are oriented as in Figure 2, with input wires $A$ entering the bottom left, input wires $B$ entering the bottom right, and output wires $C$ leaving the top left and top right. Messages flow from bottom to top. The output wires $C_1, C_2, \ldots, C_m$ of a merge box of size $m$ are the input wires of a merge box of size $2m$, either $A_1, A_2, \ldots, A_m$ or $B_1, B_2, \ldots, B_m$. Valid bit values are shown entering the first stage and leaving the last stage of the cascade. The electrical paths established within the merge boxes and the switch during setup are shown in heavy lines.

## 5 Applications

This section discusses two applications of the hyperconcentrator switch. One application, the one for which the switch was designed, allows us to use the available clock period more efficiently in bit-serial routing networks. Another application is its use in building a superconcentrator switch.

We can replace small, simple switches in a bit-serial routing network by concentrator switches to successfully route more messages in a single clock cycle, thus using the available clock period more efficiently. The routing network switches we shall consider route valid messages either left or right, based on an address bit immediately following the valid bit. Such a routing scheme is used, for example, in a butterfly network. An address bit of 0 indicates that the valid message should be routed to a left output of a switch, and an address bit of 1 indicates that the valid message should be routed to the right.

Consider the 2-input, 2-output butterfly node shown in Figure 5. A single level of a routing net-

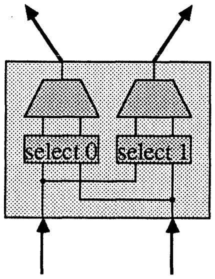

**Figure 5**: A 2-input, 2-output butterfly node. The selectors and 2-by-1 concentrator switches ensure that both input messages reach output wires if their address bits specify that they are going in different directions. If the messages contend for the same output wire, the concentrator switches ensure that one makes it through. With randomly chosen address bits, we expect $3n/4$ of the $n$ messages to be successfully routed through this node.

work such as a butterfly would typically have several such nodes side-by-side. The node contains two simple 2-by-1 concentrator switches, depicted as trapezoids, one with outputs going left and one with outputs going right. Each simple concentrator switch is preceded by a selector circuit that, given an input valid bit and an address bit, produces a new valid bit which is 1 if and only if the input valid bit is 1 and the address bit matches the output direction of the concentrator switch. If two valid messages with equal address bits enter a butterfly node, only one is successfully routed.

The problem with this scheme is that it does not use the available clock period efficiently. The simple node uses only a few levels of logic, so the delay through it is only a few nanoseconds. But because of the time required to get signals on and off chips in current technologies, we cannot distribute a clock with a frequency high enough to match the short delay of this node. In fact, the clock period we can distribute is at least an order of magnitude greater than the delay through this node. This node therefore performs no useful work in at least 90 percent of each clock cycle.

Now consider the generalized $n$-input, $n$-output butterfly node shown for $n = 8$ in Figure 6. Like four simple butterfly nodes of Figure 5 laid side-by-side, it has a total of 8 input wires and 8 output wires, with 4 outputs going left and 4 outputs going right. But here we use two $n$-by-$n/2$ concentrator switches, one with outputs only going left and one with outputs only going right.

The advantage held by the larger node is that at the same clock speed as the simple nodes, it can successfully route more valid messages in each clock cycle. The clock speed remains the same because the additional delay introduced by the larger concentrator switches is just soaked up by the unused portion of the clock period. These nodes use a larger portion of the available clock period. Since the simple nodes leave so much of the available clock period unused, we can even scale these concentrator switches up considerably before the delay introduced exceeds the original clock period. To see that more valid messages are routed by the larger node, assume that a valid message arrives at each input wire of each switch and that the address bit is 0 with probability 1/2, independent of the address bits of other messages. A simple calculation shows that we can expect the simple nodes to successfully route $3n/4$ of the $n$ arriving messages. A more complex calculation [2] shows that the expected number of valid messages successfully routed by the larger nodes with $n$ input wires is $n - O(\sqrt{n})$. Intuitively, the larger nodes successfully route more valid messages because they have more freedom in mapping inputs to outputs.

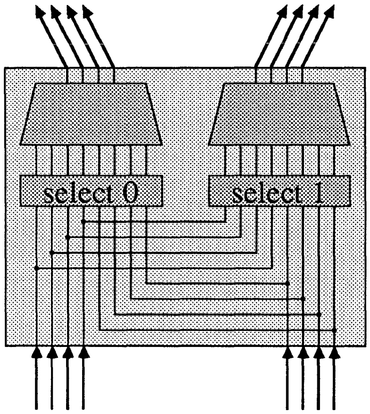

**Figure 6**: A generalized butterfly node with $n$ inputs and $n$ outputs, shown here for $n = 8$. There are two $n$-by-$n/2$ concentrator switches. With randomly chosen address bits, we expect $n - O(\sqrt{n})$ messages to be successfully routed through this node.

The approach of replacing many small routing nodes by fewer nodes with larger concentrator switches is used by the cross-omega network [5]. Part of the cross-omega network is based on a truncated butterfly network. Single wires of the butterfly network are replaced by bundles of 32 wires, and the simple butterfly network nodes are replaced by nodes like that of Figure 6, but with 32 inputs, 32 outputs, and two 32-by-16 concentrator switches.

Fat-trees serve as an example of a class of routing networks that makes use of concentrator switches whose pin counts increase with the network size. The interested reader is referred to [4] and [7] for details.

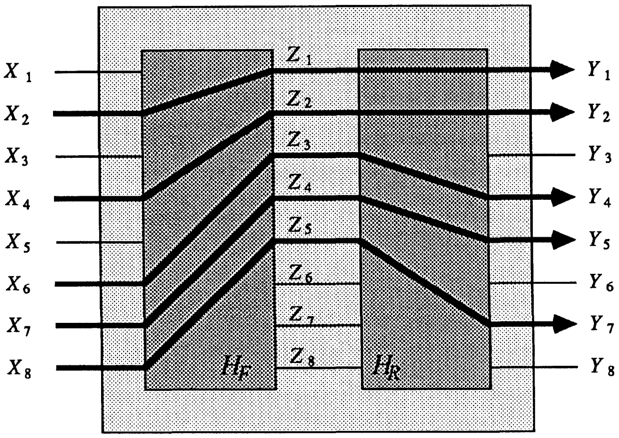

**Figure 7**: A superconcentrator switch built out of two hyperconcentrator switches. The hyperconcentrator switch $H_R$ is set up the connect the first $l$ reverse input wires $Z_1, Z_2, \ldots, Z_l$ to the $l$ good reverse output wires, which also serve as the output wires of the superconcentrator switch. The $k$ valid messages are then routed by the hyperconcentrator switch $H_F$ to the wires $Z_1, Z_2, \ldots, Z_k$ and through the switch $H_R$ to the first $k$ good output wires.

Another application of hyperconcentrator switches is in building superconcentrator switches. An *n-by-n superconcentrator switch* has $n$ input wires $X_1, X_2, \ldots, X_n$ and $n$ output wires $Y_1, Y_2, \ldots, Y_n$. For any $1 \leq k \leq n$, disjoint electrical paths may be established from any set of $k$ input wires to any arbitrarily chosen set of $k$ output wires. Superconcentrator switches are useful in fault-tolerant systems. If some of the output wires of a concentrator switch may be faulty, we can use a superconcentrator switch that routes signals to only the good output wires.

We can build a superconcentrator switch out of two full-duplex hyperconcentrator switches $H_F$ and $H_R$, as shown in Figure 7.[3] (After setup in a full-duplex hyperconcentrator switch, signals can travel along the established paths simultaneously in both forward and reverse directions. Extending the design of the hyperconcentrator switch to make it full-duplex is straightforward.) The output wires of the switch $H_F$ (a "forward" hyperconcentrator switch) feed directly into the reverse input wires of the full-duplex hyperconcentrator switch $H_R$ (a "reverse" hyperconcentrator switch). Suppose there are $l$ good output wires of the superconcentrator switch. Before setup of the superconcentrator switch, the switch $H_R$ sets up electrical paths from its first $l$ reverse input wires $Z_1, Z_2, \ldots, Z_l$ to the $l$ good reverse output wires. These paths are established by assigning a 1 to each forward input wire of the switch $H_R$ that corresponds to a good output wire, assigning a 0 to the forward input wires corresponding to faulty output wires, and running a setup cycle of the switch $H_R$.

Setup of the superconcentrator switch is then just setup of the hyperconcentrator switch $H_F$. The $k$ valid messages are routed through the switch $H_F$ to the wires $Z_1, Z_2, \ldots, Z_k$ and then along the reverse paths through the switch $H_R$ to the first $k$ good output wires.

## 6 Concluding Remarks

In this section, we describe a circuit containing the hyperconcentrator switch which has been fabricated. We also discuss how the switch can be implemented in domino CMOS, and how the switch can be used to build larger concentrators. Finally, we pose some open questions.

We have implemented a 4$\mu$m nMOS 16-by-16 hyperconcentrator switch, which was fabricated by MOSIS. The chip contains programmable selector circuitry preceding the hyperconcentrator switch so that an independent routing decision can be made for each input, as in Figures 5 and 6. Each of the 16 selectors includes a UV write-enabled PROM cell, described in [3]. The bit value stored in each PROM cell is compared with an address bit in the input message to determine whether the message is going in the correct direction. The device is currently under test.

The hyperconcentrator switch can be implemented using precharged design methodologies, such as domino CMOS, instead of ratioed nMOS technology. Although the output inverters used in domino CMOS design are already present in the merge box circuit, the conversion from ratioed nMOS to domino CMOS design is not as straightforward as it may seem at first glance. The functions which define the switch settings $S$ are not monotonic increasing, a violation of domino CMOS design principles. This problem occurs only during setup.

One solution involves an alternative computation of the $S$ values during setup, as follows:

$$\begin{aligned} S_1 &= 1 \\ S_i &= A_{i-1} \quad \text{for } 2 \leq i \leq m+1 \end{aligned}$$

It can be verified that these $S$ values produce the correct valid bit values at the merge box output wires during setup. These $S$ values, however, are not the switch settings stored in the registers. To ensure that subsequent bits are correctly routed through the merge box, we compute the switch settings as in the

[3] This construction is shown in [11].

ratioed nMOS design and store them in the registers during setup, without connecting them to any pulldown circuits. After setup we connect the switch settings to the pulldowns, as in the ratioed nMOS case, and the routing of subsequent bits takes place just as in the ratioed nMOS circuit.

The hyperconcentrator switch can be used as a building block in large concentrators. For example, replacing the comparators in an arbitrary sorting network by $n$-by-$n$ hyperconcentrator switches yields a large hyperconcentrator. (Actually, only the first level of comparators must be replaced by hyperconcentrator switches; merge boxes suffice at all subsequent levels.) We have also found that efficient partial concentrator switches can be built from hyperconcentrator chips. An $(n, m, \alpha)$ *partial concentrator switch* has $n$ inputs, $m$ outputs, and a fraction $\alpha$ such that any set of $k \leq \alpha m$ valid messages is successfully routed to output wires. Using $3\sqrt{n}$ hyperconcentrator chips, each with $\sqrt{n}$ inputs, we can build an $(n, m, \alpha)$ partial concentrator switch with $\alpha = 1 - O(n^{3/4}/m)$ [2].

It is natural to wonder whether a simple design for a concentrator switch exists when we relax the constraint that all the valid messages arrive at the same time. A crossbar switch has the capability of allowing valid messages to come and go at any time, but switch setup can be expensive. It may be that a concentrator switch can be designed that allows new messages to be routed in batches while preserving old connections.

Pittsburgh, PA. 15213

## Abstract

*A hardware solution to low-level (semantic) concurrency extraction is considered. The focus is on the reduction of data-flow inhibitors of concurrency in sequential instruction streams. The reduced procedural dependency techniques of prior work are combined with new high-speed reduced data dependency techniques to yield a new machine model executing standard sequential code in a data-flow-like manner. Also considered is a conceptually simple form of branch prediction. The model is simulated both with and without the branch prediction technique, using a wide range of benchmarks as input. The results are presented and analyzed, showing the model's functionality and performance improvement.*

## 1 Introduction

Computer system performance may be improved via application of *concurrent* or *parallel* processing techniques at many levels. This paper explores the use of *low-level* or *semantic* concurrency extraction techniques applied at the implementation stratum of processor design; the concurrency is extracted directly from the machine code, with no software pre-processing. It is assumed that the machine code is a sequential instruction stream, consisting solely of branches and assignment statements[d], in which each instruction takes one cycle to execute. The specific problem addressed by this work is increasing the concurrency extractable from sequential instruction streams, thereby improving performance, while keeping the hardware extraction techniques used both high-speed and efficient.

Low-level concurrent operation of a computer allows machine-level instructions to execute independently when the semantic restrictions between them allow; e.g., two assignment instructions may execute concurrently if they share no operand sources and sinks. Using low-level concurrency allows multiple instructions to be issued at once, typically more than one per execution cycle. Low-level concurrency was first exploited in the CDC 6600 [10] and the IBM 360/91 [1, 12], although neither machine issued more than one instruction per cycle. Also, neither computer employed significant techniques to reduce the ill effects of branches. Since these machines were built, some research progress has been made by Tjaden [11] in the quantity of low-level concurrency extractable. More recently, with the advent of lower-cost hardware, the utilization of low-level concurrency is being re-examined [4, 5, 7, 13, 16], resulting in new concurrency extraction techniques. In [15] Uht examines improved concurrency extraction techniques in which the negative effects of branches are minimized (this did not include branch prediction methods). In this paper the techniques are extended to include both reduced assignment statement constraints and a form of branch prediction. The prediction technique requires no backtracking or state restoration upon discovery that a branch target prediction was wrong.

The initial applications for this work are both super- and mainframe-(large general purpose) computers, aiding in the speedup of both scientific and general-purpose instruction streams. Future applications are widespread. With the continuing decline of hardware costs, such techniques may be realizable in single-chip machines.

In the next section the problem is further described and refined, previous work is reviewed, and the approach of the solution is outlined. In Section 3 details of the new approach are given. In Section 4 both simulation and hardware estimate data are presented and analyzed. Lastly, a summary is given in Section 5, overviewing the achievements of this work.

## 2 Previous Work and New Approach Outline

### 2.1 Dependency Types

Concurrency extraction starts as *dependency* detection. Two instructions are dependent if their execution must be ordered, due to either *semantic* or *resource* dependencies.

A semantic dependency exists between two instructions if their execution must be serialized to ensure correct operation of the code. This type of dependency arises due to ordering relationships occurring in the code itself. There are two forms of semantic dependencies, *data* and *procedural*.

### 2.1.1 Data Dependencies

Data dependencies arise due to instructions sharing source and sink names in certain combinations. Examples of data dependencies are shown in Figure 1. Referring to Relation 1, a data dependency exists between instructions 1 and 2 since instruction 1 modifies **A**, an input to (source of) instruction 2. Therefore instruction 2 must not execute in a given iteration until instruction 1 has executed in that iteration.

Examples of the three possible types of data dependency relations [2] are shown in Figure 1. Under normal circumstances (when only one copy of a variable exists in the machine at any given time) any one of the relations existing implies that a data dependency exists between the two instructions. But, as demonstrated by Tjaden [11] and Wedig [16], if multiple copies of a variable exist, then Relations 2 and 3 (collectively known as *shadow effects*) do not apply. As an example, consider the Relation 2 situation in Figure 1. Say two copies of A exist, then instruction 1 sources from the first copy and instruction 2 writes (sinks) into the second copy; therefore instructions 1 and 2 may execute concurrently. It is desired to have a machine execute such that shadow effects do not inhibit execution, consequently multiple copies of variables should be provided.

```
     Relation 1:      Relation 2:      Relation 3:
     -----------      -----------      -----------
 1.   A = B + 1        C = A * 2        A = B + 1
 2.   C = A * 2        A = B + 1        A = C * 2

  (in all of the examples, the common use of
   the variable A creates the data dependency)
```

**Figure 1:** Examples of the data dependency relations.

[c] Dr. Wedig is currently an independent consultant. His address is: 580 College Ave., Palo Alto, California 94306.

[d] Procedural instructions; e.g., CALL and RETURN; are special cases of branches, and are included in the models described herein. An overlapped memory-mapped register set is used by the calling mechanism.

### 2.1.2 Procedural Dependencies

Procedural dependencies arise as the result of the presence of branches in the input code. Any type of instruction may be procedurally dependent on one or more branches, but only on branches, and they must be previously-occurring branches, since procedural dependencies are unidirectional (not reflexive) [11, 14]. For example, an instruction which is between a forward branch and its target is procedurally dependent on the forward branch, since its execution is conditional upon how the branch executes. An instruction after the target is not procedurally dependent on the forward branch, since it is guaranteed to execute regardless of how the branch executes, true or false [11]. The type of procedural dependency mentioned above is one of several types, descriptions of which are in [14].

For emphasis, we re-iterate: the union of data and procedural dependencies in code forms the set of semantic dependencies existing in the code, and exists independently of any and all hardware the code might run on.

### 2.1.3 Resource Dependencies

Resource dependencies exist solely due to hardware restrictions of a particular machine's realization. For example, if in a given cycle, three add instructions are eligible for execution, and only two adders are available, then a resource dependency exists. In this work, unless otherwise noted, resource dependencies are assumed not to exist.

### 2.1.4 Related Work

Riseman and Foster [9], and Fisher [4] have shown that much concurrency is extractable if the procedural dependencies can be reduced. Tjaden made the first attempt to reduce procedural dependencies, allowing more concurrency. In [14, 15] procedural dependencies are further reduced, using a *domain* model of control flow. This model, along with the relevant hardware structures appearing in the machine paradigm of [15] (called CONDEL-1), is used in the implementation described herein (called CONDEL-2). (CONDEL stands for CONcurrent Directly Executed Language machine, the emphasis being on CONcurrent.)

The data dependency models used traditionally enforce all three of the data dependency relations enumerated in Section 2.1.1. This has been necessary due to either a lack of duplicate sinks or the use of restrictive algorithms. Less constrained techniques [11, 16] result in either the partial or complete elimination of shadow effects, but suffer from unpleasant implementation features. Specifically, the algorithms for instruction execution are essentially sequential, requiring many steps per cycle, thereby negating any performance gain resulting from concurrency extraction; this is particularly true (many steps needed) for the execution of branches. The prior techniques also only allow one iteration of an instruction to execute per cycle, are potentially costly, and, more importantly, are incompatible with the reduced procedural dependency techniques of CONDEL-1.

Classical machines frequently seek to increase performance via *branch prediction*, in which branches are assumed to execute in one direction before their conditionals have been fully evaluated [6]. This decreases pipeline breaks, improving performance. Another similar technique is to conditionally execute code along both control flow paths from a branch, eliminating the wrong branch when the branch conditional has been fully evaluated. Two problems with these techniques are: rarely can more than one branch prediction be active at any given time, and some state restoration (backtracking) must take place upon a bad prediction. To date, no known branch prediction scheme solving these problems has been implemented, particularly in low-level concurrent machines. In a form of CONDEL-2 a type of branch prediction is allowed which does not require state restoration, and allows multiple branches to execute ahead of time. It is described in Section 3.5.

Other work in the area of hardware low-level concurrency extraction is being done by Torng [13], Patt's group [5], and Cocke [3].

### 2.2 Instruction Streams

There are two possible ways a CPU's execution unit can examine a program's instruction stream during the program's execution, dynamically or statically. The *dynamic instruction stream* is the code as seen in an order determined by the run-time control flow of the code, i.e., as indicated by the contents of a *program counter* (PC) in a traditional machine. The *static instruction stream* is the code as stored in memory, which is normally just the source code order of the program (see Figure 6). Tjaden's and Wedig's [11, 16] schemes both examine the static instruction stream.

Executing the static representation of a program has two major advantages over executing its dynamic representation. If an entire loop fits in CPU storage, then memory accesses due to instruction fetches decrease dramatically. Also, both branches and other types of instructions can execute simultaneously without changing the program's results, reducing the effects of procedural dependencies. The static instruction stream is used in this work.

### 2.3 Problem Definition - Narrowed Version

What is needed is a hardware algorithm for semantic concurrency extraction that exploits a maximal amount of concurrency (not including branch prediction). The model must be high speed, in that the total critical path gate delays must remain low so as not to negate the effect of increased concurrency; the algorithm should also exhibit reasonable cost. It is also desired that some form of branch prediction be developed that does not require backtracking. These requirements specifically indicate a need for efficient representations of instruction execution state and semantic dependencies (partially developed in [11, 15, 16]), and new parallel, high-speed, and affordable techniques to perform the basic concurrency calculations.

### 2.4 Previously Developed Elements, Used in the New Model

The requirements for efficient dependency and state representations are satisfied by modifications of structures proposed by Tjaden and Wedig, as developed by Uht in [14, 15].

The original data dependency matrix, used in CONDEL-1, is upper right triangular, indicating all possible data dependencies between two instructions in a single element. Examples of the new data dependency matrices are shown in Figure 7, with their associated code in Figure 6, indicating the data dependencies between two instructions separately. The matrices are composed of binary elements, and are $n$X$n$ square. A 1 in a matrix indicates a data dependency between the instructions corresponding to the row and column indices, e.g., matrix element $DD^1_{1,2} = 1$ indicates a Relation 1 data dependency between instructions 1 and 2. Upper-right triangular versions of the matrices in Figure 7 exist for procedural dependencies [15]. Note that the static instruction stream model is used. The dependencies are calculated at run-time, as described in [14]; this eliminates extra storage and memory bandwidth that would be necessitated with a compile-time calculation.

Wedig [16] also uses the static instruction stream model. He employs an *Instruction Queue* (see Figure 2) to hold a portion of the static instruction stream. Instructions enter at the bottom and are shifted up, into lower-numbered Instruction Queue rows, as the upper instructions finish executing. Any necessary decoding is performed *relatively statically* [14], one instruction at a time, as an instruction enters the Queue. Each row of the Instruction Queue holds the code data corresponding to instruction *i*, including instruction *i*'s opcode and operand identifiers, as well as a jump destination address if the instruction is a branch. The instructions in the Instruction Queue are accessed in parallel.

Wedig [16] also proposes the *Advanced Execution (AE)* matrix to hold the dynamic instruction state. Each row of the matrix ($AE_{i,*}$) contains the execution state of instruction *i* for a subset of its total number of iterations. The nominal execution order of the instructions corresponding to the Advanced Execution matrix rows is shown in Figure 3. This enforces the basic sequentiality of the serial input code when necessary (when dependencies are present). $AE_{i,j}$ is set either upon an actual execution of instruction *i* in iteration *j*, or upon execution of one or more branches in the Instruction Queue. Setting Advance Execution elements as the result of branch execution is called *virtually executing* the corresponding instructions. A register called the *b-element* stores an integer indicating the total number of iterations that each instruction in the Instruction Queue is to execute (really or virtually). The b-element is incremented when a backward branch executes true (enabling a new iteration for execution), and is decremented when an entire iteration has been executed.

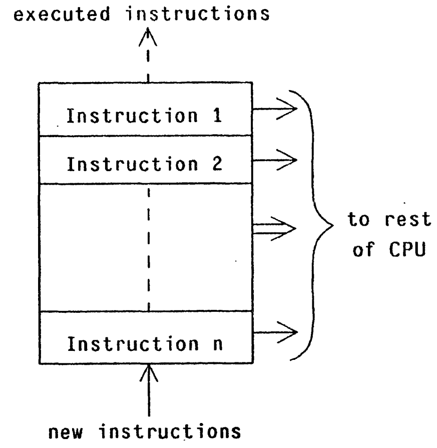

**Figure 2:** Basic Instruction Queue.

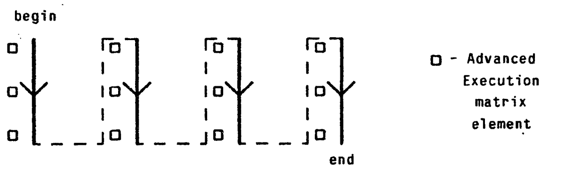

**Figure 3:** Nominal instruction iteration execution order in AE matrix.

An example of code execution with the AE matrix is shown in Figure 4. In the figure, $AE_{1,2}$, $AE_{2,1}$, and $AE_{5,1}$ are set to indicate actual or *real* execution of the corresponding instructions, i.e., an assignment actually occurred or a branch was actually taken. The instructions are all issued in the same cycle since there are no unresolved dependencies between them. Since b = 2, instruction 1 is fully executed. $AE_{3,1}$ and $AE_{4,1}$ are set as a result of the forward branch (instruction 2) executing true (the branch is taken) in iteration 1. Since instructions 3 and 4 are in the domain[e] of the forward branch, they must be kept from really executing, and thus are virtually executed in their first iterations, i.e., their AE elements are set, but they are <u>not</u> issued for execution (no real execution takes place). Therefore, virtual execution of an instruction in a given iteration is the same as disabling the instruction from really executing in the iteration.

```
        Code                          AE matrix   AE matrix
                                      (before 2   (after 2
                  b=2                  executes    executes
                                        true)       true)
                  iteration #:         1 2 3 4     1 2 3 4

1.      A = A + 1                      1 0 0 0     1 1 0 0
2.      IF  A > 0  GOTO  5.            0 0 0 0     1 0 0 0
3.          B = C + D                  0 0 0 0     1 0 0 0
4.          E = F + G                  0 0 0 0     1 0 0 0
5.      W = A                          0 0 0 0     1 0 0 0

    Instructions 3 and 4 are procedurally
       dependent on instruction 1.
```

**Figure 4:** Code execution and the *AE* matrix.

In Wedig's shadow effects reduction model, a matrix of registers called the *Shadow Sink (SSI)* array is used to store multiple copies of instruction sinks, or outputs. The matrix has the same dimensions as the AE matrix (*n*X*m*), and each element of SSI corresponds to the similarly located AE element; in other words, there is one sink register for each AE-represented iteration of each instruction held in the Instruction Queue.

### 2.5 Basic Execution Algorithm

During execution cycles, the dependency information is combined with the dynamic execution state held in the Advanced Execution matrix to generate a list of instructions to be executed in the current cycle. These instructions are issued for execution. This list of executing instructions and the domain information is used to update the Advanced Execution matrix, whence the cycle repeats.

### 2.6 Approach of Solution

Our approach is to develop a new machine model, CONDEL-2, that uses the best features of Tjaden's and Wedig's approaches, the reduced procedural dependency model of CONDEL-1 [15], and new ideas to solve the problem. Specifically, CONDEL-2 employs the static instruction stream model, the basic execution algorithm of [15] (see Section 2.5), and Wedig's Shadow Sink matrix. Modifications of Wedig's AE matrix [16] and the data dependency matrix [14, 15] are also used. New parallel high-speed logic is described that both performs the concurrency calculations, and links instruction outputs (sinks) to other instructions' inputs (sources). Other logic and structures are used to decouple sink storage from instruction execution, both improving performance, and allowing the implementation of a simple form of branch prediction, further improving performance.

## 3 New Solution Description

In this section the major elements of the new model CONDEL-2 are overviewed; details may be found in [14]. In [14] the Relation 1 data dependency in conjunction with a reduced set of procedural dependencies are shown to constitute a minimal set of semantic dependencies for virtually all sequential code. The reduced set of procedural dependencies was established via both exhaustive consideration of control flow types and a recursive proof. This section describes the hardware necessary to implement the minimal semantic dependencies (with restrictive array accesses, described in Section 3.4). The solution description concludes with an example of the operation of the hardware. (The reader may find it helpful to refer to Figures 3 and 6 - 8 as the hardware is introduced.)

### 3.1 Basic Elements of the Solution

The basic problem is to determine which, if any, sink element of the instructions in the IQ should be used as the source element of an instruction in the IQ (it may be the same instruction). In any case the model must allow for independent writing of multiple instruction iterations' sink operands. The SSI matrix of Wedig [16] satisfies this requirement. It is helpful to consider the model of program execution vis-a-vis the AE matrix presented by Wedig [16]; see Figure 3. (For the remainder of the discussion, one source per instruction is assumed[f]. The presentation is easily generalized to accommodate multiple sources.) The directed line shows the nominal or *serial* order of execution of the sequentially biased code in the IQ. A specific iteration of an instruction uses as a source a sink generated previously and residing in either memory or the SSI. Therefore the previous sink is somewhere *serially* previous to the specific iteration, back along the line. The particular SSI word to be used is indicated by both the data dependencies and the execution state of the relevant instructions.

It has been determined [14] that knowing just the Advanced Execution state is insufficient, as the validity of an instruction's sink cannot be determined from the AE state. What is needed is a separation of the *real* from the *virtual* execution state held in the

[e] In the CONDEL models, branch domain indicators are stored in matrices similar to those holding dependencies; see [14, 15].

[f] Adding a source requires adding a like amount of linking logic, as well as requiring an additional data dependency matrix.

AE matrix. Therefore two new matrices are used, the Real Execution (RE) and the Virtual Execution (VE) matrices, described in Section 3.2. Note that AE = RE + VE; this is a *logic* equation.

Only one *serial data dependency* (that of Relation 1) is needed for all instructions, with the exception of array accesses (see Section 3.4). This data dependency occurs when the sink of one instruction's iteration is the same as the source of a serially later instruction's iteration. The data dependency information kept in the DD matrix of CONDEL-1 is separated into multiple square matrices in CONDEL-2, one per possible source-sink pair, to allow for individual access to an instruction's Relation 1 data dependencies (those of an instruction's source on other instructions' sinks). In the new model, an instruction in a given iteration may be data dependent on the same instruction in a previous iteration, e.g., an instruction of the form: I = I + 1.

It is both conceptually and notationally convenient in many cases to look at the AE, RE, and VE matrices (or any nXm matrix) as one-dimensional vectors with length nm, with the elements column ordered as indicated by the line in Figure 3. This is then just the serial ordering of the instructions' iterations. For the remainder of this document, either serial or row and column indexing of an array may be used for the array; the default is the latter; if serial indexing is used, it will be noted.

The Virtual and Real Execution matrices and the separated Data Dependency (DD) matrices are the primary new structures needed to solve the problems. The key element tying them together is the new linking logic, described in Section 3.3.1.

### 3.2 The Hardware Matrices

With the exception of the dependency matrices previously discussed, all of the hardware matrices in CONDEL-2 are similar to the Advanced Execution matrix. There is a one-to-one correspondence between each element in the AE matrix and each element in the other matrices, each element indicating some state corresponding to a particular instruction's iteration. The matrices are of dimension nXm, as is the AE matrix. The new matrices are individually described as follows.

#### 3.2.1 Real Execution (RE) Matrix

Each element of RE is binary. $RE_{i,j} = 1$ (is set to one) iff instruction $IQ_i$ has *really* executed in iteration j. An instruction really executes if, for an assignment statement, an assignment has really occurred; or for a branch, a conditional has really been evaluated and a branch decision made.

#### 3.2.2 Virtual Execution (VE) Matrix

Each element of VE is binary. $VE_{i,j} = 1$ (is set to one) iff instruction $IQ_i$ has *virtually* executed in iteration j. An instruction virtually executes if it is to be disabled (for execution) by a branch's true execution (the branch is taken).

#### 3.2.3 Shadow SInk (SSI) Matrix

Created by Wedig [16], each element of SSI is typically the size of an architectural machine register, i.e., is large enough to hold variables' values. $SSI_{i,j}$ is loaded with the sink value (result) of an assignment instruction $IQ_i$ having executed in iteration j. Variables' values are normally held in SSI at least until they have been copied to memory. Since there are multiple locations (in SSI) to store instruction results (i.e., there are multiple copies of variables), basic shadow effects need not occur.

#### 3.2.4 Instruction Sink Address (ISA) Matrix

Each ISA element is large enough to hold addresses (e.g., main memory addresses) of variables. There is one ISA element for each SSI element. $ISA_{i,j}$ holds the sink address of the sink value held in $SSI_{i,j}$. For non-array write instructions, $ISA_{i,*} = AA_i$, where AA is operand A's address (held in the IQ). For array write instructions, ISA is determined for each iteration at run-time.

The previous model of execution (CONDEL-1) is modified so that now during every cycle each eligible SSI value is written into memory at the location pointed to by the contents of the corresponding ISA element. The determination of eligibility is discussed later.

#### 3.2.5 Advanced STorage (AST) Matrix

The AST matrix is a binary matrix with the same dimensions as the AE matrix. $AST_{i,j}$ is set to 1 if either $VE_{i,j}$ is set to 1 (instruction i receives a virtual execution in iteration j), or $SSI_{i,j}$ has been written to memory. In other words, $AST_{i,j}$ equals 1 iff it may be considered that $SSI_{i,j}$ has been stored; conceptually it is similar to the AE matrix, in that either real or virtual writes cause the matrix elements to be set.

### 3.3 Hardware Logic

#### 3.3.1 Basic Linking and Executable Independence Logic

The fundamental state storage structures necessary to solve the problem have been described. The primary logic that generates the source-to-sink links and calculates executable independence is now outlined[g]. The problem may be re-formulated to a more concrete specification as follows. It is required to have nm sets of less than nm output enabling lines each, one set per source per IQ instruction iteration, each line of which potentially enables (connects) a serially previous sink word to the instruction iteration's source input. These lines are designated

$SEN^u_{t,z}$ (SEN stands for Sink ENable);

where:

- *u* is the serial index to the IQ instruction iteration under consideration for execution;
- *t* indicates the serial SSI element under consideration for linking to an input of *u*, it is always serially previous to u;
- *z* indicates the source of instruction *i* that corresponds to a particular SEN matrix, it is a source index;

($i$ = row($u$); $j$ = col($u$)).

The SEN elements are calculated simply from the RE, VE, and DD state. An instruction iteration u can only link (take a source from) an instruction iteration t if: t is both really executed and data dependent on u, and all instruction iterations serially between u and t are virtually executed (if they are data dependent on u). For each u and z combination, at most one $SEN^u_{t,z}$ is equal to one. If none equal one, then either the source is not in SSI, i.e., it is in memory, or the source has not yet been produced. The rough location (whether or not in memory) of a source is given by the Source From Storage ($SFS_{u,z}$) indicators, u and z defined as above. The SFS values are calculated from DD and VE. A source should be taken from storage if for all serially previous iterations, no valid sink exists in Shadow SInk storage; otherwise, the source should be taken from an appropriate SSI element.

It follows that iteration j of instruction $IQ_i$ (with serial index u) is data executably independent (all data dependencies resolved) if either its source is in memory or one SEN element is set (i.e., a valid sink exists in SSI). Complete Semantic Executable Independence is determined from this and the procedurally executably independent conditions, given in [14].

#### 3.3.2 Decoupling of Sink Storage from Instruction Execution

New logic and structures have been developed to allow memory updates to be decoupled from instruction execution. The write enable lines are called Write Sink Enable, and there is one per Shadow Sink element. The system works as follows. Basically, each $WSE_u$ (Write Sink Enable for serial iteration u) equals one during a cycle iff the corresponding $SSI_u$ is to be written into memory (at location $ISA_u$). The WSE logic is also used to update the contents of the Advanced Storage matrix every cycle; if $WSE_u$ is true, then $AST_u$ is set to indicate that Shadow Sink u has been stored into memory. The combination of the WSE logic and the ISA and AST matrices allow the decoupling of instruction execution from memory updating. This in turn allows the form of branch prediction described in Section 3.5, as well as reducing the

[g] Complete versions of the logic, including the restrictive array accesses, may be found in [14].

negative effects of certain array access sequences. The detailed derivation of the WSE logic may be found in [14].

### 3.4 Less Restrictive Array Accesses

As in CONDEL-1, array accesses are restrictive in CONDEL-2, but not to the same degree. In the implementation of CONDEL-2, data dependency Relation 3 (common sink) type array accesses may be executed concurrently, due to the presence of multiple sink copies (Shadow Sinks). However, since all array reads are made from memory[h], Relation 1 and 2 type array accesses may not execute concurrently. In other words, any two array accesses involving both an array read and an array write to the same array must be sequentialized; otherwise (with only array writes or only array reads taking place) the accesses may proceed concurrently.

### 3.5 Implementation and Discussion of Branch Prediction

Classically, branch prediction techniques have been used to conditionally execute code beyond branches in the dynamic instruction stream ordering. Since such execution is conditional, a certain amount of code-backtracking or state-restoration must be made if the prediction is subsequently found to be wrong. This complicates the hardware of machines using such techniques, and can reduce performance in branch intensive situations. Also recall that with the dynamic instruction stream ordering, and considering the degree of hardware complexity needed with multiple simultaneous branch predictions, usually only one branch is conditionally executed at a given time.

The model described thus far (CONDEL-2) is strictly deterministic, in that no branch prediction is used. A modification to CONDEL-2 is now described that allows a simple form of branch prediction; this form is called *Super Advanced Execution (SAE)*. The basic rule of SAE is as follows:

> *Instructions within an innermost loop assume that the Backward Branch comprising the loop will always execute true.*

This means that inner loops will be presumed to execute an infinite number of iterations (in reality as many as there are in the AE matrix [m]). Note that forward branches within an inner loop may therefore also execute ahead of time, increasing the degree of branch prediction possible. Inner loops are flagged by the hardware at run-time, using a Backward Branch Domain matrix [14]. The way SAE works in the hardware is now described.

Referring to Figure 5, note that b = 3, and therefore normally only those instructions' iterations in columns 1-3 are allowed to execute. Indeed, they must execute for the output of the code to be correct. With SAE these instructions (indicated by X's and T's) execute as before, but in addition those instructions' iterations (indicated by S's) to the right of column 3 (to the right of the b pointer) and within the inner loop are also allowed to execute. This is possible, with slight modifications of the Sink ENable and Semantically Executably Independent logic, by considering the other instructions' iterations (indicated by V's) to be virtually executed[i]; thus, no links are made to these iterations, and the V iterations allow S iterations to link to X or T iterations. The Write Sink Enable (WSE) logic is not modified, however, so that only those sinks whose instructions' iterations are guaranteed to actually execute (i.e., those sinks to the left of and including the column pointed to by the b element) are eligible to be written into memory. This means that instructions' iterations S can execute ahead of time, writing to their corresponding sink in the Shadow Sink matrix, but the sink is not copied into memory at least until the instruction's iteration becomes an X instruction iteration[j]. Therefore no state-restoration or backtracking is needed. See [14] for implementation details of SAE.

The execution algorithm is the same as in the basic CONDEL-2 machine, with the following addendum. When an outer backward branch executes true in a given iteration, it causes all future state (SAE) to be reset. This is necessary to maintain potential dependencies.

Summarizing:

1. No state-restoration or backtracking is necessary for the branch prediction technique of Super Advanced Execution.
2. In this technique, multiple branches, both forward and backward, may execute ahead of time.

```
                AE Matrix - (b = 3)
iteration #  1   2   3   4   5   6

                   virtually executed
             T - (see footnote in text)
```

Figure 5: Super Advanced Execution and the AE matrix.

### 3.6 Example of CONDEL-2's Instruction Issuing Mechanism

A brief, simple example is now presented illustrating the concepts and logic of CONDEL-2 including Super Advanced Execution. The major logic structures are shown after several cycles of the execution of a small piece of code. The code segment used for the example is shown in Figure 6. The associated dependency matrices are displayed in Figure 7. $DD^1$ holds source 1 data dependencies, $DD^2$ holds source 2 data dependencies, and $DD^3$ holds the Relation 3 data dependencies (only needed for array accesses).

Array "A" has the values:

A(1)=4     A(2)=3     A(3)=2     A(4)=1     A(5)=5

The AE matrix iterations are numbered:

| | | column #: | | | | |
|---|---|---|---|---|---|---|
| | | 1 | 2 | 3 | 4 | 5 |
| | 1 | 1 | 7 | 13 | 19 | 25 |
| | 2 | 2 | 8 | 14 | 20 | 26 |
| row #: | 3 | 3 | 9 | 15 | 21 | 27 |
| | 4 | 4 | 10 | 16 | 22 | 28 |
| | 5 | 5 | 11 | 17 | 23 | 29 |
| | 6 | 6 | 12 | 18 | 24 | 30 |

The concurrency structures' contents and logic values represent the machine state at the beginning of the cycle, with the following exceptions. The SSI values shown are those occurring after the SEI (Semantically Executably Independent) indicated instructions have executed. The SEI values shown in a cycle are those occurring just prior to the updating of AE, etc., in the same cycle. The SAEVE matrix indicates those iterations assumed to have virtually executed for Super Advanced Execution. Also note that only some of the SEN matrices are shown, due to space limitations.

The steady-state instruction execution rate (five instructions executing per cycle) is reached in cycle 5 (see Figure 8). This is an instance of *saturation*, in which every instruction within a loop

[h] This can be avoided if $O(n^2m^2)$ address comparators are provided to match array sources with array sinks, the addresses of which are not known until execute time; in this case the dependencies with previous array read instructions need not hold. The technique of CONDEL-2 uses much less hardware and is more practical; no comparators are used (for a similar execute-time function).

[i] The instructions in the T region are also considered to be virtually executed by instruction iterations in the S region. This is so that T sinks are not used as inputs to S instruction iterations. Otherwise, T instruction iterations are both viewed, and allowed to execute, as normal (X) instruction iterations.

[j] This can occur only upon the inner loop's Backward Branch actually executing true.

```
I#  Instruction          Sink   Src. 1  Src. 2
--  -----------          ----   ------  ------
1.  I=0                   I       0       -
2.      I=I+1             I       I       1
3.      B=A(I)            B       A       I
4.      C=B*2             C       B       2
5.      D(I)=C            D       I       C
6.      IF I<6 GOTO 2.    -       I       6

   Instructions 2-6 comprise the inner loop.
```

**Figure 6:** Example code segment.

$$\begin{array}{cccccc} \multicolumn{6}{c}{DD^1} \\ 0&1&0&0&1&1 \\ 0&1&0&0&1&1 \\ 0&0&0&1&0&0 \\ 0&0&0&0&0&0 \\ 0&0&0&0&0&0 \\ 0&0&0&0&0&0 \end{array} \qquad \begin{array}{cccccc} \multicolumn{6}{c}{DD^2} \\ 0&0&1&0&0&0 \\ 0&0&1&0&0&0 \\ 0&0&0&0&0&0 \\ 0&0&0&0&1&0 \\ 0&0&0&0&0&0 \\ 0&0&0&0&0&0 \end{array} \qquad \begin{array}{cccccc} \multicolumn{6}{c}{DD^3} \\ 1&1&0&0&0&0 \\ 1&1&0&0&0&0 \\ 0&0&1&0&0&0 \\ 0&0&0&1&0&0 \\ 0&0&0&0&1&0 \\ 0&0&0&0&0&1 \end{array}$$

(the procedural dependency
matrices contain all 0's)

**Figure 7:** Example dependency matrices.

executes in one iteration every cycle. In this cycle, the first column of the structures will be retired (the storage matrices shifted left and b decremented) since the first column of AE is all 1's. Therefore more state space is made in the storage matrices to continue to allow five instructions to execute per cycle, until the loop terminates. Also, the first SEN matrix indicates that instruction 5 should use the first iteration copy of instruction 2's sink as its source 1. Note that the execution of instruction 2 in iteration 4 is an example of Super Advanced Execution.

## 4 Evaluation Data and its Analysis

### 4.1 Introduction

Measurement data evaluating the new solution follows. The solution is critiqued via both simulations and hardware estimates. In the following sections the benchmarks are briefly described, the performance measurements are given with analyses, and hardware estimates are presented.

### 4.2 Benchmark Descriptions

Two sets of benchmarks were used, a General Purpose set and a Scientific set. The General Purpose benchmarks contain a relatively high degree of control flow complexity; the benchmarks perform a wide variety of tasks and are representative; **Dhrystone** [17] is included. The Scientific benchmarks exhibit a very low degree of control flow complexity, perhaps too low to be realistic. They consist of the 14 standard Lawrence Livermore Loops [8], with the number of loop iterations of each loop reduced by about a factor of 10, to reduce simulation time[k]. All of the benchmarks were hand-coded into an intermediate assembly code; unless noted otherwise, the coder mimicked a typical compiler[l].

b=3

$$\begin{array}{ccccc} \multicolumn{5}{c}{RE} \\ 1&0&0&0&0 \\ 1&1&1&0&0 \\ 1&1&0&0&0 \\ 1&0&0&0&0 \\ 0&0&0&0&0 \\ 1&1&0&0&0 \end{array} \quad \begin{array}{ccccc} \multicolumn{5}{c}{VE} \\ 0&1&1&0&0 \\ 0&0&0&0&0 \\ 0&0&0&0&0 \\ 0&0&0&0&0 \\ 0&0&0&0&0 \\ 0&0&0&0&0 \end{array} \quad \begin{array}{ccccc} \multicolumn{5}{c}{AE} \\ 1&1&1&0&0 \\ 1&1&1&0&0 \\ 1&1&0&0&0 \\ 1&0&0&0&0 \\ 0&0&0&0&0 \\ 1&1&0&0&0 \end{array} \quad \begin{array}{ccccc} \multicolumn{5}{c}{SSI} \\ 0&x&x&x&x \\ 1&2&3&4&x \\ 4&3&2&x&x \\ 8&6&x&x&x \\ 8&x&x&x&x \\ x&x&x&x&x \end{array} \quad \begin{array}{ccccc} \multicolumn{5}{c}{AST} \\ 1&1&1&0&0 \\ 1&1&1&0&0 \\ 1&1&0&0&0 \\ 1&0&0&0&0 \\ 0&0&0&0&0 \\ 0&0&0&0&0 \end{array} \quad \begin{array}{ccccc} \multicolumn{5}{c}{WSE} \\ 0&0&0&0&0 \\ 0&0&0&0&0 \\ 0&0&1&0&0 \\ 0&1&0&0&0 \\ 1&0&0&0&0 \\ 0&0&0&0&0 \end{array}$$

**Figure 8:** Example concurrency structures and logic: cycle 5.

### 4.3 Performance Evaluation - Simulation Results

#### 4.3.1 Introduction

Simulations were run both to verify functionality of the hardware algorithms and to measure their performance, particularly with respect to standard sequential execution. To these ends the execution of a variety of benchmarks was simulated in software assuming both the new hardware algorithms previously described, and, for comparison purposes, a more restrictive algorithm. The simulator mimicked the hardware structures and logic present in the various machine models. All of the simulations produced the correct results, so functionality has been verified. The main performance measurement is the speedup $S$; for a given benchmark, $S$ is defined as the number of cycles necessary to execute the benchmark purely sequentially, divided by the number of cycles necessary to execute the benchmark concurrently. For a set of benchmarks, $S$ is the average of the component benchmarks' speedups, all weighed evenly.

The machine model independent-variable is data concurrency type *dct*. The data dependency and branch prediction models implemented in the simulator are indicated by the *dct* value, defined as:

- 1 - maximally restrictive data dependencies; all data dependency relations shown in Figure 1 hold; note that this model of data dependencies, as implemented in CONDEL-1, precludes the use of Super Advanced Execution (SAE)
- 2 - reduced data dependencies without SAE; only data dependency Relation 1 holds for non-array accesses, and no branch prediction is used
- 3 - reduced data dependencies with SAE; same as 2, but using the branch prediction technique of Section 3.5

In the remainder of this section the simulation results of the machine model of Section 3, CONDEL-2, are presented for both sets of benchmarks. The very reduced procedural dependency model of [15], i.e., procedural concurrency type (*pct*) C, is assumed throughout; the results of the Scientific set are independent of *pct*. For all of the simulations, the Instruction Queue length *n* is fixed at 16 or 32.

#### 4.3.2 General Purpose Set Simulation Results

The simulation results are summarized in the plot of Figure 9. Within the plot, the three curves correspond to the different data

[k] If anything, this makes the simulation results more conservative, since better performance of the models typically occurs as the number of loop iterations increases (reducing the effects of startup execution transients).

[l] The following simple compiler features were assumed: mapping of assignment expressions to low-height binary execution trees, little re-use of registers, and HLL statement translation as described in [14].

concurrency types (*dct* values). The data corresponding to the restrictive data dependency model of CONDEL-1 (*dct* = 1) is included in the plot for comparison purposes. The range of the speedups for individual benchmarks with m = 8 is from 1.59 to 2.77 for *dct* = 2, and from 1.61 to 4.79 for *dct* = 3. In the plot, it is seen that reducing data dependencies improves performance, as does the use of Super Advanced Execution. Increasing Advanced Execution matrix width *m* improves performance, when SAE is used, as it allows more iterations to be active at any given time, and with the branch prediction technique of SAE more iterations are likely to be used. Note that no prior model implements either of the most advanced concurrency types: very reduced procedural dependencies, or reduced data dependencies with Super Advanced Execution.

### 4.3.3 Scientific Set Simulation Results

The Scientific benchmark set simulation results are shown in Figures 10 and 11. Figure 10 includes the results of all of the loops. Figure 11 includes the results for just those loops for which loop capture[m] occurred (Loops 1-6, 11, and 12). The plot of Figure 11 demonstrates the benefits of loop capture. In both plots the performance improvements of the reduced data dependency techniques are seen to be significant, particularly with Super Advanced Execution. Also note that a wider Advanced Execution matrix (larger *m*) gives greater performance in the same situations as with the General Purpose benchmark set results. The individual speedups for each of the loops ranged from 1.66 to 9.55 for *dct* = 2, and a range of 1.66 to 11.69 for *dct* = 3. From the data, it was seen that many of the benchmarks are resistant to performance enhancements. Six performance inhibiting mechanisms have been identified [14]. With the elimination of these mechanisms via relatively simple software preprocessing techniques (extent in a compiler), 9-12 of the loops should execute in saturation (see Section 3.6); this situation currently occurs with only 3 of the loops.

## 4.4 CONDEL-2 Hardware Estimates

### 4.4.1 Hardware Cost

The hardware cost of the reduced data dependency hardware is $O(Kn^2m^2)$, where K is about 7. (We assume unlimited fan-out, fan-in of 10 [except for some wired-OR connections], and 6 gates per storage element.) The main contributors to the cost are the Sink ENable and Write Sink Enable logic. Being conservative (pessimistic), and taking n = 32 and m = 8 (large enough to extract most of the concurrency of the Scientific benchmark set), the cost is about 1 Mgates. If General Purpose code is the primary application of a target machine, then n and m may be reduced (while the machine will still capture most of the concurrency), giving a vastly reduced hardware cost.

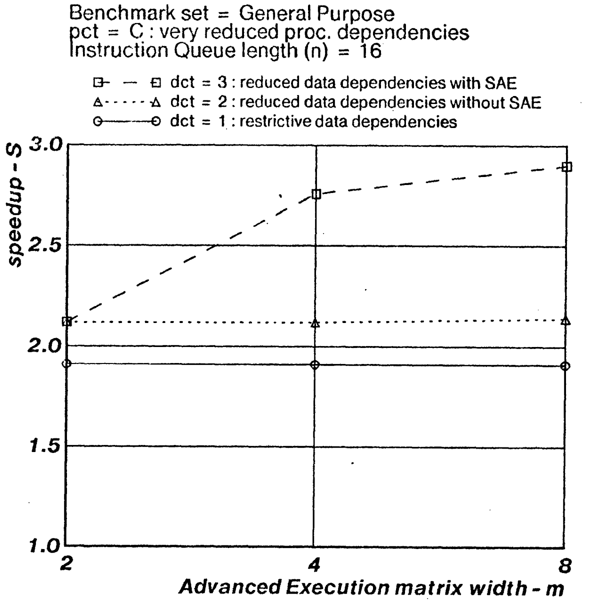

Figure 9: GP performance summary, *pct* = C.

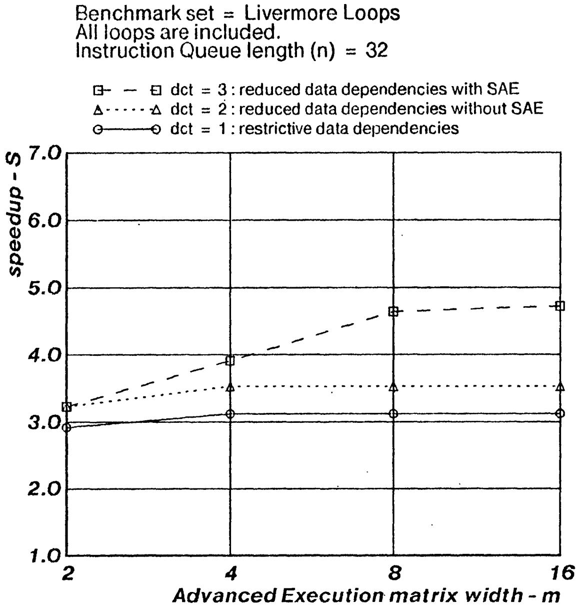

Figure 10: Scientific set performance summary, all loops included.

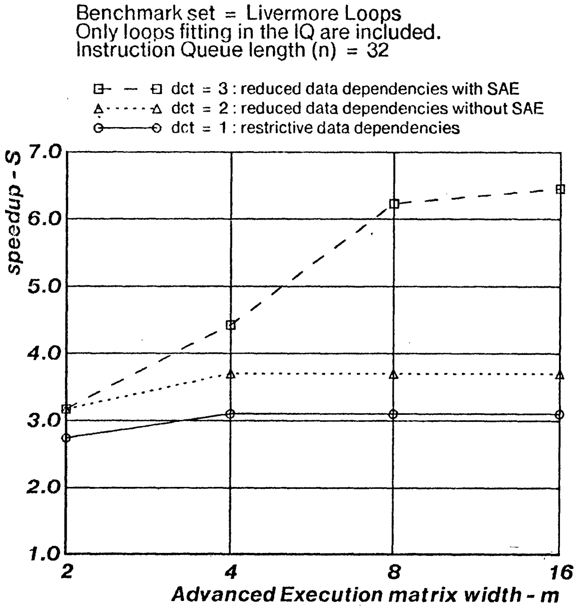

Figure 11: Scientific set performance summary, with loop capture.

The prior techniques have the following costs.

- Tjaden's model: $O(n^2R)$, R is size of reassignable storage
- Wedig's model: $O(n^2m + R\log_2 n)$, R is size of reassignable storage

[m] Loop capture occurs when the loop is completely contained in the Instruction Queue.

The costs of these models may or may not be greater than CONDEL-2, depending on the choice of parameters; however, neither model is as functionally advanced as CONDEL-2.

### 4.4.2 Hardware Delay

The hardware delay is low because CONDEL-2's logic and update algorithms are inherently parallel; limited fan-in and fan-out should not increase the delay excessively, depending on the logic family used and the choices of n and m. This compares very favorably to the prior models of Tjaden and Wedig, in which the algorithms were basically sequential, leading to extremely large delays. In [14, 15] CONDEL-1, a similar kind of machine, is estimated to have a critical path delay of 8 gate-delays; this is the same as a Cray-1, and less than any other machine examined. A preliminary analysis shows that CONDEL-2's critical path delay is about the same as CONDEL-1's, given similar amounts of hardware resources (Processing Elements, etc.).

## 5 Summary

The major concepts presented in this document are functionally sound and provide significant performance gains over standard sequential execution techniques. There are indications that performance may be further improved via software concurrency enhancement.

A significant speedup of sequential imperative code has been demonstrated through the use of low-level concurrency extraction. Reduced data dependencies enhance the concurrency detectable. Although a complete set of restricted resource measurements must yet be made on CONDEL-2, it has been found that the efficiency approaches 1 when execution saturation occurs, where efficiency is the speedup divided by the number of peak resources (Processing Elements) used. CONDEL-2 exhibits improved performance over both sequential machines and the concurrent models of Tjaden and Wedig with reduced hardware delay compared to their models; the hardware cost may or may not be comparable, depending on machine parameters. With the previously mentioned constraints, and disregarding branch prediction, CONDEL-2 extracts all semantic concurrency from an input imperative instruction stream; a parallel logic algorithm is used. A simple branch prediction technique has been implemented which requires no backtracking and allows multiple branches to execute ahead of time.

CONDEL-2, with or without Super Advanced Execution, achieves data-flow execution of typical sequential code (consisting of branches and assignment statements, and assuming restrictive array accesses) with minimal deterministic control-flow constraints.

Planned future work includes:

- increasing the degree of branch prediction implemented in the model;
- making a detailed design study of CONDEL-2, including investigating reductions in its hardware cost;
- investigating compile-time techniques to increase the concurrency extractable (as mentioned in Section 4.3.3);
- examining the performance effects of reduced resources (limited processing elements);
- and performing simulations of more benchmark programs.

University Park, PA 16802

*Abstract* -- A fault detection and location procedure for $\Omega^r\Omega^{-1}$ networks is presented in this paper. Test vectors, with length independent of the size of the network, are first generated; then single fault is detected and various strategies, depending on the type of the fault, are used to locate it. Using other test vectors with length proportional to the size of the network is also discussed.

## 1. Introduction

In this paper, we present a fault diagnostic procedure for rearrangeable $\Omega^r\Omega^{-1}$ networks with $N(=2^n)$ input/output terminals. This procedure also applies to Benes networks which are deducible from $\Omega^r\Omega^{-1}$ networks as discussed in [1]. It is much simpler and faster than the method in [2] which involves complicated computation using the looping algorithm.

We assume individual switching elements are not accessible and use the following notations throughout this paper. An $N=2^n$ input/output $\Omega^r\Omega^{-1}$ network is described by $sE^0sE^1...sE^{n-1}uE^n...uE^{2n-2}$, where s and u are the shuffle and the unshuffle respectively and $(E^i)$'s are switching element stages indexed from 0 to 2n-2. Input/output lines are indexed from 0 to N-1 and $(i)^j=(i_{n-1}i_{n-2}...i_0)^j$ is the ith input/output of the jth stage, if the index of the stage should be emphasized, where $i_{n-1}i_{n-2}...i_0$ is the binary representation of i. Both indexing schemes are viewed from top down in figures. A path in a network, under a certain set of switching element settings, is a route from an input terminal to an output terminal, through intermediate links and connections of switching elements under that set of settings. We also use $\bar{x}$ to denote the complement of x. We shall use the fault model and similar fault classifications in [3]. A brief review is given below.

A fault can occur at either a link or a switching element. A faulty link is one being stuck-at-zero (s-a-0) or stuck-at-one (s-a-1). On the other hand, we have sixteen possible states for a 2x2 cross point switching element, as shown in Table 1. Only states $S_{10}$ and $S_5$ are considered to be valid. Let S be the set of all sixteen possible states in Table 1. We define the cartesian product S×S as the set of functional states. Assuming that the first valid state is $S_{10}$ and the second $S_5$, a functional state $(S_i,S_j)$ of a switching element is interpreted as the switching element responds in states $S_i$ and $S_j$ while it should be in states $S_{10}$ and $S_5$ respectively. In states $S_0$, $S_1$, $S_2$, $S_4$, $S_6$, $S_8$ and $S_9$ we have logically unidentified outputs denoted by "-" and in $S_6$, $S_7$, $S_9$, $S_{11}$, $S_{13}$, $S_{14}$ and $S_{15}$, we have logically erroneous outputs denoted by "$\phi$". The output values of "-" and "$\phi$" depend on the circuit implementation. However, an arbitrary assignment of 0 or 1 to them will not affect our capability of differentiating normal outputs from faulty outputs. It is clear that the cardinality of S×S is 256, only $(S_{10},S_5)$ is considered normal and the remaining 255 states are all considered faulty. Here we only consider the case of single fault, i.e. either a link stuck fault or a switching element fault, but not both.

## 2. Fault Detection

Let $\oplus i=i_{n-1}\oplus i_{n-2}\oplus...\oplus i_0$, where $\oplus$ is the exclusive-or operator. Also let $a=(a_0,a_1,...,a_{N-1})$, where $a_i=\oplus i$ and $0\leq i<N$, and $b=(b_0,b_1,...,b_{N-1})$, where $b_i=1$ if $\oplus i=0$ and 0 if $\oplus i=1$, and $0\leq i<N$, be the two test vectors in our diagnostic procedure. Notice that $\bar{a}=b$ or $\bar{a}_i=b_i$ for all i. It is easy to see that each switching element receives both 0 and 1 as its inputs when the input vector of the network is a or b, if all the switching elements are set to $S_{10}$ or $S_5$ respectively.

A switching element in states $S_{10}$ and $S_5$ is shown in Figure 1. Table 2 and Table 3 show its normal and faulty output patterns when tested in $S_{10}$ and $S_5$ respectively. It is clear from the tables that we need only to apply both (0,1) and (1,0) to each switching element in order to detect a fault. There are two test phases; in phase-1, all switching elements are set to $S_{10}$ and in phase-2, $S_5$. Figure 2 and Figure 3 show the normal inputs and outputs of a network in phase-1 test and phase-2 test with a and b applied when N=8. Notice that each input vector to a switching element is either (1,0) or (0,1) and so is every output vector. It is easy to see that the output vector is the same as the input vector of a network in a phase-1 test. But in a phase-2 test, the output vector is the complement of the input vector because input i is routed to $\bar{i}$ after the middle stage and then to $i^{\bar{0}}$ (i with the $i_0$ bit complemented) at the output side and inputs i and $i^{\bar{0}}$ are complements to each other. This shows that both input and output vectors are very easy to generate.

It is obvious that we only need to apply a and b in one of the two phases to detect a link stuck fault. However, we may have to test both phases to detect a switching element fault. In any case, four tests are enough for detection.

## 3. Fault Location

Since a switching element can produce none, one or two faulty outputs in either phase of the test, there are several combinations. We divide them into three categories, similar to the cases in [3]. (1)One faulty output appears in the four tests. (2)Two faulty outputs appear in either phase-1 or phase-2 test. (3)Two faulty outputs appear in the four tests, one from phase-1 and the other from phase-2.

There are twelve faulty functional states in category 1. Table 4 shows each faulty functional state, the position and pattern of the faulty output, and the phase of test in which a fault occurs. It is clear that every switching element on the path leading to the faulty output could be faulty. A process, similar to the one in [3], using the principle of binary search, can pinpoint the fault in $\lceil\log(2n-1)\rceil$ steps. Then, by supplying the faulty switching element identical inputs, we are able to distinguish the $\phi\phi$ case from the -- case. In summary, for category 1, the location and the functional state of a faulty switching element can be determined within $6+2\lceil\log(2n-1)\rceil$ tests.

For category 2, every state of $S_0$, $S_1$, $S_4$, $S_5$, $S_6$, $S_7$, $S_9$, $S_{13}$, $S_{15}$ in phase-1 and $S_0$, $S_2$, $S_6$, $S_8$, $S_9$, $S_{10}$, $S_{11}$, $S_{14}$, $S_{15}$ in phase-2 produces two faulty outputs associated with two paths. In most cases, except the one in which the faulty switching element is in the middle stage, the two paths have two switching elements in common, as the following theorem shows.

**Lemma 1:** For a switching element in stage j, $0\leq j<n-1$, there is another switching element in stage 2n-2-j, which takes the two outputs of the former as its inputs in either phase-1 test or phase-2 test.

**Proof:** Let i and $i^{\bar{0}}$ be the two output links of a switching element in stage j where $0\leq j<n-1$. In the phase-1 test, they go to $i_j...i_0i_{n-1}...i_{j+1}$ and $i_j...\bar{i}_0i_{n-1}i_{j+1}$ on the output side of the middle stage respectively after n-1-j shuffles. Now n-1-j unshuffles take them to i and $i^0$, which are the two inputs of a switching element,

0190-3918/86/0000/0737 $01.00 © 1986 IEEE

on the input side of stage 2n-2-j. In the phase-2 test, they go to $i_j \ldots i_0 \bar{i}_{n-1} \ldots \bar{i}_{j+1}$ and $i_j \ldots \bar{i}_0 \bar{i}_{n-1} \ldots \bar{i}_{j+1}$ on the output side of the middle stage respectively after n-1-j shuffles and exchanges. Now n-1-j unshuffles and exchanges take them to $i_{n-1} \ldots \bar{i}_{j+1} \ldots i_0$ and $i_{n-1} \ldots \bar{i}_{j+1} \ldots \bar{i}_0$ on the input side of stage 2n-2-j. Hence in either case, the lemma is true.□

**Theorem 2:** In either phase-1 test or phase-2 test, two paths can only meet on at most two switching elements.

**Proof:** If two paths meet on a switching element, whose indices of input/output links are i and $i^{\bar{0}}$, in the middle stage, then they do not meet in any other switching element. Because, in the phase-1 test, the two paths take on the links $i_{n-j-2} \ldots i_0 i_{n-1} \ldots i_{n-j-1}$ and $i_{n-j-2} \ldots \bar{i}_0 i_{n-1} \ldots i_{n-j-1}$ on the output side of the jth stage and on the input side of the (2n-2-j)th stage, where $0 \leq j < n-1$. It is clear that in every stage, except the middle one, the two $i_0$ bits are always different and they are never on the least significant bit. Hence they only meet in the middle stage. Similarly, the conclusion is proved for phase-2 test.

If they meet in a switching element in the first half of the network, then they also meet in the second half as proved in the last lemma. We claim that they do not meet anywhere else. Notice that, in the proof of the above lemma, the $i_0$ bits are always different and not on the least significant position between stages j and 2n-2-j, hence they do not meet there. Beyond stages j and 2n-2-j, the two paths do not meet either, because unshuffles only move the $i_0$ bits away from the least significant bit position. Due to the symmetry of the network, we have the same conclusion for the case that if the two paths meet in the second half.

Therefore, the two paths, if they ever meet, can meet only on at most two switching elements.□

*Example:* Figure 4 shows two faulty paths meeting in the first and the last stage in the phase-2 test.

Now we describe a procedure to differentiate the two possible faulty switching elements in the following theorem, if the two paths have two switching elements in common.

**Theorem 3:** The two switching elements common to the two faulty paths can be differentiated in two tests.

**Proof:** The two faulty paths clearly pass two switching elements in the middle stage. By the last theorem, they must be different. If the fault occurs in the phase-1 test, set the two switching elements in the middle stage to $S_5$ while leaving all others in $S_{10}$ and test the network with a and b. If the faulty switching element is in the second half of the network, the faulty outputs clearly will appear in the original faulty output teminals. If the faulty switching element, with output links i and $i^{\bar{0}}$, is in the first half, say in stage j, where $j \leq n-1$. The two output links go to $i_j \ldots i_0 i_{n-1} \ldots \bar{i}_{j+1}$ and $i_j \ldots \bar{i}_0 i_{n-1} \ldots \bar{i}_{j+1}$ on the output side of the middle stage and also on the output side of the network through the n unshuffles following the middle stage. However, in the original phase-1 test, the two faulty outputs are on $i_j \ldots i_0 i_{n-1} \ldots i_{j+1}$ and $i_j \ldots \bar{i}_0 i_{n-1} \ldots i_{j+1}$ which are clearly different from the two faulty outputs obtained from the above modified phase-1 test. Therefore, we only have to observe the positions of the faulty outputs in the modified test to determine which switching element is really at fault. If the fault is in the phase-2 test, we set the two switching elements in the middle stage to $S_{10}$ leaving all the rest in $S_5$ and test the network with a and b. A similar argument will give us the same conclusion.

Therefore, in any case, we need only two tests with either of the two modified control settings to locate the fault.□

*Example:* Figure 5 shows the two paths coming out from a switching element in the first stage when the settings of the two switching elements in the middle stage are complemented. Comparing to Figure 4, we see that the switching element in the first stage is the same, but the output terminals from the two paths are different.

**Theorem 4:** In category 2, the location and the functional state of a faulty switching element can be determined within ten tests.

**Proof:** Conduct the first four basic tests. Then find the common switching element(s) of the two faulty paths using the last theorem, if necessary, to obtain a single switching element. After the above six tests, the faulty switching element should have been located. If both the faulty outputs are binary vectors, the functional state is obvious from Table 1. If not, we have to conduct the test process discussed before to differentiate $\phi\phi$ from -- and after these extra tests, the functional state should be obvious. Notice that we may need two more tests for a fault in another test phase. Therefore, we need six tests to locate the fault and two more for each test phase to determine the functional state, which is a total of ten tests.□

Category 3 consists of the cartesian product of $\{S_2,S_3,S_8,S_{11},S_{12},S_{14}\}$ and $\{S_1,S_3,S_4,S_7,S_{12},S_{13}\}$. Every member in the first set produces one fault in phase-1 and every member in the second set produces one fault in phase-2. Again we calculate two faulty paths leading to two faulty outputs, but one from each phase. In order to locate the faulty switching element, we need the following theorem.

**Theorem 5:** The two faulty paths can have at most one link and two switching elements in common in category 3.

**Proof:** Consider a faulty switching element in category 3. It is clear that if it produces one fault in the phase-1 test and the other in the phase-2 test but both on one of its output links, then the switching element, having this faulty link as one of its inputs, in the next stage, if any, is also on both faulty paths. If the faulty switching element produces faults on different output links in different phases, the two faulty paths must join together on one of its input links. Therefore, the switching element, having this link as one of its outputs, in the previous stage, if any, is also on both faulty paths. Accordingly, two faulty paths pass at least one common link and may go through one, two or more common switching elements. Depending on the position of the link, we can prove, in each case, at most one common link and hence two common switching elements may appear as follows:

(1)The link is in the first shuffle, say at the position i of the input side of 0th stage. It goes to i in the phase-1 test and to $i^{\bar{0}}$ in the phase-2 test. Then n-1 shuffles (left circular shifts) and switching stages take them to $i_0 i_{n-1} \ldots i_1$ and $\bar{i}_0 \bar{i}_{n-1} \ldots \bar{i}_1$ respectively on the output side of stage n-1 while for a stage j between 0 and n-1, the two indices should be $i_{n-j-1} \ldots i_0 i_{n-1} \ldots i_{n-j}$ and $i_{n-j-1} \ldots \bar{i}_0 \bar{i}_{n-1} \ldots \bar{i}_{n-j}$ respectively on the output side of that stage. We can see that the two paths do not intersect in the first half of the network after the first shuffle, because the $i_0$ bits are always different. Continuing traversing in the second half, we have n-1 unshuffles and switching stages which take the two paths to $i_{k-n+1} \ldots i_0 i_{n-1} \ldots i_{k-n+2}$ and $i_{k-n+1} \ldots \bar{i}_1 \bar{i}_0 \bar{i}_{n-1} \ldots \bar{i}_{k-n+2}$ respectively at the output side of stage k, where $n-1 < k < 2n-2$, and to $i_{n-1} i_{n-2} \ldots i_0$ and $i_{n-1} \ldots \bar{i}_1 i_0$ respectively on the output side of stage 2n-2. Then followed by the last unshuffle, they go to $i_0 i_{n-1} \ldots i_1$ and $i_0 i_{n-1} \ldots \bar{i}_1$ respectively. In any stage, the $i_1$ bits are always different. Therefore, the two paths can join only at one link.

(2)The link is in the last unshuffle. Since an $\Omega^r\Omega^{-1}$ network is symmetrical with respect to the middle stage, we obtain another $\Omega^r\Omega^{-1}$ network if we view the former in the reversed direction, that is interchanging the roles inputs and outputs. Therefore, this case is the same as (1), if considered in reversed direction. Consequently, the claim is also true in this case.

(3)The link is in the first half of the network but not in the first shuffle, say at input position i of the jth stage where $0 < j < n$. The two paths coming out from the jth stage are on i and $i^{\bar{0}}$ respectively. Shuffles and switching stages take them to $i_{n-k+j-1} \ldots i_0 i_{n-1} \ldots i_{n-k+j}$ and $i_{n-k+j-1} \ldots \bar{i}_0 \bar{i}_{n-1} \ldots \bar{i}_{n-k+j}$ on the output side of stage k, $j \leq k < n$. They differ from each other at least on the $i_0$ bit. Now unshuffles and switching stages route them to different positions in each stage of the second half, since the $i_{n-k+j}$ bits of the two paths are always different from each other. Hence the two paths do not join on the right side of the faulty link. For the left side, i goes to output position $i_0i_{n-1}...i_1$ of the (j-1)th stage, on the input side of the same stage, the two paths take on positions $i_0i_{n-1}...i_1$ and $i_0i_{n-1}...\bar{i}_1$ respectively. Then we have j-1 shuffles and j-2 switching stages. The two paths do not join in this part either, because the $i_1$ bits are different from each other. Therefore, the two paths coincide only on the faulty link.

(4)The link is in the second half of the network but not in the last unshuffle. Due to the symmetry of $\Omega^r\Omega^{-1}$ networks, this case viewed reversely is the same as (3). Hence the claim is also true here.□

*Example:* Figure 6 shows two faulty paths in category 3. As we can see, there are two switching elements and one link in common.

Excluding the one switching element case, we are guaranteed to locate two possible faulty switching elements by the above theorem. This category can further be divided into six cases defined in Table 5 and Table 6 as in [3]. Case F and link stuck fault are not distinguishable as suggested in the proof of the above theorem. Processes similar to those in [3] are used to derive the following result: the location and functional state of a faulty switching element can be determined within eight tests for case A, ten for cases B and C and twelve for cases D and E.

## 4. An Alternative Procedure

If we allow more bits for test vectors, some speedup may be achieved. Instead having the previous a nd b, we shall use n+1 bits for each input/output. Numbers between 0 and 2N-1 are used when their binary representations (n+1 bits) being mentioned for the purpose of convenience. Let $e=(e_0,e_1,...,e_{N-1})$, where $e_i=i+1$ for $0\leq i<N$, be our test vector, that is $e_i$ will be fed into input terminal i in a test. Similarly we have two phases, again, called phase-1 test and phase-2 test. In phase-1, all switching elements are set to $S_{10}$ except those, in the middle stage, whose $(\oplus i)$'s of the indicies of their upper input/output links are equal to 1, being set to $S_5$. In phase-2, the settings are all complements to those of phase-1. In other words, all switching elements are set to $S_5$ except those, in the middle stage, with $(\oplus i)$'s of the indices of their upper input/output links equal to 1, being set to $S_{10}$. Figure 7 and Figure 8 show the normal inputs and outputs in each phase of test when N=8. In either phase, the test vector is e. Outputs can easily be calculated as follows. Let $\ominus i=i_{n-1}\oplus i_{n-2}\oplus...\oplus i_1$, i.e. the exclusive-or of all bits except the 0th bit. In phase-1, the input terminal i goes to link i on the input side of the middle stage. If $\ominus i=0$, it goes to i on the output side and goes also to the output terminal i. If $\ominus i=1$, then it goes to $i^{\bar{0}}$ on the output side and goes to the output terminal $i^{\bar{0}}$. Therefore, on the output terminal side, position i has $e_i=i+1$, the number at input i, if $\ominus i=0$ and has $e_{(i^{\bar{0}})}=i^{\bar{0}}+1$, the number at the neighbor of input i, if $\ominus i=1$. However, in phase-2, it is more complicated. Input terminal i goes to $(\bar{i}_{n-1}...\bar{i}_1i_0)=\bar{i}^0$ (this means that every bit is complemented except the 0th bit) on the input side of the middle stage. The value of $\ominus\bar{i}^0$ depends on n and $\ominus i$. We have four cases: (1) n even and $\ominus i=0$, then $\ominus\bar{i}^0=1$. (2) n even and $\ominus i=1$, then $\ominus\bar{i}^0=0$. (3) n odd and $\ominus i=0$, then $\ominus\bar{i}^0=0$. (4) n odd and $\ominus i=1$, then $\ominus\bar{i}^0=1$. Hence, on the output side of the middle stage, i goes to $\bar{i}^0$ in cases (1) and (4) and to $\bar{i}$ in cases (2) and (3). Finally on the output terminal side, i goes to i in cases (1) and (4) and to $i^{\bar{0}}$ in cases (2) and (3). Therefore, output terminal i has $e_i=i+1$ in cases (1) and (4) and has $e_{(i^{\bar{0}})}=i^{\bar{0}}+1$ in cases (2) and (3). Thus both the control settings and the outputs of the network in each phase can be calculated efficiently.

It is obvious that each switching element in the tests receives two different numbers as inputs under normal conditions. Any switching element fault or link stuck fault will show eventually at the output side of the network. Therefore, in this procedure, we need only to perform two basic tests, phase-1 with e and phase-2 with e, in order to detect any single fault. However, we should bear in mind that there is a factor n+1 left out in this count. Some notations are modified, for example, $\phi\phi$ is replaced by a number between 0 and 2N-1, -- by -, 00 by 0 and 11 by 2N-1. A basic theorem without proof is given below.

**Theorem 6:** Two paths (in either phase) have at most one switching element in common.

*Example:* Figure 9 shows two paths in the phase-1 test of the procedure. As we can see, they meet at exactly one switching element.

Based on the above theorem, similar diagnostic procedure can be developed. In many cases, the latter is faster due to more information from more bits and special settings for switching elements.

## 5. Conclusion

A fault diagnostic procedure for rearrangeable $\Omega^r\Omega^{-1}$ netwroks has been presented. The number of tests in most cases is a constant, which makes this procedure very efficient compared to the one in [2]. Faster procedures are expected if more information is used to conduct tests. However, the number of tests may very with the size of the network. Therefore, a mix of the above may achieve better efficiency.

# IMPACT OF CLUSTER NETWORK FAILURE ON THE PERFORMANCE OF CLUSTER-BASED SUPERSYSTEMS

Imad E. O. Mahgoub and Dharma P. Agrawal

North Carolina State University
Raleigh, NC 27695

## Abstract

This paper investigates the effect of Cluster Interconnection Network (CINs) failure on the performance of a Cluster-based Supersystem [1]. Three different cases of memory request distribution have been treated. The first case assumes uniform distribution while the second employs the concept of favorite memory. Further generalization of the second case is made in the third case by adding a private memory and associating one with each processor. System performance degradation due to the failure of a single Cluster IN and due to the failure of multiple Cluster INs has been evaluated analytically in terms of available Bandwidth.

## I Introduction

It is a well known fact that the switching speed of logic has almost attained its physical limit and only incremental speed improvement can be expected in future. Multiprocessor/Multicomputer based supersystems [2-8] offer a great potential for substantial performance enha9 offer a great potential for substantial is how to design an appropriate Interconnection Network to cater to communication between various functional modules in the system [10]. Several interconnection schemes have been proposed [11] and there are relative advantages and disadvantages of each one of them. A single shared bus scheme is the simplest and economical while cross-bar switches represent another end of the spectrum. The bus scheme suffers from the contention problem while the complexity and the cost of a crossbar is proportional to its total number of cross-points. As a compromise between the two, several multistage networks [10-12] and multibus systems [13-14] have been proposed which could provide a reasonable performance at an acceptable cost.

In [1] we described and analyzed Cluster-based Supersystems which have a hierarchy that reduces the network complexity. Conflict-free access within each cluster is secured by relatively smaller crossbar switches. To maintain the hierarchy and the regularity of the structure, clusters are connected by a network similar to the one used for interconnecting processors within each cluster. These systems take full advantage of program locality and they have been shown to perform very close to the crossbar-based systems for higher rate of favorite requests. However, the analysis carried out in [1] assumed that the system operates in a fault-free mode which may not be realistic . In reallity, cluster-based supersystems are prone to faults that could at least degrade their performance.

In this paper we have dealt with the situation where one or more cluster INs could fail. Basic assumptions and other essential background material is included in section II. Performance degradation due to the loss of one cluster IN has been calculated in section III. In section IV, the performance degradation is determined in the event of total loss of all cluster INs. Concluding remarks have been included in section V.

## II Background

In the analysis of the cluster-based supersystems [1], we assume the following model to exist:

(i) The multiprocessor system is synchronous with N processors and N memory modules , in which the processors issue their requests at the beginning of a memory cycle.

(ii) Memory cycle time is the same as the processor cycle time and is constant.

(iii) The requests generated in a cycle are random and are independent of one another.

(iv) The requests issued in successive cycles are independent of the requests issued in the previous cycle.

(v) The requests which are not accepted are discarded.

(vi) Propagation delay of the interconnection network is neglected.

(vii) $\psi$ is the probability with which a processor generates a request in a cycle.

The fourth assumption is unrealistic because a discarded request will indeed be resubmitted in the next cycle. However, this assumption simplifies the analysis and produces negligible discrepancies from the actual results [17].

It is also assumed that $N = n.k$ [1]. This enables us to have k - clusters with each cluster consisting of n - processors. Crossbar switches of size n x n are used for each cluster ( cluster IN ) while a kxk global crossbar switch is used to interconnect all k - clusters together (Fig.2). All the processors forming an individual cluster , have to pass through an associated single bus to gain access to the global IN.

The system's performance is analyzed on the basis of the analysis of crossbar [15,14] and shared-bus schemes , both of which have been included here just for the completeness of the text.

### Analysis of a crossbar

Consider an NxN crossbar , and let $p_c$ be the probability that a request is delivered to an input of the crossbar. The probability that this request is directed to a particular output of the N outputs is $p_c$/N. The probability that this particular output is not requested by any of the N inputs is $(1 - p_{c/N})^N$. The probability that this particular output is requested by at least one input

$$= 1 - (1 - p_{c/N})^N \tag{1}$$

This is the well known formula for the crossbar [15].

### Shared bus analysis

We adopt the model for the shared bus Introduced in [16] which views the shared bus as a cascade of an Nx1 crossbar and a 1xN crossbar. Let $p_0$ be the probability that the bus is requested by a processor out of the N processors tied to the bus , then the probability that none of the N processors request the bus is $(1 - p_0)^N$. The probability at least one processor will request the bus is $1 - (1 - p_0)^N$.

Hence the rate of request at the bus

$$= 1 - (1 - p_0)^N \tag{2}$$

Rate of request at a particular output line out of the N output lines tied to the bus

$$= (1 - (1 - p_0)^N)/N \tag{3}$$

It may be noted that if there is only one output line tied to the bus then eq.(3) reduces to eq.(2).

### Fault-free crossbar-based and cluster-based Multiprocessors

The fault-free analysis of the crossbar-based and the cluster-based multiprocessors has been carried out in [1] for three different cases (based on the distribution of requests among the memory modules) namely: Equally likely , favorite memories , and favorite with private memories. To avoid the duplication, analysis for the fault-free system will not be included here. Some data is presented in the form of Tables (Tables I, II, III) and graphs (Figs. 5, 6, 7) so that a comparison between performance of the fault-free and the faulty systems could be done.

It may be noted that minor modifications in analysis given in [1] is needed to allow for the restriction imposed in this paper, namely, a processor is internally connected only to its private memory. This change is deemed necessary for a fair comparison between the fault-free and faulty cases.

### Faulty cluster-based multiprocessors

The analysis performed here, deals only with the failure of the cluster interconnection networks. There are k nxn CINs while there is only one kxk global IN and the global network is most important from the point of view of keeping all the clusters connected together. Hence, it is desirable to have a reliable global IN by designing it with appropriate care, or alternatively to duplicate the global IN and keep the second global IN as a standby spare. For our analysis, the global IN is assumed to be fault-tolerant and failures are assumed to occur only in the CINs.

In the event of failure of a cluster IN requests from the processors to the memory modules in that cluster are directed through the global IN. Although the system is still operational , its performance will be degraded. This degradation will be the least when a single cluster IN fails , and the most when the cluster INs in all the clusters fail. Bearing in mind that the performance of the system for any number of failed cluster INs will lie between these two limits , we are only going to concern ourselves with the analysis of these two extreme cases.

## III Failure of a single cluster IN

Failure of a single cluster IN results in a situation where two groups of memory modules are formed and each group has a different rate of request (Fig.3). The first group consists of those memory modules which are part of the cluster with failed IN , while the remaining memory modules residing in the remaining healthy clusters form the second group.

Let

$p_{ext} \overset{\Delta}{=}$ the probability that a processor issues a request to a memory module external to its own cluster.

$p_G \overset{\Delta}{=}$ the rate at which an input of the global IN is requested.

$p_C \overset{\Delta}{=}$ the rate at which an input of the cluster IN is requested.

$p_{fi} \overset{\Delta}{=}$ the rate of request at a memory module due to requests from favorite processors directed through the cluster IN.

$p_{fo} \overset{\Delta}{=}$ the rate of request at a memory module due to requests from favorite processors directed through the global IN (in the event of failure of the cluster IN).

$p_{nf} \overset{\Delta}{=}$ the rate of requests at a memory module due to requests from nonfavorite processors through the global IN.

### 3.1 Equally likely case

This is the case where the requests generated by a processor are uniformly distributed among the memory modules.

(a) First group analysis ( group1 )

Let $p_{ext1}$ be the probability that a request generated by a processor of group1 will be directed through the global IN, hence

$$p_{ext1} = \psi \tag{4}$$

( since no requests can be made through the cluster IN )

Let $p_{G1}$ be the rate at which the input of the global IN (accessible by processors of group1) is requested, hence

$$p_{G1} = 1 - (1 - p_{ext1})^n \tag{5}$$

Let $p_1^{(1)}$ be the rate of request at a memory module of group1 due to requests issued by processors in group1.

$$p_1^{(1)} = p_{G1/N} \tag{6}$$

Let $p_2^{(1)}$ be the rate of request at a memory module of group1 due to requests issued by processors in the second group.

$$p_2^{(1)} = [1 - (1 - \frac{p_{G2}}{k-1})^{k\ \ 1}]/n \tag{7}$$

Hence the total rate of request at a memory module of group1

$$\equiv p_1 = p_1^{(1)} + p_2^{(1)} - p_1^{(1)} p_2^{(1)} \tag{8}$$

(b) Second group analysis ( group2 )

Let $p_{ext2}$ be the probability that a processor of group2 will issue a request to a memory module external to its own cluster, hence

$$p_{ext2} = (k - 1)\psi/k \tag{9}$$

Let $p_{G2}$ be the rate at which an input of the global IN (accessible by processors of group2) is requested, hence

$$p_{G2} = 1 - (1 - p_{ext2})^{n} \tag{10}$$

Let $p_2^{(2)}$ be The rate of request at a memory module of group2 due to requests issued by the processors of group2 but not belonging to the same cluster.

$$p_2^{(2)} = [1 - (1 - \frac{p_{G2}}{k-1})^{k\quad 2}]/n \tag{11}$$

Let $p_1^{(2)}$ be The rate of request at a memory module of group2 due to requests issued by processors of group1.

$$p_1^{(2)} = p_{G1}/N \tag{12}$$

$$p_C = \psi/k \tag{13}$$

Let $p_{i2}^{(2)}$ be The rate of request at a memory module of group2 due to requests issued by processors of group2 and in the same cluster.

$$p_{i2}^{(2)} = 1 - (1 - p_C/n)^{n} \tag{14}$$

Hence the total rate of request at a memory module of group2

$$\equiv p_2 = p_{i2}^{(2)} + p_1^{(2)} + p_2^{(2)} - p_{i2}^{(2)}p_1^{(2)} - p_{i2}^{(2)}p_2^{(2)}$$
$$- p_1^{(2)}p_2^{(2)} + p_{i2}^{(2)}p_1^{(2)}p_2^{(2)} \tag{15}$$

The Bandwidth

$$\equiv BW = p_1.n + p_2.(N - n) \tag{16}$$

Table IV gives the degraded performance of the cluster-based multicomputer system for the equally likely case.

### 3.2 Favorite memories case

In this case processors (favorite) communicate more often with memory modules (favorite) in the same cluster as the processors. Let s be the probability that a processor addresses a particular favorite memory given that it has generated a request.

(a) First group analysis

$$p_{ext1} = \psi \tag{17}$$

$$p_{G1} = 1 - (1 - p_{ext1})^{n} \tag{18}$$

$$p_{fo} = sp_{G1} \tag{19}$$

Let $p_{nf2}^{(1)}$ be The rate of request at a memory module of group1 due to requests issued by nonfavorite processors.

$$p_{nf2}^{(1)} = [1 - (1 - \frac{p_{G2}}{k-1})^{k\quad 1}]/n \tag{20}$$

Hence the rate of request at a memory module of group1

$$\equiv p_1 = p_{fo} + p_{nf2}^{(1)} - p_{fo}p_{nf2}^{(1)} \tag{21}$$

(b) Second group analysis

$$p_{ext2} = (1 - ns)\psi \tag{22}$$

$$p_{G2} = 1 - (1 - p_{ext2})^{n} \tag{23}$$

Let $p_{nf2}^{(2)}$ be the Rate of request at a memory module of group2 due to requests issued by the non favorite processors in group2.

$$p_{nf2}^{(2)} = [1 - (1 - \frac{p_{G2}}{k-1})^{k\quad 2}]/n \tag{24}$$

Let $p_{nf1}^{(2)}$ be the Rate of request at a memory module of group2 due to requests issued by the nonfavorite processors in group1.

$$p_{nf1}^{(2)} = [(1 - ns)\frac{p_{G1}}{k-1}]/n \tag{25}$$

$$p_C = ns\psi \tag{26}$$

$$p_{fi} = 1 - (1 - p_C/n)^{n} \tag{27}$$

Hence the total rate of request at a memory module of group2

$$\equiv p_2 = p_{fi} + p_{nf2}^{(2)} + p_{nf1}^{(2)} - p_{fi}p_{nf2}^{(2)} - p_{fi}p_{nf1}^{(2)}$$
$$- p_{nf1}^{(2)}p_{nf2}^{(2)} + p_{fi}p_{nf2}^{(2)}p_{nf1}^{(2)} \tag{28}$$

$$BW = p_1.n + p_2.(N - n) \tag{29}$$

The results for this case are given in Table V.

### 3.3 Favorite with private memories case

A private memory is added to each processor and each processor accesses its private memory through an internal bus connection.

Let m be the probability that a processor requests its private memory given that it has generated a request.

(a) First group analysis

$$p_{ext1} = (1 - m)\psi \tag{30}$$

$$p_{G1} = 1 - (1 - p_{ext1})^{n} \tag{31}$$

$$p_{fo} = sp_{G1} \tag{32}$$

The rate of request at a memory module of group1 due to requests issued by nonfavorite processors

$$\equiv p_{nf2}^{(1)} = [1 - (1 - \frac{p_{G2}}{k-1})^{k\quad 1}]/n \tag{33}$$

Hence the total rate of request at a memory module of group1

$$\equiv p_1 = p_{fo} + p_{nf2}^{(1)} - p_{fo}p_{nf2}^{(1)} \tag{34}$$

(b) Second group analysis

$$p_{ext2} = (1 - ns - m)\psi \tag{35}$$

$$p_{G2} = 1 - (1 - p_{ext2})^{n} \tag{36}$$

The rate of request at a memory module of group2 due to requests issued by the non favorite processors in group2

$$\equiv p^{(2)}_{nf2} = [1 - (1 - \frac{p_{G2}}{k-1})^{k\ \ 2}]/n \tag{37}$$

The Rate of request at a memory module of group2 due to requests issued by the nonfavorite processors in group1

$$\equiv p^{(2)}_{nf1} = [(1 - ns)\frac{p_{G1}}{k-1}]/n \tag{38}$$

$$p_C = ns\psi \tag{39}$$

$$p_{fi} = 1 - (1 - p_C/n)^n \tag{40}$$

Hence the total rate of request at a memory module of group2

$$\equiv p_2 = p_{fi} + p^{(2)}_{nf2} + p^{(2)}_{nf1} - p_{fi}p^{(2)}_{nf2} - p_{fi}p^{(2)}_{nf1} - p^{(2)}_{nf1}p^{(2)}_{nf2} + p_{fi}p^{(2)}_{nf2}p^{(2)}_{nf1} \tag{41}$$

$$BW = p_1.n + p_2.(N - n) \tag{42}$$

Table VI indicates the performance degradation for this case.

## IV Failure of the INs in all the clusters

In this situation, all requests generated by processors will be delivered to memory modules through the global IN (Fig.4).

Hence,

$$p_{ext} = \psi \tag{43}$$

$$p_G = 1 - (1 - p_{ext})^n \tag{44}$$

### 4.1 Equally likely case

The total rate of request at a memory module

$$\equiv p = [1 - (1 - p_G/k)^k]/n \tag{45}$$

$$BW = pN. \tag{46}$$

Results for this case are given in Table VII.

### 4.2 Favorite memories case

$$p_{fo} = p_G s \tag{47}$$

$$p_{nf} = [1 - (1 - (1 - sn)\frac{p_G}{k-1})^{k\ \ 1}]/n \tag{48}$$

The total rate of request

$$\equiv p = p_{fo} + p_{nf} - p_{fo}p_{nf} \tag{49}$$

$$BW = pN. \tag{50}$$

Table VIII indicates the degradation of performance for this case.

### 4.3 Favorite with private memories case

Again, with the exception of requests to the private memories, all requests are delivered through the global IN.

$$p_{ext} = (1 - m)\psi \tag{51}$$

$$p_G = 1 - (1 - p_{ext})^n \tag{52}$$

$$p_{fo} = p_G s \tag{53}$$

$$p_{nf} = (1 - (1 - (1 - sn)\frac{p_G}{k-1})^{k\ \ 1})/n \tag{54}$$

The total rate of request

$$\equiv p = p_{fo} + p_{nf} - p_{fo}p_{nf} \tag{55}$$

$$BW = pN. \tag{57}$$

The degraded performance for this case is given in Table IX.

## V Conclusions

Performance degradation of cluster-based supersystems due to failure of cluster INS has been analytically determined. Two limiting situations of only one cluster IN failure and all the cluster INs failures have been considered. The analysis has been carried out for three different cases : Equally likely, Favorite memories, and Favorite with Private memories. It has been concluded that the Favorite memories scheme is still superior over the other two schemes (Figs. 5, 6, 7), in spite of steep performance degradation - for the same values of the system parameters.

# RESOURCE SHARING INTERCONNECTION NETWORKS IN MULTIPROCESSORS

*Jie-Yong Juang and Benjamin W. Wah*[*]

## ABSTRACT

In this paper circuit-switched interconnection networks for resource sharing in multiprocessors, named *resource sharing interconnection networks*, are studied. Resource scheduling in systems with such an interconnection network entails the efficient search of a mapping from requesting processors to free resources such that circuit blockages in the network are minimized and resources are maximally used. The optimal mapping is obtained by transforming the scheduling problems into various network-flow problems for which existing algorithms can be applied. A distributed architecture to realize a maximum-flow algorithm using token propagations is also described. The proposed method is applicable to any general network configuration modeled as a digraph in which the requesting processors and free resources can be partitioned into two disjoint subsets.

## 1. INTRODUCTION

In this paper we investigate the problem on the sharing of computing resources in multiprocessors and the distributed scheduling of shared resources in a circuit-switched interconnection network.

A *resource* is a processing element to carry out a designated function. Examples include a general purpose processor, a special functional unit, a VLSI systolic array, an input/output device, and a communication channel. A resource is accessible by any processor via an interconnection network. A *request* generated by a processor can be directed to any one of a pool of free resources that are capable of executing the designated task. An interconnection network is an essential element of these systems as it interconnects processors and resources. Its function is to route requests initiated from one point to another point connected on the network. The network topology is dynamic, and the links can be reconfigured by setting the network's active switching elements. The notable characteristic of these networks is that they operate with address mapping. That is, a request is initiated with a specific destination or a set of destinations, and routing is done by examining the address bits. Routing of requests is usually done in parallel. As classified by Feng [8], these networks include the single or multistage networks and the crossbar switch. Examples are the banyan, indirect binary n-cube, cube, perfect shuffle, flip, Omega, data manipulator, augmented data manipulator, delta, baseline, Benes, and Clos. Examples of systems designed with interconnection networks are Trac, Staran, C.mmp, Illiac IV, Pluribus, Numerical Aerodynamic Simulation Facility (NASF), the Ballistic Missile Defense testbed, MPP, and Connection Machine. The performance of resource sharing systems under address mapping has been studied by Rathi, Tripathi and Lipovski [21], Fung and Torng [10], and Marsan, et al [17].

Wah proposed a network with distributed scheduling intelligence, called *resource sharing interconnection network* (*RSIN*) [23, 22]. Instead of using an address-mapping scheme, which requires a centralized scheduler to seek and give the address of a free resource to a request before it enters the network, the request is sent into the network without any destination tags. It is the responsibility of the network to route the maximum number of requests to the free resources. In this way the scheduling intelligence is distributed in the network. Distributed resource scheduling avoids the bottleneck of a centralized scheduler [21]. The objective of a good scheduling scheme is to avoid network blockages and to maximize resource utilization, which requires an efficient algorithm at each switching node to collect the minimum amount of status information.

The PUMPS architecture (see Figure 1) for image analysis and pictorial database management [3] is a typical example of resource sharing multiprocessors in which VLSI systolic arrays, each realizing an image processing function, are organized into a pool of resources. Most dataflow architectures can also be considered as resource sharing systems. The processing units are the pool of resources, and a RSIN connects them to memory cells. In a resource sharing system with load balancing, processors are considered as resources, thus requests generated are queued at the processors as well as the resources. An imbalance of workload at the processors will be balanced by a load balancing scheme.

The design of a RSIN with optimal resource scheduling is studied in this paper. The results are derived with respect to multistage interconnection networks, called *multistage resource sharing interconnection networks* (*MRSIN*), and are applicable to any general network configuration modeled as a digraph in which the requesting processors and free resources are partitioned into two disjoint subsets. interconnection network is the development of an efficient distributed algorithm to disseminate status information through the complex interconnection structure. The algorithm to be presented is simple, efficient, and independent of the interconnection topology.

## 2. RESOURCE SHARING INTERCONNECTION NETWORKS

The assumptions of the RSIN used in this study are summaried as follows.

(a) Circuit switching is assumed rather than packet switching for the following reasons. First, packet switching is used in conventional networks with address mapping because it allows a network path to be shared by more than one request concurrently. Reducing the packet delay by balancing loads among alternate paths is less critical in a RSIN because a request can always search for another available resource if a path is blocked. Moreover, the overhead of rerouting a packet is higher than that of rerouting a resource request [16]. Second, owing to the resource characteristics, a task cannot be processed until it is completely received. The extra delay in breaking a task into multiple packets may decrease the utilization of resources, and hence increase the response time of the system.

(b) One or more types of resources may exist in the system. A RSIN connecting only one type of resources is called a *homogeneous* RSIN, while a RSIN connecting multiple types of resources is a *heterogeneous* one.

(c) A priority level may be associated with a request to show the urgency of the request. A preference value may be associated with a resource to show the desirability of being used for service. The costs of allocation are inversely related to the priorities and preferences.

(d) Each request needs one resource only.

(e) A processor can transmit one task at a time to the resources. Other tasks arriving during the task transmission time are queued. The circuit between a processor and a resource can be released once the request has been transmitted. The processor can continue to make other requests, while the resource will be busy until the task is completed.

We have not investigated the problem on the selection of the number of resources in each type and their placements in the output ports. This problem has been studied by Briggs et al., who have considered the problem of choosing the number of resources in each type in which one resource is connected to each output port and one resource is requested each time [2]. We have not considered the case in which more than one resource or multiple types of resources are requested by one request. Here, the scheduling algorithm is dependent on the number of resources in each type, the way that resources are distributed to the output ports, and the network characteristics. Further, deadlocks may occur, and distributed resolution of deadlock may have a high overhead.

The goal of the scheduling algorithm is to find a request-resource mapping such that the total cost is minimized. In the special case in which all requests are of equal priorities and all resources have equal preferences, the scheduling problem becomes the mapping of the maximum number of requests to the free resources.

The maximal request-resource mapping may be hampered by blockages in the system. In a conventional address-mapped interconnection network, blockages may be caused by conflicts in either the same resource being requested by more than one request or a network link requested by two circuits. In a RSIN, a resource conflict can be resolved by rerouting all but one request to other free resources. However, this may not always lead to better resource utilization because the allocation of one request to a resource may block one or more other requests from accessing free resources. A scheduling algorithm that schedules requests according to the state of the network and resources is, therefore, essential. As an example, consider an 8-by-8 Omega network** in Figure 2a with switch-boxes that can be individually set to either a straight or an exchange connection. Processors $p_1$, $p_3$, $p_5$, $p_7$ and $p_8$ are requesting one resource each, and resources $r_1$, $r_3$, $r_5$, $r_7$ and $r_8$ are available. The circuits between $p_2$ and $r_6$ and $p_4$ and $r_4$ have been established previously. $p_6$ is not making request, and $r_2$ is busy. All free resources will be allocated if one of the following request-resource mappings is used: $\{(p_1, r_3), (p_3, r_5), (p_5, r_7), (p_7, r_1), (p_8, r_8)\}$ or $\{(p_1, r_3), (p_3, r_8), (p_5, r_7), (p_7, r_1), (p_8, r_5)\}$. But if the mapping $\{(p_1, r_1), (p_3, r_5), (p_5, r_3), (p_7, r_7), (p_8, r_8)\}$ is used, a maximum of four out of five resources can be allocated, since the path from $p_8$ to $r_8$ is blocked. Simulation results showed that the average blocking probability can be as low as 2% for a MRSIN embedded in an 8-by-8 cube network [22, 12]. If a heuristic routing algorithm is used, the average blocking probability increases to 20%. Further degradation occurs if the network is not completely free.

## 3. OPTIMAL RESOURCE SCHEDULING IN MRSIN

To bind a request to a resource in the system, a RSIN determines a mapping from pending requests to free resources, and provides connections to as many request-resource pairs as possible. In this section, methods to optimize request-resource mappings are discussed. Exhaustive methods that examine all possible ordered mappings have exponential complexity. In a homogeneous MRSIN, suppose x processors are making requests, y

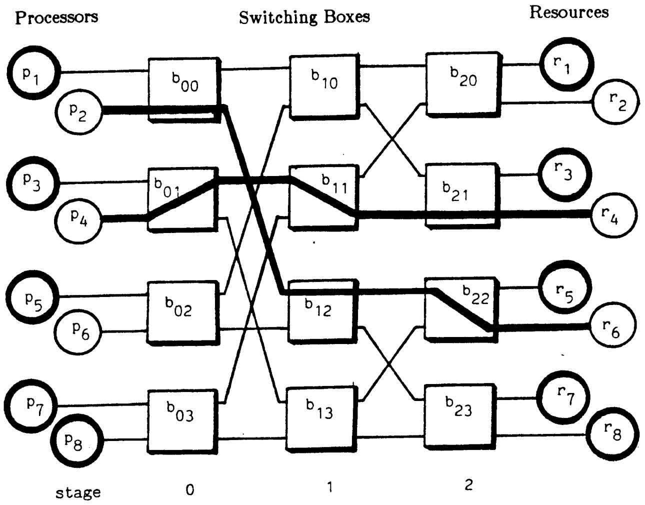

Figure 2a. A MRSIN embedded in an 8-by-8 Omega network (dark paths in the network show circuits that are already occupied; processors $p_1$, $p_3$, $p_5$, $p_7$ and $p_8$ are making requests; resources $r_1$, $r_3$, $r_5$, $r_7$ and $r_8$ are available).

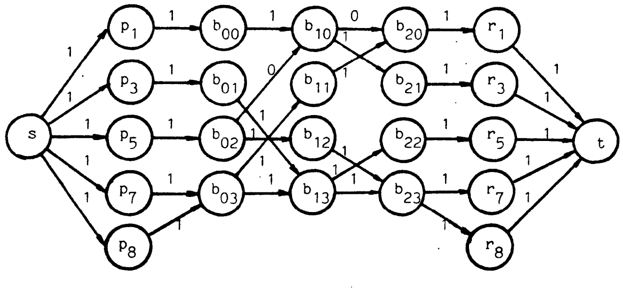

Figure 2b. The flow network transformed from the MRSIN in Figure 2a using Transformation 1 (the number associated with each arc is the amount of flow assigned to it by the maximum-flow algorithm; all arcs have unit capacity).

resources are available, and the network is completely free. The scheduler has to try a maximum of $C_y^x \bullet y!$ (for $x \geqslant y$) or $C_x^y \bullet x!$ (for $y \geqslant x$) mappings to find the best one, where $C_i^j$ is the number of combinations of choosing i objects out of j objects [22, 12]. Suboptimal heuristics can be used but is only practical when x and y are small.

In this section we transform the optimal request-resource mapping problem into various network-flow problems for which many efficient algorithms exists [11, 13]. The basic concepts of flow networks are briefly reviewed first.

### 3.1. Flow Networks

A flow network is usually represented by a digraph in which each arc is associated with a capacity and possibly a cost. Let $D = (V, E)$ be a digraph with two distinct nodes s (*source*) and t (*sink*). A capacity function, c(e), is defined on every arc of the graph, where c(e) is a non-negative real number for all $e \in E$. A flow function $f$ assigns a real number $f(e)$ to arc e such that the following conditions hold.

(1) *Capacity limitation*:

$$0 \leqslant f(e) \leqslant c(e) \quad \text{for every arc } e \in E \tag{1}$$

(2) *Flow conservation*: Let $\alpha(v)$ (resp. $\beta(v)$) be the set of incoming (resp. outgoing) arcs of vertex v. For every $v \in V$,

$$\sum_{e \in \alpha(v)} f(e) - \sum_{e \in \beta(v)} f(e) = \begin{cases} -F & v = s \\ F & v = t \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

The capacity constraint restricts the amount of flow that can be assigned to a link, and flow conservation implies that an intermediate node in the network does not absorb or create flows.

A *legal flow* is a flow assignment that satisfies the capacity and flow-conservation constraints. In a network flow problem, it is necessary to find the legal flow that optimizes a given objective function. For example, in the maximum-flow problem, it is necessary to find the maximum amount of flow that can be advanced from source to sink in a flow network $G(V, E, s, t, c)$ under the capacity and flow-conservation constraints. The problem can be formulated as a linear program.

*Maximum-Flow Problem*

Maximize F
subject to:
(1) Flow conservation (Eq. (1));
(2) Capacity limitation (Eq. (2)).

Many other examples of network flow problems, including the minimum-cost flow and the trans-shipment problems, can be found in the literature [11].

An *s-t path* is a directed path from s to t. Insertion of a dummy node in a path will increase the path length but will not affect the flow assignment. Increasing the length of s-t paths in this way such that all s-t paths are of equal length is called *s-t path equalization* in this paper. All s-t paths are assumed to be equalized when the network is loop-free.

### 3.2. Optimal Resource Mapping in Homogeneous MRSIN

A switch-box in a MRSIN is a crossbar switch without broadcast connections. The following theorem shows that the setting of a non-broadcasting switch is equivalent to a legal integral flow assignment in a flow network of unit capacity. Note that an integral flow is a flow assignment in which the amount of flow assigned to each link is of integral value.

**Theorem 1*****: For any MRSIN, there exists a flow network for which a legal integral flow is equivalent to a valid request-resource mapping.

To use existing algorithms to solve a flow problem, a MRSIN has to be transformed into a flow network such that the optimization of request-resource mappings is equivalent to the optimization of the corresponding objective function in the flow network. To this end, additional nodes may be introduced, the capacity of a link may be greater than one, and a cost may be associated with a link.

The following transformation produces a flow network such that the optimal request-resource mapping can be derived from its maximum flow.

**Transformation 1**: Generate a flow network $G(V, E, s, t, c)$ from a homogeneous MRSIN.

(T1) Create three node-sets **P**, **X** and **R** for processors, switch-boxes and resources, respectively. Introduce two additional nodes: source s and sink t. Let

$$V' = \{s, t\} \cup P \cup X \cup R$$

(T2) Add an arc from the source to every node associated with a processor. Denote this set of arcs by **S**.

$$S = \{ (s,v) \mid v \in P \}$$

Add an arc between every node associated with a resource and the sink. This set of arcs is called **T**.

$$T = \{ (v,t) \mid v \in R \}$$

For each link in the MRSIN that connects two switch-boxes, or a processor to a switch-box, or a switch-box to a resource, add an arc between the corresponding nodes in the flow graph. Denote this set of arcs by **B**.

$$B = \{ (v,w) \mid v \in P \cup X, w \in X \cup R \}$$

Define $E' = S \cup T \cup B$

(T3) Assign link capacities according to the following function.

$$\underset{e \in B}{c(e)} = \begin{cases} 0 & \text{associated link is occupied} \\ & \quad \text{or non-existent in the MRSIN} \\ 1 & \text{associated link is free} \end{cases}$$

$$\underset{e \in S}{c(e)} = \begin{cases} 0 & \text{associated processor does not generate request} \\ 1 & \text{associated processor generates request} \end{cases}$$

$$\underset{e \in T}{c(e)} = \begin{cases} 0 & \text{associated resource is unavailable} \\ 1 & \text{associated resource is available} \end{cases}$$

(T4) Obtain arc-set **E** by removing those arcs with zero capacity.

$$E = E' - \{e \mid e \in E', c(e) = 0\}$$

Obtain node-set **V** by deleting those nodes that are not reachable from s.

$$V = V' - \{v \mid \alpha(v) \cup \beta(v) = \emptyset, v \in V'\}$$

Applying the above transformation to the MRSIN in Figure 2a results in the flow network in Figure 2b. The following theorem shows that Transformation 1 can be used to find the optimal request-resource mapping.

**Theorem 2**: In a homogeneous MRSIN, the number of resources allocated by a mapping is equal to the amount of flow that can be advanced from the source to the sink in the flow network obtained by Transformation 1.

From Theorem 2 and a known result that the maximum flow of a network with integral capacity is integral [11], we conclude that the optimal mapping can be derived from the maximum flow in the transformed flow network.

Many algorithms have been developed to obtain the maximum flow in a flow network. The algorithm by Ford and Fulkerson [9] is a primal-dual algorithm in which the flow value is increased by iteratively searching for *flow augmenting paths* until the minimum cut-set of the network is saturated. At this

** The input ports are numbered in a way different from Lawrie's Omega network [15] because all resources are homogeneous, and the permutation of requesting processors will not affect the resource utilization. Broadcast connection is not needed in the switch-boxes since each request needs one resource.

*** All theorems are stated without proof due to space limitation.

point, no more flow can be advanced since the minimum cut-set is the bottleneck. A flow augmenting path is an s-t path through which additional flow can be advanced from the source to the sink. When arc e on the s-t path points in the direction as the s-t path, additional flow may be advanced through e if the current flow assigned to e is less than c(e). In contrast, if arc e points in the opposite direction, then additional flow may be pushed through the s-t path by canceling its current flow. Advancing flow through an augmenting path in this way will always increase the total amount of flow, and the flow-conservation and capacity limitations will not be violated. For example, in Figure 3, an original flow $f$ is assigned along the path s-a-d-t. Then path s-c-d-a-b-t is a flow augmenting path. Advancing one unit of flow through this augmenting path results in a new flow assignment $f$ '. Two units of flow are pushed through two separate paths s-a-b-t and s-c-d-t according to this assignment.

In the MRSIN, advancing flow through an augmenting path is equivalent to a *resource re-allocation*, i.e., a permutation of the possible request-resource mappings. Consider the MRSIN in Figure 4, which is the counterpart of the flow network in Figure 3.[****] The original flow $f$ is equivalent to the request-resource mapping $\{(p_a, r_d), (p_c, r_b)\}$. The allocation of resource $r_b$ to request $p_c$ is blocked according to this mapping. The existence of the flow augmenting path s-c-d-a-b-t shows that this blockage can be removed. Advancing flow through this augmenting path results in a new mapping $\{(p_a, r_b), (p_c, r_d)\}$ and the allocation of both resources. As another example, applying the maximum-flow algorithm to the flow network in Figure 2b, the flow assignment as shown in the figure is obtained, and the request-resource mapping $\{(p_1, r_3), (p_3, r_5), (p_5, r_8), (p_7, r_1), (p_8, r_7)\}$ is derived. Note that the optimal mapping may not be unique, but suboptimal mappings are eliminated.

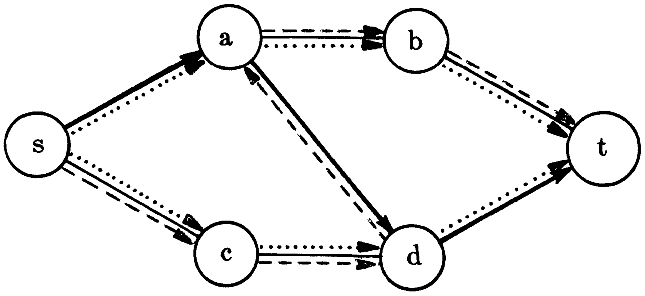

Figure 3. An illustration of advancing flow through a flow augmenting path. (All arcs have unit capacity. The initial flow is assigned to path s-a-d-t. The flow augmenting path s-c-d-a-b-t is indicated as dashed lines. The final flow assignment is obtained after advancing a unit of flow through the flow augmenting path and is indicated as dotted lines.)

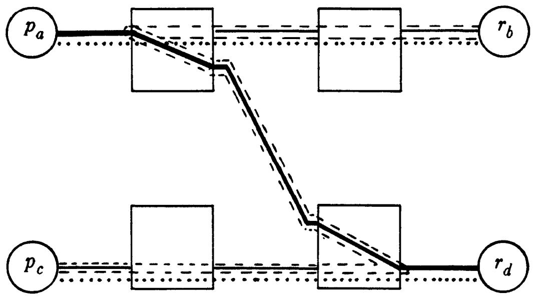

Figure 4. Resource re-allocation corresponding to flow augmentation in Figure 3. (Initially, one resource is allocated—dark lines. The flow augmenting path is indicated as dotted lines. Two resources are allocated after re-allocation—dotted lines.)

Finding a flow augmenting path from the source to the sink in a flow network is the central idea in most maximum-flow algorithms. The improvement lies in the efficient search of the flow augmenting paths [5, 4]. For example, in Dinic's algorithm, the shortest augmenting path is always advanced first with the aid of an auxiliary layered network, and hence the computational complexity is bounded by $O(|E|^3)$ for general networks. In our case, the links have unit capacity, and the time complexity is reduced to $O(|V|^{2/3} \cdot |E|)$ [11].

### 3.3. Homogeneous MRSIN with Request Priority and Resource Preference

In a homogeneous MRSIN with request priority and resource preference, each request is associated with a priority level, and each resource is assigned a preference value. Many application-dependent attributes, such as workload, execution speed, utilization and capability, can be encoded into request priorities and resource preferences. The objective of resource scheduling here is to maximize the number of resources allocated, while allowing requests of higher priority to be allocated and resources of higher preference to be chosen. However, it is not necessary for requests and resources to be allocated in order of their priorities and preferences. The allocation of a resource to a request may be blocked by requests of higher priority, and the resource may be allocated to a request of lower priority. A similar argument applies to resources.

With respect to a flow network, the request priority can be considered as the cost of carrying a flow through the path associated with this request. The resource preference can be considered similarly. As a result, the request-resource mapping problem in this class of MRSIN can be transformed into finding a flow assignment to minimize the total cost of flows in the network.

Consider a flow network $\mathbf{G}(\mathbf{V}, \mathbf{E}, s, t, c, w)$ in which w(e), the cost per unit flow, is associated with arc $e \in \mathbf{E}$. In the minimum-cost flow problem, a legal s-t flow assignment is sought that allows a given amount of flow F to be circulated from source to sink with the minimum cost. The objective is to determine the set of least expensive s-t paths through which the fixed flow F can be advanced. The constraints in this problem are the same as those in the maximum-flow problem. The problem may be defined in a linear programming formulation.

*Minimum-Cost Flow Problem*

Minimize $\sum_{e \in \mathbf{E}} w(e) f(e)$

subject to:

(1) Flow conservation (Eq. (1));
(2) Capacity limitation (Eq. (2)).

In allocating resources, the objective is to find a corresponding flow network whose optimal flow leads to an optimal request-resource mapping. The main idea behind the transformation is to embed priority and preference information into the objective function by proper cost assignments on links. The amount of flow to be circulated can be considered as the number of requests pending for allocation. However, this amount may exceed the capacity of the flow network or the number of available resources, and additional paths have to be introduced to prevent overflow. A possible transformation is given as follows.

**Transformation 2**: Generate a flow network $\mathbf{G}(\mathbf{V}, \mathbf{E}, s, t, c, w)$ from a homogeneous MRSIN with request priorities and resource preferences.

(T1) Create node-sets **P**, **X** and **R** for processors, switch-boxes and resources, respectively, and introduce special nodes: source, s, sink, t, and a *bypass node*, u. Let

$$\mathbf{V}' = \{s, t, u\} \cup \mathbf{P} \cup \mathbf{X} \cup \mathbf{R}$$

[****] The switch-boxes are combined with the processors or resources in the flow network in Figure 3, but will not affect the discussion.

(T2) Create arc-sets **S**, **T** and **B** as in Step (T2) of Transformation 1. Add an arc from the node associated with a processor to the bypass node, and connect the bypass node to the sink. This set of arcs is denoted as **L**.

$$\mathbf{L} = \{(v, u) \mid v \in \mathbf{P}\} \cup \{(u, t)\}$$

Define $\mathbf{E}' = \mathbf{S} \cup \mathbf{T} \cup \mathbf{B} \cup \mathbf{L}$

(T3) Define capacity function c as in Step (T3) of Transformation 1. In addition, define

$$\underset{e\in\mathbf{L}}{c(e)} = \begin{cases} 1 & e\neq(u,t) \\ \alpha(u) & e=(u,t) \end{cases}$$

(T4) Define cost function w that represents the cost of advancing one unit of flow through a link as follows.

$$w(e) = \begin{cases} 0 & \text{for } e\in\mathbf{B} \\ \max(y_{max}+1, q_{max}+1) & \text{for } e\in\mathbf{L} \\ y_{max}-y_p & \text{for } e\in\mathbf{S},\ p\in\mathbf{P} \\ q_{max}-q_w & \text{for } e\in\mathbf{T},\ w\in\mathbf{R} \end{cases}$$

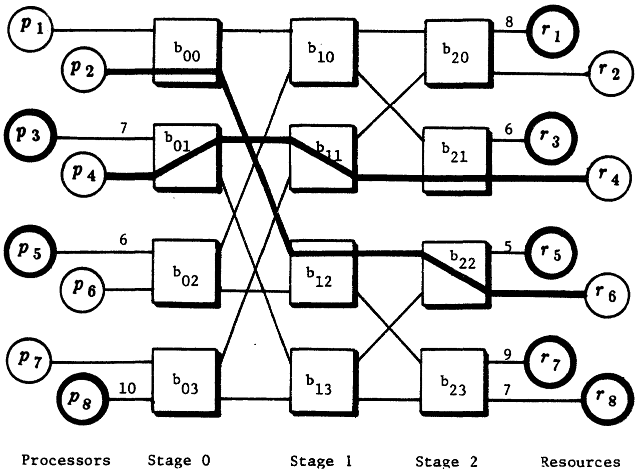

Figure 5a. A MRSIN with request priority and resource preference (highest priority is 10; highest preference is 10; dark paths in the network are already occupied; processors $p_3$, $p_5$ and $p_8$ are making requests; resources $r_1$, $r_3$, $r_5$, $r_7$ and $r_8$ are available).

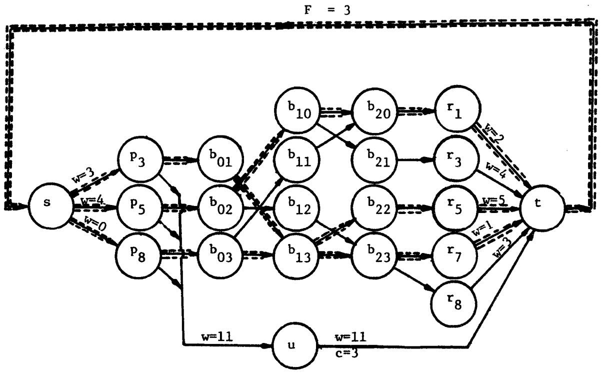

Figure 5b. The flow network transformed from the MRSIN in Figure 5a using Transformation 2 (non-zero flows assigned by the out-of-kilter algorithm are shown as dashed lines in the figure; return flow from t to s is added by the out-of-kilter algorithm; all arcs have unit capacity; cost of arc is zero except where indicated).

where $y_{max}$ is the highest priority level, $y_p$ is the priority of request from processor p, $q_{max}$ is the highest preference level, and $q_w$ is the preference of resource w. Note that any cost function that is inversely related to priorities and preferences can be used.

(T5) Create arc-set **E** and node-set **V** as in Step (T4) of Transformation 1.

(T6) Set the total flow F to the number of requests.

As an example, in the MRSIN in Figure 5a, each request is attributed a priority level, and an available resource is given a preference value. The preference and priority levels range from 1 to 10. A minimum-cost flow network obtained from Transformation 2 is shown in Figure 5b. The following theorem shows the correctness of Transformation 2.

**Theorem 3:** The optimal request-resource mapping on a homogeneous MRSIN with request priority and resource preference can be derived from the minimum-cost integral flow of the flow network, which is obtained by Transformation 2.

Edmonds and Karp have developed a scaled out-of-kilter algorithm to obtain the minimum-cost flow of a general flow network in polynominal time [5]. For a flow network of 0-1 capacity, the time complexity is bounded by $O(|V|\cdot|E|^2)$. Furthermore, in the minimum-cost flow assignment obtained, the flow assigned to a link is integral if the links have integral capacities. As an example, applying the minimum-cost flow algorithm on the flow network in Figure 5b results in the request-resource mapping $\{(p_3, r_5), (p_5, r_1), (p_8, r_7)\}$. The selected paths are shown as dashed lines in Figure 5b. Note that the minimum-cost flow obtained may not be unique, and alternate minimum-cost flows are possible. However, alternative mappings will not improve the cost of allocation.

### 3.4. Optimal Resource Scheduling in Heterogeneous MRSIN

A heterogeneous MRSIN consists of multiple types of resources, and a processor may generate a request of a given type of resource. Such a MRSIN is equivalent to a flow network carrying different types of commodities. A multicommodity flow network has multiple source-sink pairs, each of which is associated with one type of commodity. A flow coming out of a source of a given commodity can only be absorbed by the sink of the same type of commodity. Flows of different commodities may share a link as long as the total flow does not exceed the capacity of the link.

For a flow network with k types of commodities, there are k source-sink pairs, $(s^i, t^i)$, for i=1 to k. Let $F^i$ be the total flow of the i'th commodity and $f^i(e)$ be the flow of the i'th commodity on edge e. The search for the maximum flow can be formulated as follows [1].

*Multicommodity Maximum-Flow Problem*

Maximize $\sum_{i=1}^{k} F^i$

subject to:

(1) Flow conservation: For i = 1, ...., k

$$\sum_{e\in\alpha(v)} f^i(e) - \sum_{e\in\beta(v)} f^i(e) = \begin{cases} -F^i & v = s^i \\ F^i & v = t^i \\ 0 & \text{otherwise} \end{cases}$$

(2) Capacity limitation:

$$0 \leqslant \sum_{i=1}^{k} f^i(e) \leqslant c(e) \quad \text{for all } e\in\mathbf{E}$$

A multicommodity flow network may be visualized as the superposition of k single-commodity flow networks. Each layer in the superposition represents a single-commodity flow. To obtain the optimal request-resource mapping in a heterogeneous MRSIN without priority and preference, a transformation similar to Transformation 1 can be applied to obtain a layer for each type of resources, and the layers are superposed to form a multicommodity flow network.

The optimal mapping for a heterogeneous MRSIN with request priorities and resource preferences can be obtained by transforming the problem into the multicommodity minimum-cost flow problem. Let $w^i(e)$ be the cost per unit flow for the i'th commodity on edge e. The problem can be formulated as follows.

*Multicommodity Minimum-Cost Flow Problem*

$$\text{Minimize } \sum_{i=1}^{k} \sum_{e\in E} w^i(e)\, f^i(e)$$

subject to:

(1) Flow conservation: For i = 1, ..., k

$$\sum_{e\in\alpha(v)} f^i(e) - \sum_{e\in\beta(v)} f^i(e) = \begin{cases} -F^i & v = s^i \\ F^i & v = t^i \\ 0 & \text{otherwise} \end{cases}$$

(2) Capacity limitation:

$$0 \leq \sum_{i=1}^{k} f^i(e) \leq c(e) \quad \text{for all } e\in E$$

The equivalent flow network consists of k source-sink pairs and k bypass nodes, where k is the number of types of requested resources. As for requests without priority, the flow network can be regarded as the superposition of k single-commodity flow networks, and Transformation 2 can be applied to each of them.

The problem of finding the maximum integral flow in a multicommodity flow network of general topology has been shown to be NP-hard. Fortunately, circuit switched loop-free interconnection networks have transformations that belong to a restricted class of multicommodity flow networks in which the optimal flow values are always integral [6]. For this class of flow networks, the integral multicommodity optimal flows can be obtained efficiently by the *Simplex Method*, which has been shown empirically to be a linear-time algorithm [18].

## 4. ARCHITECTURE OF MRSIN TO SUPPORT OPTIMAL SCHEDULING

Two architectures to carry out the optimal resource scheduling algorithms have been studied. In the first approach, a dedicated monitor is responsible for resource scheduling (see Figure 6). It maintains the status of the interconnection network and resources. The monitor enters a scheduling cycle when there are pending requests. Requests received during a scheduling cycle will not be processed until the next cycle. In a scheduling cycle, a flow network is generated, and the optimal request-resource mapping is derived. Then the monitor sends an acknowledgement to each requesting processor that has been allocated a resource, notifies resources that are allocated, and establishes paths in the network. The implementation is sequential, and the overhead is measured by the number of instructions executed in the algorithm.

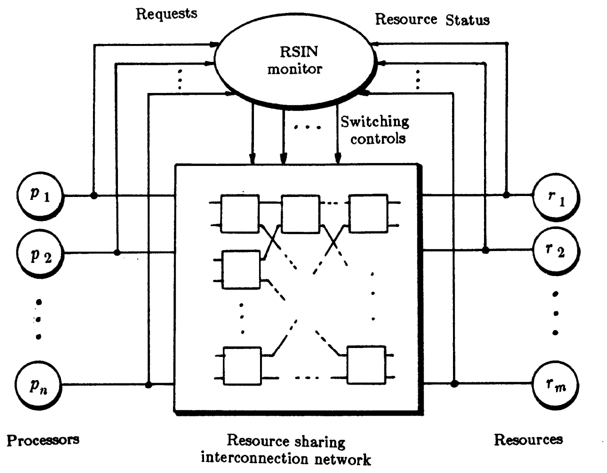

Figure 6. A monitor architecture to carry out optimal resource scheduling in a RSIN.

A distributed architecture, on the other hand, distributes the scheduling intelligence in the switch-boxes of the interconnection network. Optimal scheduling is achieved through cooperations among processes in the switch-boxes. No transformation to a network-flow problem is necessary because the network-flow algorithm is carried out in a distributed fashion in the switch-boxes. The complexity of the process in each switch-box is central to the design of the distributed architecture. Our previous study shows that the maximum-flow algorithm for homogeneous MRSIN without priority and preference can be efficiently implemented in a distributed fashion [14]. For systems with heterogeneous resources or with priorities and preferences, there is no improvement over a monitor except for reasons such as fault tolerance and modularity.

In the following sections, we describe a distributed realization of Dinic's maximum-flow algorithm to obtain the optimal request-resource mapping.

### 4.1. Dinic's Maximum-Flow Algorithm

Dinic's algorithm is based on the flow augmentation method described in Section 3.2. It improves over Ford and Fulkerson's algorithm by advancing flow through the shortest augmenting path, which can be found from a *layered network* derived from the original flow graph. A procedure summarizing Dinic's algorithm is as follows.

```
procedure dinic (V, E);
/* The algorithm has two alternating phases. The algorithm
   alternates between these two phases until no more flow can
   be augmented. */
(1) Initialization: Flow network with an initial flow assignment.
(2) Layered Network Construction Phase:
      (2a) Include s in the first layer;
      (2b) Construct the next layer;
      (2c) If layer is empty, then go to Step (4);
      (2d) If t is not in this layer, then go to Step (2b);
(3) Maximal-Flow Search Phase:
      /* Determine an increment to the flow assignment by finding
      the maximal flow in the layered network. */
      (3a) Search for s-t paths;
      (3b) If an s-t path does not exist, then go to Step (2a);
      (3c) Advance flow through this path; Go to Step (3a);
(4) Stop: Maximum flow assignment has been obtained.
```

In the layered network, nodes of the original flow network are organized into stages. The first stage consists of the source node(s) of the network, and the remaining stages are constructed iteratively. A stage consists of nodes that are not included in the previous stages and have either an unsaturated arc or an arc with non-zero flow originating from nodes in the previous stage. These two types of arcs, called *useful links*, are transformed to arcs in the layered network. Depending on the direction of the associated useful link, its capacity in the layered network can be either the remaining capacity or its current flow. As a result, nodes in a layered network are arranged into disjoint subsets, $V_0, \ldots, V_\ell$, such that no arc points from $V_j$ to $V_i$ ($i \leq j$).

A legal flow in a layered network is said to be maximal if every (s,t)-directed path in the layered network is saturated. Note that a maximal flow in a layered network is not necessarily the maximum flow because flows in opposite directions in the same arc are not considered. Moreover, computing the maximal flow is easier than computing the maximum flow. In Dinic's algorithm, the maximal flow is obtained by a depth-first search.

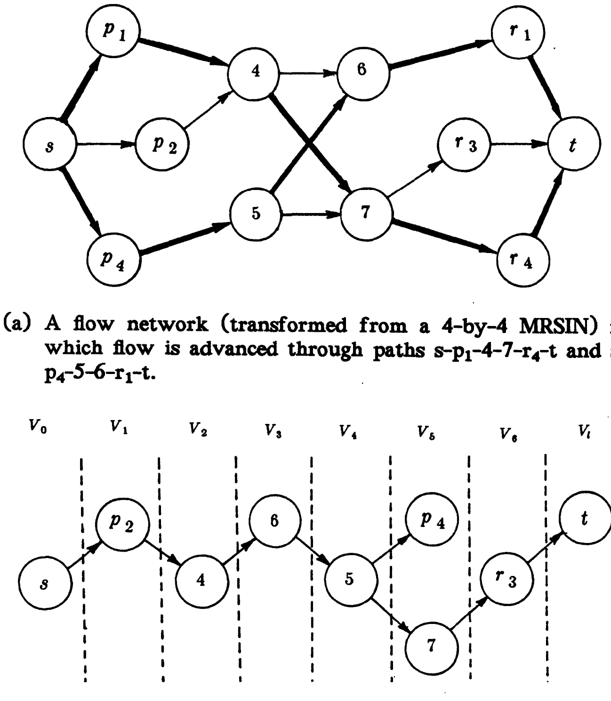
Since the amount of flow that can be advanced through an arc in the layered network is the net increase of flow to the associated arc in the original network, the maximal flow obtained in the layered network is a net increment to the existing flow. Further, the maximum flow of a flow network is finite. Hence, the maximum flow can be obtained in a finite number of iterations in constructing the layered network.

An example illustrating the construction of a layered network is shown in Figure 7. Figure 7a is a flow network associated with a MRSIN in which three processors, $p_1$, $p_2$ and $p_4$, are making requests and three resources, $r_1$, $r_3$ and $r_4$, are available. The flow assignment shown by darkened arcs in Figure 7a results in a mapping such that $p_1$ is mapped to $r_4$ and $p_4$ is mapped to $r_1$. The request generated by $p_2$ is blocked. Figure 7b is a layered network constructed from the flow network in Figure 7a. The layered network shows that there is a flow augmenting path from $p_2$ to $r_3$. This path includes the arc leading from node 6 to node 5, which is associated with the arc leading from node 5 to node 6 in the original network (see Figure 7a). This flow augmenting path shows that all three resources can be allocated if $p_4$ is re-allocated to $r_3$ and $p_2$ is re-allocated to $r_1$.

### 4.2. A Distributed Architecture for Homogeneous MRSIN without priority

A distributed MRSIN embedded in an 8-by-8 Omega network is shown in Figure 8. The scheduling intelligence is distributed in the switch-boxes (NS). A processor is connected to the network through a request server (RQ), and a resource is monitored by a resource server (RS). A common status bus connects these components together. Autonomous process in each component communicates with other processes by passing tokens via direct links, and are synchronized by exchanging status via the status bus.

A scheduling cycle begins when there are pending requests and ready resources. A request generated in the middle of a scheduling cycle has to wait until the next cycle. The procedure indicating the flow of phase transitions in a scheduling cycle is shown as follows.



(a) A flow network (transformed from a 4-by-4 MRSIN) in which flow is advanced through paths s-$p_1$-4-7-$r_4$-t and s-$p_4$-5-6-$r_1$-t.

(b) The layered network derived from the flow network in (a). The (s,t)-path s-$p_2$-4-6-5-7-$r_3$-t is equivalent to an augmenting path in the original flow network.

Figure 7. An illustration of a layered-network construction (all arcs have unit capacity).

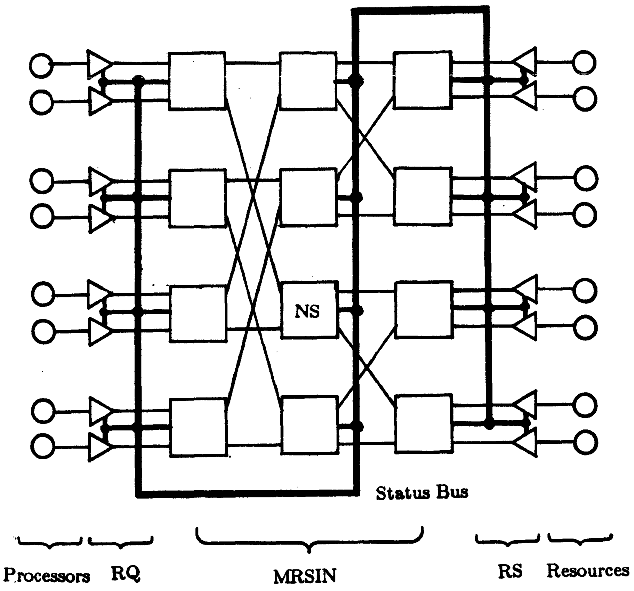


Figure 8. A distributed MRSIN embedded in an 8-by-8 Omega network.

```
procedure mrsin (P, X, R);
/* During a scheduling cycle, the network alternates between
   two phases until all request tokens are blocked. */
(1) Initialization: MRSIN with pending requests and ready
    resources;
(2) Request-Propagation Phase:
    /* In this phase, each requesting RQ sends a request token to
    the network, which will eventually arrive at the resources if
    there are free resources to allocate. */
    (2a) Requesting RQs send tokens;
    (2b) Propagate tokens to next NSs;
    (2c) If all request tokens are blocked, then go to Step (4);
    (2d) If request tokens are not received by the RSs associated
         with free resources, then go to Step (2b);
(3) Resource-Acknowledgment Phase:
    /* The RSs associated with free resources and receiving
    request tokens will send resource tokens to the network to
    acknowledge the acceptance of requests. When a resource
    token is received by a requesting RQ, the RQ and RS will
    form a matched pair, and the path connecting them is
    registered. The network returns to the request-propagation
    phase when all resource tokens are blocked. */
    (3a) Propagate resource tokens to RQs;
    (3b) If all resource tokens are blocked, then go to Step (2a);
    (3c) Register path; Go to Step (3a);
(4) Stop: Optimal request-resource mapping has been obtained.
```

Note that the flow of this procedure is exactly the same as the control flow of Dinic's algorithm.

To carry out Dinic's algorithm by token propagations, a switching element has to follow several token-propagation rules. If a link is free, a switch-box will deliver any request token received from the processor side to the resource side. These directions are reversed if the link is already registered. If there are more than one path to send the request token, the token is duplicated and sent along all paths. A resource token is expected from where a request token was delivered. However, no duplication of resource token is done, and one path is chosen at random. It can be verified that these token-propagation rules correctly implement the layered-network construction process and the search for the maximal flow.

To avoid chaos in token propagations, processes residing in different switch-boxes have to be synchronized on phase transitions. This synchronization can be achieved by broadcasting the status of each process on the status bus. The status of the network can be one of four independent possibilities: request-pending, resource-ready, request-token-propagation, and resource-token-propagation, and can be represented as a Boolean vector (RP, SR, RTP, STP). Each process will synchronize the broadcast of its status on the bus with other processes. The result is a wired-OR of the statuses broadcast by all processes. The occurrence of events that cause a phase transition can be detected by observing the status bus. For example, the transition from a request-propagation phase to a resource-acknowledgement phase is known to every process when each observes a change of the status vector from (1,1,1,0) to either (1,1,1,1) or (1,1,0,1).

We have shown that every process involved can be carried out by a simple sequential machine and is realizable in logic circuits [14]. With this design, there are two factors that contribute to a significant speedup as compared to a monitor architecture: (a) the augmenting paths are searched in parallel, and (b) the time complexity is measured in gate delays instead of instruction execution cycles. As a result, the scheduling algorithm will run at least 100 times faster than a software implementation of the network flow algorithm.

## 5. CONCLUSIONS

A RSIN is suitable to support resource sharing in multiprocessors. Optimal request-resource mapping in RSIN is obtained by maximizing the number of communication paths that interconnect pairs of processors and resources. In this paper, we have transformed various request-resource mapping problems into network flow problems for which efficient algorithms exist. Table 1 is a summary of the results we have obtained. The proposed method is independent of the interconnection structure and is applicable to all configurations in which the requesting processors and free resources are partitioned into two disjoint subsets. In particular, the method is applicable to networks with multiple paths between source-destination pairs, such as the data manipulator [7], the augmented data manipulator [19], and the Gamma network [20]. The resource utilization, however, will depend on the network configuration, the resources available, the permutation of the various types of resources, and the permutation of the requesting processors.

## ABSTRACT

We consider linear, data-driven, arrays in which each cell is augmented with the capability of recognizing and skipping operations that involve zero operands. This type of networks is shown to be efficient for highly sparse matrices, despite the potential data conflict that may result due to irregular zero distributions. Two different approaches, which take advantage of the sparsity of the matrix, are considered; The first is aimed at the reduction of the execution time, and the second is aimed at the reduction of the number of cells in the network.

## 1. INTRODUCTION

Many techniques have been suggested for the efficient solution of sparse linear systems through clever, but highly irregular, storage and manipulation of the non-zero coefficients in the system [1]. These techniques, however, are not suitable for parallel processing, which requires, in general, a rather regular pattern of computation. In this paper, we consider a fundamental operation in iterative solution schemes for linear systems. Namely, the multiplication of a matrix by a vector.

The computation involved in the matrix/vector multiplication is quite regular, and thus appropriate for regular VLSI networks. That is systolic [2] and data-driven [3] arrays. Obviously, the benefits of this type of networks may become visible only when the size of the matrix is large. However, large systems that appear in practice are usually sparse, and hence seem inefficient for solution on regular VLSI networks due to the potential loss of resources in operations which involve zero operands.

In order to avoid the waste of resources caused by trivial operations, and, in the same time, retain the advantages of fast specialized cells and efficient local communications, we suggest to add to each cell in the network the capability of recognizing and skipping trivial operations. With data-driven synchronization, this results in a shorter average cycle for each cell, which may reduce the execution time of the entire network.

Two different approaches for the multiplication of sparse matrices by vectors are introduced. In the first approach, the same number of cells which would be needed if the matrix were dense is used, but a considerable speed-up is obtained by skipping trivial operations. In the second approach, the non-zero elements of the matrix are grouped in few stripes which are almost parallel to the diagonal of the matrix, and a specific cell is assigned to perform the operations associated with the elements of a particular stripe. This approach is aimed at the reduction of the number of cells without slowing down the speed of the computation.

## 2. COMPUTATIONAL CELLS WITH DATA DEPENDENT OPERATIONS

Consider a data driven version of the systolic network given in [2] for the multiplication of an $n \times n$ banded matrix $A$ by a vector $x$. For simplicity, we assume that the number of upper diagonals of $A$ is equal to the number of lower diagonals, namely $B_h$, and hence, the band-width of $A$ is $B = 2B_h + 1$. The network, called from now on $MV_1$, is shown in Fig. 1.

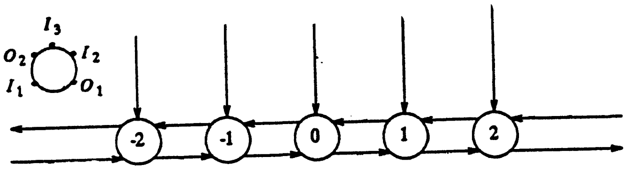

Fig. 1 - The network $MV_1$ with $B_h = 2$.

Every cell in $MV_1$ has three input ports and two output ports, namely $I_1, I_2, I_3, O_1$ and $O_2$, respectively. Its operation may be described by the following cycle which is repeated indefinitely (Here, $[I]$ denotes the content of port $I$, and $O \leftarrow \alpha$ means that $\alpha$ is written on port $O$).

*CYCLE 1:*

```
(1) Wait until data is available on $I_1, I_2$ and $I_3$ ;
      $\alpha = [I_1]$ ; $\beta = [I_2]$ ; $\gamma = [I_3]$
(2) $\rho = \alpha + \beta * \gamma$
(3) Wait until previous data on $O_1$ and $O_2$ is consumed ;
      $O_2 \leftarrow \beta$ ; $O_1 \leftarrow \rho$.
```

Each internal communication link directed from cell $q$ to cell $k$ may be regarded as a queue. Only cell $q$ may write on this queue and only cell $k$ may read (and delete) its front element. The maximum capacity of this queue will be denoted by $d$. In addition to internal links, the network has external links for communication with a host system. More specifically, the host supplies the elements of the $k^{th}$ diagonal of $A$, $-B_h \leqslant k \leqslant B_h$, on port $I_3$ of cell $k$, the elements of the vector x on port $I_2$ of cell $B_h$, and the elements of the result vector $y$ (initialized to zero) on port $I_1$ of cell $-B_h$. With this it is easy to see that the elements of the product vector $y = Ax$ are produced on port $O_1$ of cell $B_h$.

Now assuming that $\zeta\%$ of the elements in the band of $A$ are zeroes, then it is clear that $\zeta\%$ of the resources in $MV_1$ are wasted in the execution of trivial operations in step 2 of CYCLE 1. In order to reduce this waste, we may attempt to skip the multiply/add operation whenever $[I_3] = 0$. More specifically, consider a network $MV_2$, which is identical to $MV_1$ except that each cell executes the following cycle instead of CYCLE 1.

*CYCLE 2:*

```
(1) As in step 1 of CYCLE 1
(2) If ($\gamma \equiv 0$) Then 2.1) $\rho = \alpha$
                     Else 2.2) $\rho = \alpha + \beta * \gamma$
(3) As in step 3 of CYCLE 1
```

An execution of CYCLE 2 which goes through step 2.1 is called a trivial execution of the cycle, otherwise the execution is called non-trivial. Trivial executions of CYCLE 2 may, or may not, be shorter than non-trivial executions, depending on

the waiting time spent in steps 1 and 3. Hence, the total execution time $T_2$ of $MV_2$ depends primarily on the effect of data conflict on the execution of individual cells.

One way of obtaining an upper bound on the execution time of data driven networks of the type discussed above is to force some hypothetical synchronization on the computation, such that execution alternates between two phases. Namely a communication phase and a processing phase. We call the resulting computation a pseudo systolic computation and we call a communication phase followed by a processing phase a global cycle. Given that the additional synchronization may only slow down execution, then it is clear that the execution time of a data driven computation is bounded by the execution time of the corresponding pseudo systolic computation.

For example, a pseudo systolic version of $MV_1$, called $MV_{1,p}$, may be obtained by replacing step 2 in CYCLE 1 with

```
(2) Wait for a synchronization signal SYNC
    $\rho = \alpha + \beta * \gamma$
```

Where we assume that all the cells in $MV_{1,p}$ are connected to a hypothetical controller that issues the signal SYNC after it detects the termination of a communication phase. That is when all the cells are waiting in step 2. With this it is easy to see that the execution time $T_1$ of $MV_1$ is bounded by the execution time $T_{1,p}$ of its pseudo systolic version, namely

$$T_1 \leqslant T_{1,p} = 2\,(B_h + n)\,(\tau_c + \tau_m)$$

where $\tau_m$ is the time for a floating point multiply/add operation (step 2) and $\tau_c$ is the time for the transmission of one data item between two cells.

Tracing the execution of $MV_2$ is more complicated than $MV_1$ because of possible trivial executions of CYCLE 2. A pseudo systolic version of $MV_2$, namely $MV_{2,p}$, may be obtained if CYCLE 2 is replaced by the following cycle:

```
CYCLE 2P: /* Pseudo Systolic Version of CYCLE 2 */
(1) Wait until data is available on $I_1$, $I_2$ and $I_3$ ;
    $\alpha = [I_1]$ ; $\beta = [I_2]$ ; $\gamma = [I_3]$
(2) If ($\gamma \equiv 0$) then
    2.1) wait until previous data on $O_1$ and $O_2$ are consumed
    2.2) $O_1 \leftarrow \alpha$ ; $O_2 \leftarrow \beta$
    2.3) Go To step 1
(3) Wait for a synchronization signal SYNC
(4) $\rho = \alpha + \beta * \gamma$
(5) Wait until previous data on $O_1$ and $O_2$ are consumed ;
    $O_1 \leftarrow \rho$ ; $O_2 \leftarrow \beta$.
```

In other words, trivial operations are first skipped until a non-trivial operand is found in $[I_3]$, then the multiplication is performed. As in $MV_{1,p}$ , we assume that all the cells are connected to a controller that issues the signal SYNC in such a way that execution alternates between communication and processing phases. During the communication phase, the data is moving in the network until each cell is either blocked due to lack of data (step 1, 2.1 or 5), or is blocked in step 3 (with $[I_3] \neq 0$). When this state is reached, the controller issues SYNC and all the cells which are blocked at step 3 executes the multiplication (step 4), simultaneously, while the other cells remain idle until the end of the global cycle.

In order to isolate the effect of internal data conflict from any delay caused by slow communication with the host, we assume that external inputs on $I_3$ of cells $B_{-h}, \ldots, B_h$ as well as on $I_1$ of cell $-B_h$ and $I_2$ of cell $B_h$ are available when needed. We also assume that $MV_{2,p}$ terminates execution, for a specific input matrix $A$ , in $N_2$ global cycles. With this, we may define the function $\alpha$:$[-B_h, B_h] \times [1, N_2] \rightarrow A$ such that $\alpha(k,t)$ is the element of $A$ that appears on port $I_3$ of cell $k$ at the beginning of the processing phase of the $t^{th}$ global cycle.

Although a data item is always available on $I_3$ of any cell during a specific processing phase, only those cells which receive the corresponding elements of the vectors $y$ and $x$ on $I_1$ and $I_2$, respectively, perform a multiply/add operation, while the other cells remain idle. Let $M_t$ be the subset of cells which are not idle during the $t^{th}$ processing phase and define the $t^{th}$ computation front as the set of elements of $A$ which are operated upon during this phase. More precisely,

$$CF_t = \{\alpha(k,t) \mid k \in M_t\}$$

Note that the members of $CF_t$ , for any $t$ , are non zero elements of $A$ .

The succession of computation fronts represents the progress in the execution of the pseudo systolic computation. More specifically, given a certain matrix, we may connect the elements of each front by a piece-wise linear curve and thus obtain a visual picture that describes the propagation of the computation. For example, we show in Fig. 2 the computation fronts corresponding to the specific given matrix pattern. Note that the concept of computation fronts is the same as that suggested in [6]. However, by allowing irregular fronts, we are able to model computations that depend on the value of the input as well as its availability.

In [5], we give a method for the automatic construction of computation fronts for pseudo systolic computations. Clearly, the number of such fronts is equal to the number of global cycles needed to complete the computation.

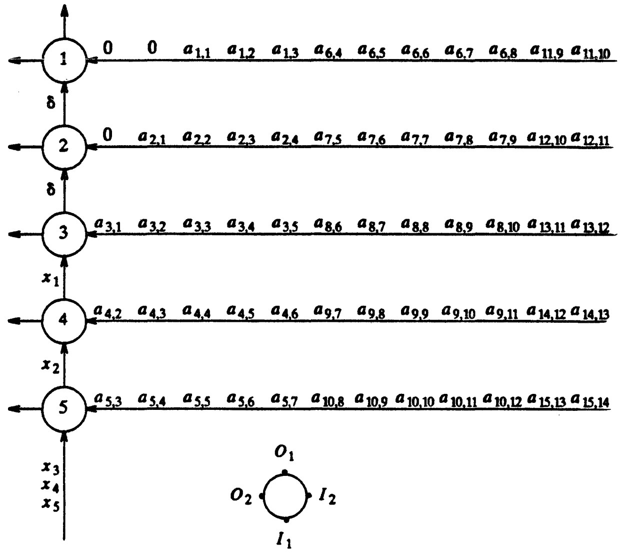
## 3. A NETWORK FOR MATRICES WITH NON-ZERO DIAGONAL ELEMENTS

Most of the matrices resulting in practical applications have non-zero diagonal elements, and it may be shown [5] that $MV_2$ is not suitable for this type of matrices because it does not allow computation fronts to be parallel to the diagonal of the matrix. In this section, we introduce a network, $MV_3$, which allows the fronts to be parallel to the diagonal.

For simplicity, we introduce $MV_3$ for dense, banded, matrices. It is composed of B cells (see Fig 3). Each cell has two input ports and two output ports, and is equipped with a counter "Ct" and an accumulator "Acc". The cycle of a cell may be described as follows:



1
0 0 $a_{1,1}$ $a_{1,2}$ $a_{1,3}$ $a_{6,4}$ $a_{6,5}$ $a_{6,6}$ $a_{6,7}$ $a_{6,8}$ $a_{11,9}$ $a_{11,10}$

$O_2$
$I_2$
$I_1$

Fig. 3 - $MV_{3,p}$ after two cycles ($B = 5$)

```
CYCLE 3: /* Initially, $Ct = B_h + 1$. This allows data
           to fill-in during the first $B_h$ cycles */
(1) Wait until data is available on $I_1$ and $I_2$ ;
    $\alpha = [I_1]$ ; $\beta = [I_2]$
(2) $\rho = [Acc] + \alpha * \beta$
(3) Wait until previous data on $O_1$ and $O_2$ are consumed
(4) If $Ct = B$ THEN $O_1 \leftarrow \alpha$ ; $O_2 \leftarrow \rho$ ; $Acc \leftarrow 0$ ; $Ct = 1$
                 ELSE $O_1 \leftarrow \alpha$ ; $Acc \leftarrow \rho$ ; $Ct = Ct + 1$
```

The elements of the vector $x$ are applied to port $I_1$ of cell $B$, and the elements in the rows $k$, $k+B$, $k+2B$,..., of the matrix $A$ are concatenated and applied to port $I_2$ of cell $k$ (see Fig 3). Given this input, and assuming pseudo systolic synchronization, it may be easily seen that the elements $y_1,...,y_B$ of the result vector are produced on ports $O_2$ of cells $1,...,B$, respectively, after $B_h+B$ global cycles. The elements $y_{B+1},...,y_{2B}$ are produced on the same ports at the end of cycle $B_h+2B$, and in general, $y_{rB+1},...,y_{rB+B}$, $r=0,1,...$ are produced at the end of cycle $B_h+(r+1)B$. In other words,

$$T_{3,p} = (B_h + \beta B)(\tau_m + \tau_c)$$

where, $\beta=((n-1)\div B)+1$. Similar to the case of $MV_1$, the execution time of $MV_3$ may be reduced for sparse matrices, if step 2 in CYCLE 3 is replaced by a conditional statement that skips trivial operations. We call the resulting network $MV_4$. The construction of the computation fronts for the pseudo systolic version of $MV_4$ provides a means for the estimation of its speed-up over $MV_3$, obtained by skipping trivial operations.

## 4. A NETWORK WITH REDUCED NUMBER OF CELLS

Numerical Techniques for the solution of partial differential equations are major sources of large sparse matrices. The matrices resulting from these techniques have a band with $B = O(\sqrt{n})$, and hence the number of cells needed in $MV_2$ and $MV_4$ grows with the size of the matrix.

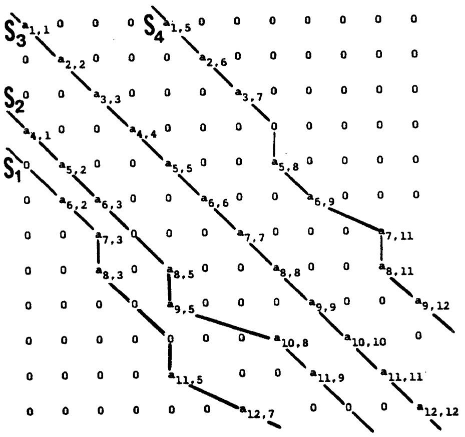
In order to obtain a network with a number of cells independent of $n$, we use the property in these matrices that the number of elements in each row is bounded by a constant which is independent of $n$. This property permits the inclusion of all the non-zero elements of the matrix into a stripe structure that contains few stripes which are, almost, parallel to the diagonal. A specific cell is then assigned to perform the operations associated with each stripe. First, we define a stripe structure of a matrix.

*Definition* : A $Q$-stripe $S$ of an $n \times n$ matrix $A$ is a set of positions $S = \{(i, \sigma(i)) \mid i = 1,...,n\}$ where $\sigma$ is a non-decreasing function. The prefix $Q$ (stands for "Quasi") is used to distinguish Q-stripes from a more restrictive definition of stripes that is given in [4]. However, only $Q$-stripes are referred to in this paper, and hence the prefix Q will be omitted.

*Definition:* A stripe structure of $A$ is a sequence of stripes $S_1=\{(i, \sigma_1(i))\}$, ..., $S_\pi=\{(i, \sigma_\pi(i))\}$ such that

$$\sigma_k(i) < \sigma_{k+1}(i) \quad i=1,...,n, \quad k=1,...,\pi-1$$

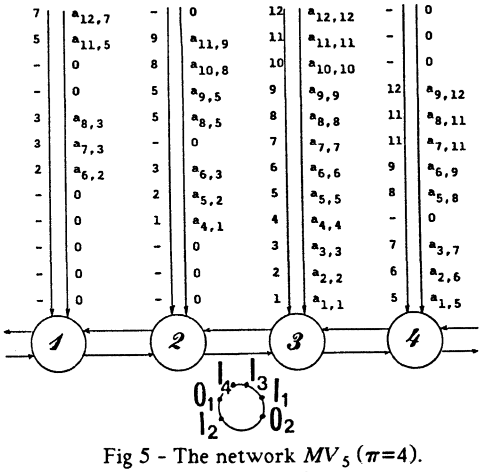
and $S_1 U...U\ S_\pi$ contains all the positions of nonzero elements in $A$. That is $a_{i,j} \neq 0$ only if $(i,j) \epsilon\ S_1 U...U\ S_\pi$. For example, we show in Fig. 4 the stripe structure of a specific matrix. Note that some zero elements are included in each stripe because, by definition, a stripe should contain a position for each row.



$S_3$ $a_{1,1}$ 0 0 0 $S_4$ $a_{1,5}$ 0 0 0 0 0 0 0
0 $a_{2,2}$ 0 0 0 $a_{2,6}$ 0 0 0 0 0 0
$S_2$ 0 0 $a_{3,3}$ 0 0 0 $a_{3,7}$ 0 0 0 0 0
$a_{4,1}$ 0 0 $a_{4,4}$ 0 0 0 0 0 0 0 0
$S_1$ 0 $a_{5,2}$ 0 0 $a_{5,5}$ 0 0 $a_{5,8}$ 0 0 0 0
0 $a_{6,2}$ $a_{6,3}$ 0 0 $a_{6,6}$ 0 0 $a_{6,9}$ 0 0 0
0 0 $a_{7,3}$ 0 0 0 $a_{7,7}$ 0 0 0 $a_{7,11}$
0 0 $a_{8,3}$ 0 $a_{8,5}$ 0 0 $a_{8,8}$ 0 0 $a_{8,11}$
0 0 0 0 $a_{9,5}$ 0 0 0 $a_{9,9}$ 0 0 $a_{9,12}$
0 0 0 0 0 0 0 $a_{10,8}$ $a_{10,10}$ 0
0 0 0 0 $a_{11,5}$ 0 0 $a_{11,9}$ $a_{11,11}$
0 0 0 0 0 0 $a_{12,7}$ 0 0 0 $a_{12,12}$

Fig 4 - A stripe structure

Given a stripe structure of a matrix A, we may use the network $MV_5$ shown in Fig. 5 for the multiplication of $A$ by a vector. The elements of the vector $x$ are fed to port $I_1$ of cell $\pi$ and the elements of the result vector $y$, initialized to zero, are fed to port $I_2$ of cell 1. Successive elements in a particular stripe $S_k$ are fed to port $I_3$ of cell $k$, and along with each element $a_{i,\sigma_k(i)} \epsilon\ S_k$ supplied on $I_3$, the value of $\sigma_k(i)$ is supplied on port $I_4$.



7 $a_{12,7}$ - 0 12 $a_{12,12}$ - 0

- 0 - 0 3 $a_{3,3}$ 7 $a_{3,7}$
- 0 - 0 2 $a_{2,2}$ 6 $a_{2,6}$
- 0 - 0 1 $a_{1,1}$ 5 $a_{1,5}$
1
2
3
4
$I_4$ $I_3$
$O_1$ $I_1$
$I_2$ $O_2$

Fig 5 - The network $MV_5$ ($\pi$=4).

In order to provide the flexibility needed to deal with sparse structures, we assume that each cell contains a counter $CX$ that keeps track of the index of the data received on $I_2$.

Noting that data on $I_3$ and $I_4$ are always available, the operation of each cell may be described by

```
CYCLE 5 : /* Initially $CX = 0$ */
(1) Wait until data is available on $I_2$ ;
    $\alpha = [I_3]$ ; $j = [I_4]$ ; $\eta = [I_2]$
(2) While (CX < j) Do
        Wait until data is available on $I_1$ ;
        $\xi = [I_1]$ ; $CX = CX+1$ ; $O_1 \leftarrow \xi$
(3) $\eta = \eta + \alpha * \xi$
(4) $O_2 \leftarrow \eta$
```

More descriptively, after cell $k$ receives $a_{i,\sigma_k(i)}$, it continues to transmit the components of $x$ from $I_1$ to $O_1$ until it finds $x_{\sigma_k(i)}$. At this time the inner product is computed (step 3) and the result is written out. It is easy to see that the elements of the result vector $y = Ax$ are produced on $O_2$ of cell $\pi$. However, the network may operate correctly only if $\sigma_k(i) < \sigma_{k+1}(i)$ and $\sigma_k(i) \leqslant \sigma_k(i+1)$, which are satisfied by the definition of a stripe structure. Note that we assumed, implicitly, that the queues on the communication links which carry the x-data stream in $MV_5$ do not overflow. In [4], the maximum size, $d_x$ of these queues is found to be equal to the maximum separation between the stipes of the matrix.

A pseudo systolic version $MV_{5,p}$ of $MV_5$ may be obtained by inserting a "wait for SYNC" in step 3. The conditions for two elements of A to be in the same computation front may be easily derived [4] and used for the systematic construction of the fronts.

## 5. AN EXAMPLE

In order to compare the different networks presented in this paper, we consider the matrix that is generated from the discretization of a second order partial differential equation on the grid shown in Fig 6. For this matrix, $n = 270$ and $B = 39$, but only 16% of the elements within the band are non-zeroes. The diagonal elements of the matrix are non-zeroes, and seven non-overlapping stripes may cover all the non-zero elements.

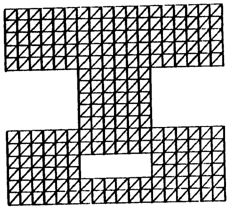

Fig 6 - A finite element grid

In Table 1, we compare the execution time of the different networks for this specific matrix. The number of global cycles is estimated by the construction of the computation fronts. The execution time of each global cycle, however, depends on the execution time of its communication and processing phases. The time of a processing phase is, roughly, $\tau_m$. However, the time of a communication phase depends on the communication activities during that phase. Although we did not discuss a way for the estimation of the communication activities, we give in Table 1 an estimate for these activities obtained by an analysis of the data profiles which are associated with the computation fronts. The details of this type of analysis may be found in [4] and [5].

For $MV_{4,p}$ and queue size d=1, execution terminates in 60 global cycles instead of 292 for $MV_{3,p}$. That is, a speed up of 4.867 is obtained (the increase in the communication time is small). Noting that only 16% of the operations in $MV_{3,p}$ involve non-zero operands, and thus that only one out of $\frac{100}{16}$=6.36 operations is useful, it is clear that, by skipping trivial operations in $MV_{4,p}$, we can retrieve $\frac{4.867}{6.36} \approx 76\%$ of the inefficiency in $MV_{3,p}$. Of course, internal data conflict accounts for the unretrieved 24%.

| | number of cells | size of comm. queues | number of global cycles | execution time |
|---|---|---|---|---|
| $MV_1$ | 39 | d=1 | 559 | $559\tau_m + 559\tau_c$ |
| $MV_2$ | 39 | d=1 | 270 | $270\tau_m + 305\tau_c$ |
| $MV_3$ | 39 | d=1 | 292 | $292\tau_m + 292\tau_c$ |
| $MV_4$ | 39 | d=1 | 60 | $60\tau_m + 425\tau_c$ |
| $MV_4$ | 39 | d=3 | 54 | $54\tau_m + 492\tau_c$ |
| $MV_5$ | 7 | $d_x$=12<br>$d_y$=1 | 279 | $279\tau_m + 305\tau_c$ |

Table 1 - Performance of the different networks

The result for $MV_5$ is obtained assuming that each y-stream communication link may buffer only one element, and that each x-stream communication link may buffer at least 12 data items. Clearly, the merit of $MV_5$ is not due to the speed up it achieves as much as it is for its small number of cells.

## 6. CONCLUSION

Pseudo systolic computations and irregular computation fronts are two tools that are used effectively in the analysis of the networks introduced in this paper. The alternative for this type of analysis is the simulation of the computations. Such simulation, however, requires explicit assumptions about the parameters $\tau_m$ and $\tau_c$, which are strongly dependent on technology and architectural details.

Our primary interest is in sparse systems that result from the solution of partial differential equations, which is one of the major sources of sparse matrices. For this reason, the networks suggested in Sections 3 and 4 take advantage of some specific properties in these matrices. However, the concept that we introduce is quite general. Namely, the inclusion of the non-zero elements of a sparse matrix in a pattern which is regular enough to allow for the efficient manipulation of the matrix on VLSI networks. The results reported in Section 5, and other similar results [4,5], support our argument.

**Abstract** -- This paper presents a parallel algorithm for the solution of the single-pair, single-source and all-pairs shortest path problems. The first time, all essential properties of the shortest paths can be computed on a pure systolic parallel processor in $O(n)$ time and on $O(n^2)$ area. If $O(n^3)$ area is spended, all single-pair shortest paths can be stored within the same time bound.

## I. Introduction

In this paper we are concerned with the well known shortest path problem. The single-pair, single-source and all-pairs problems entail finding shortest paths between two specified vertices, from one vertex to all others and between all pairs of vertices, respectively.

We concentrate on the systolic model of computation. In order to conform to the basic VLSI restrictions the parallel computer consists of single processing elements which have some local memory and are able to compute a simple set of instructions. Global communication and a severe system overhead are avoided as no shared memory is allowed.

In order to solve the all-pairs shortest path problem on a parallel computer the use of the Ford-Bellman-Moore, the matrix multiplication and the Floyd-Warshall algorithms have been proposed [1-6]. Lakhani [3] uses the Ford-Bellman-Moore algorithm to solve the all-pairs problem in $O(n^2)$ time. However, the complex architecture requires a complicated communication scheme and area consuming interconnections between processing cells. In [1,2,4,5,6] it is shown that the **distances** of the all-pairs shortest paths can be computed in $O(n)$ time and on $O(n^2)$ area if a parallel version of the Floyd-Warshall algorithm (**FWA**) is used.

But, in almost any application of the shortest path (**SP**) problem the **detection of the optimal route** itself is indispensible.

The new approach uses the same square arrangement of n×n identical processing cells as [1,2,4] or [5,6]. The following extensions are essential:

- In comparison to [7] within the same kind of loops of the FWA the predecessor and depth of each vertex w.r.t any SP is determined.
- In order to deal with the trees of SPs a conversion to an edge-based description is performed. Sorting operations are used to compute the desired path functions.

The first time, the following quantities can be computed on a systolic processor in $O(n)$ time and on $O(n^2)$ area: distance matrix, selection of a shortest route with minimal depth, predecessors and depth of any vertex w.r.t any SP, single-source trees of SPs as ordered lists of edges, adjacency matrix of a tree of SPs, single-pair SP as a list of edges, all-pairs SPs as $n^2$ lists of edges (if $O(n^3)$ area is spended).

## II. The Extended Floyd-Warshall Algorithm

Let us first clarify the notation used in the subsequent paper. We assume that each edge $(i,j)\varepsilon E$ has an associated integer valued length $l(i,j)$. A path from vertex r to t can be regarded as a tupel $P^k=(i_0,i_1,\ldots,i_k)$ of vertices $i_j$ with $k\geq 1$, $i_0=r$, $i_k=t$ and $(i_{j-1},i_j)\varepsilon E$ for all $1\geq j\geq k$. The path $P^k$ has the depth k which means that it consists of k edges and k+1 vertices. The length l of a path is the summation of the lengths of its edges. In order to clarify the extended FWA the following definitions can be used:

$\Pi_m(r,t) = \{\, P^k | k\geq 1, i_0=r, i_k=t, i_j\leq m \text{ for all } 1\leq j<k \,\}$
$\hat{=}$ set of paths at stage m from vertex r to t where all intermediate vertices are $\leq$ m

$d_m(r,t) = \text{Min}\{\, l(P^k) \mid P^k\varepsilon\Pi_m(r,t) \,\}$
$\hat{=}$ shortest distance at stage m from vertex r to t

$\Delta_m(r,t) = \{\, P^k \mid P^k\varepsilon\Pi_m(r,t) \text{ and } l(P^k)=d_m(r,t) \,\}$
$\hat{=}$ set of shortest paths from vertex r to t at stage m

$s_m(r,t) = \text{Min}\{\, k \mid P^k\varepsilon\Delta_m(r,t) \,\}$
$\hat{=}$ minimum depth at stage m from vertex r to t

$\Sigma_m(r,t) = \{\, P^k \mid P^k\varepsilon\Delta_m(r,t) \text{ and } k=s_m(r,t) \,\}$
$\hat{=}$ set of shortest paths at stage m from r to t with minimum depth

Assuming that one path $P^k\varepsilon\Sigma_m(r,t)$ has been selected it is possible to define the following values:

$p_m(r,t) = i_{k-1}$
$\hat{=}$ predecessor of t in the selected path from vertex r to t

In extension of e.g.[7] the algorithm described in Fig.1 has the following properties:

- Concurrent determination of the m-stage distance, predecessor and depth matrices
- Concurrent selection of the all-pairs SPs at stage m with minimum number of edges.

It will be seen in the next section that these improvements enable the computation of the shortest route between two specified vertices. Now, we can formulate the subsequent Lemma:

**Lemma:** If no negative cycle exists then $\Sigma_m(m,j)=\Sigma_{m-1}(m,j)$ and $\Sigma_m(j,m)=\Sigma_{m-1}(j,m)$ for each j.

**Proof:** We restrict the proof on $\Sigma_m(m,j)=\Sigma_{m-1}(m,j)$. Let us assume that $P^k\varepsilon\Sigma_m(m,j)\backslash\Sigma_{m-1}(m,j)$. Therefore $P^k$ could be partitioned into a cycle through m of depth b and $P^a=(m,\ldots,j)\varepsilon\Pi_{m-1}(m,j)$ where the length

0190-3918/86/0000/0762 $01.00 © 1986 IEEE

of the cycle is $l \geq 0$ and $b>0$. It would follow that $k=a+b>a \geq s_{m-1}(m,j)$ and $l(P^k)=l+l(P^a) \geq l(P^a) \geq d_{m-1}(m,j)$ which contradicts the assumption. □

Consequently it is possible to dispense with the modification of the elements $\cdot(m,j)$ and $\cdot(j,m)$ at stage m of the algorithm of Fig.1.

**Theorem:** At stage m the modified FWA detects a path $P^k$ from vertex r to t with $P^k \varepsilon \Sigma_m(r,t)$.

**Proof:** We assume by an inductive hypothesis that the theorem holds at stage m-1. The path $P^k$ is the resulting path from r to t of the extended FWA. We distinguish between two cases a) and b):

a) $\Sigma_{m-1}(r,t) \cap \Sigma_m(r,t) \neq \emptyset$
  $\rightarrow s_{m-1}(r,t)=s_m(r,t)$ and $d_{m-1}(r,t)=d_m(r,t)$
  $\rightarrow P^k \varepsilon \Sigma_{m-1}(r,t) \subseteq \Sigma_m(r,t)$

b) $\Sigma_{m-1}(r,t) \cap \Sigma_m(r,t)=\emptyset$
  $\rightarrow d_{m-1}(r,t)>d_m(r,t)$ or
  $( d_{m-1}(r,t)=d_m(r,t)$ and $s_{m-1}(r,t)<s_m(r,t) )$
  $\rightarrow P^k$ consists of paths $P^a \varepsilon \Sigma_{m-1}(r,m)$ and
  $P^b \varepsilon \Sigma_{m-1}(m,t)$ selected of FWA at stage m-1

  We assume that there exists $P^\kappa \varepsilon \Sigma_m(r,t)$ which consists of $P^\alpha \varepsilon \Pi_{m-1}(r,m)$ and $P^\beta \varepsilon \Pi_{m-1}(m,t)$
  $\rightarrow d_m(r,t)=l(P^\kappa)=l(P^\alpha)+l(P^\beta) \geq l(P^a)+l(P^b)=l(P^k)$
  and $s_m(r,t)=\kappa=\alpha+\beta \geq a+b=k$ if
  $P^\alpha \varepsilon \Delta_{m-1}(r,m)$ and $P^\beta \varepsilon \Delta_{m-1}(m,t)$ .

Now it has been proved that the values $d_m$, $p_m$ and $s_m$ are evaluated correctly by the extended FWA. □

The extended FWA detects for the all-pairs SP a SP with minimum depth as well as the Ford-Bellman-Moore algorithm for the single-source problem does. In contrary, the common FWA can only assure that $P^k \varepsilon \Delta_n(r,t)$.

## III. Determination of a Single-Pair Shortest Path

The detection of a SP from vertex r to t can be divided into two different steps:

- Determination of a tree which contains the SP
- Finding of the SP between the vertices r and t

Obviously, the tree of SP with the root vertex r is an appropriate one for the first part. The tree is determined by its edges (p(r,j),j) evaluated by the FWA. These values can be stored in a linear array of length n to compute the desired path according to the second step.

But problems arise as data sharing is restricted to neighboring processors only in a systolic array and the necessary data may be far apart. Up to n-1 sequential operations each of which requiring O(n) steps in the worst case are needed if no suitable order of edges exists. In contrary to [8] a much simpler sorting scheme than the Euler circuit can be used to receive a time bound of O(n) as the depth s(r,j) of each node j is available from FWA. The following solution strategy is chosen:

- Sorting of the edges (p(r,j),j) according to the depths s(r,j). The following chain is obtained:
  $(p(r,j_1),j_1)\ (p(r,j_2),j_2)\ \ldots\ (p(r,j_n),j_n)$
  with $s(r,j_i) \leq s(r,j_{i+1})$ for all $i=1,\ldots,n-1$
- Scanning of the sorted chain in descending order of depths and selection of the SP from r to t according to the following procedure:

```
procedure path
  for i=n down to 1 do begin
    if $j_i$=t then begin
      $j_i$ ε 'path from r to t'
      t:=p(r,$j_i$)
    end
```

## IV. Systolic Implementation

At first, the solution to the first subproblem is described where Fig.2 shows the interconnection scheme of the array apart from the outputs T1 to T4 and the inputs Φ,In4. As this part is similar to [5] the internal cells are described only. The following notations are used: $R(i,j)=[f_1,f_2,\ldots]$ denotes a register within cell C(i,j) where the datas $f_1,\ldots$ are stored in a common record. R(i,j).k denotes $f_k$. The sign ← denotes an assignment between cells which needs one time step. Corresponding data are transferred. The sign := denotes an assignment and :=: an exchange of data within one cell and one instant.

```
procedure C(l,m)   { 2≤l,m≤n ; $R_{123}$=[d⊙s,p] }
  $R_1$ ← $R_1$(l,m-1)
  $R_2$ ← $R_2$(l-1,m)
  $R_3$ ← $R_3$(l+1,m+1)
  if $R_3$.1>$R_1$.1+$R_2$.1  then  $R_3$:=[$R_1$.1+$R_2$.1 , $R_2$]
```

The operation of this cell corresponds to the 'if'-statement of the FWA. The executuion of the 'and'- and 'or'-operations can be avoided by the concatenation d(i,j)⊙s(i,j) where the bits of s(i,j) are linked less significantly to those of d(i,j). The sequence of input and output operations of the systolic FW-array are similar to [5,6].

### 1. Solution of the single-source SP problem

The first line of the array according to Fig.2 contains in addition to the cells C(1,m) the sorting cells S(1,m). Moreover, all registers of the FW cells contain besides d(i,j), s(i,j), p(i,j) the corresponding node j with R=[d⊙s,p,j]. The output T1 successively carries the edges (p(r,j),j) of the tree of SPs rooted from vertex r in descending order of depths s(r,j).

```
procedure S(1,1)     { In,$R_4$=[φ] ; $R_5$=[s,p,j,φ] }
  $R_4$ ← In  ;  $R_5$ ← $R_3$(2,2)
  if $R_4$=1  then  $R_5$.4:=1
              else  $R_5$  :=[∞,∞,∞,0]

procedure S(1,m)     { 2≤m≤n  ;  $R_{567}$=[s,p,j,φ] }
  $R_5$ ← $R_5$(1,m-1)  ;  $R_7$ ← $R_3$(2,m+1)
  if $R_5$.4=1     then  $R_6$:=$R_7$  ; $R_6$.4:=0
  if $R_5$.1<$R_6$.1 then  $R_5$:=:$R_6$
  if $R_6$.4=1     then  $R_5$.4:=1 ; $R_6$.4:=0

procedure S(1,n+1)  { T1,$R_5$=[s,p,j,φ] }
  $R_5$ ← $R_5$(1,n)   ;   T1:=$R_5$
```

Cell S(1,1) has to be initialized with $\phi$=1 at the time where the elements $\cdot$(r,r) are read in. This correct timing can be achieved also by detecting that $R_5$.3=r in cell S(1,1). This initialization propagates from m=1 to m=n+1.

### 2. Solution of the single-pair SP problem

In contrary to the foregoing array, cell S(1,n+1) marks all edges which belong to the SP from r to t. To this end, the vertex number t has to be read into this cell before the first edge of the single-source tree enters. The variable $\psi$ is $\psi$=1 if the edge is part of the SP from r to t.

```
**procedure** S(1,n+1)  { T1,$R_5$=[s,p,j,$\psi$] ; In4,$R_8$=[p] }
   $R_5 \leftarrow R_5(1,n)$
   **if** 'input operation' **then** $R_8$:=In4
   **if** $R_5$.3=$R_8$.1 **then** $R_8$:=[$R_5$.3] ; $R_5$.4:=[1]
                     **else** $R_5$.4:=[0]
   T1:=$R_5$
```

If the output T1 propagates to the left through the cells S(1,m) it is possible to delete the edges with $\psi$=0 such that the searched edges can be read out from S(1,1) concurrently.

### 3. Solution of the all-pairs SP problem

According to Fig.2 each row contains a copy of the linear sorting array just described. The initialization has to take place if $\cdot$(1,1) enters S(1,1). After that, the initialization propagates down and right in form of a wave front. The outputs Tl concurrently carry the edges of the trees of SPs rooted from vertices l.

If the outputs Tl are propagated to the left, it is possible to store in S(l,m) the SP from l to m in form of a list of edges (O($n^3$) area is needed).

## V. Concluding Remarks

It is noted that the above algorithms can be used to solve other combinatorial optimization problems which require the determination of a shortest paths or breadth-first spanning tree. The determination of the adjacency matrix of the single-source tree of SP is possible too in O(n) time if the cells in the first row and last column of the systolic array have additional functions.

Recently, it has been shown by the authors [9] that algorithms of the form shown in Fig.1 can be carried out on a linear systolic array in O($n^2$) time with O(n) operating cells. The data at the input and output occur in lexicographical order and pipelined arithmetic units can be used.

# SYNTHESIZING NON-UNIFORM SYSTOLIC DESIGNS*

Concettina Guerra
Rami Melhem
Department of Computer Sciences, Purdue University
West lafayette, Indiana 47907

Abstract -- In this paper we propose a method to derive systolic designs with non-uniform data flow. One of the major difficulties in systematic design is in transforming the original sequential specification of a problem into a form suitable to VLSI implementation. Our approach to automatically restructuring a problem is based on a subset of the data dependencies extracted from the original problem specification. By using such dependencies we are able to identify chains of dependent computations which are then converted into recurrence equations. The mapping of the new specification into hardware is also based on data dependencies. We illustrate the methodology by applying it to algorithms using dynamic programming.

## 1. Introduction

The development of efficient VLSI algorithms is relevant to many applications including signal and image processing, which justifies the considerable interest for this topic. In recent years, the problem of synthesizing VLSI design - and systolic design, in particular - has also received much attention. Systematic methodologies for the derivation of systolic algorithms have proved useful both in finding new designs and in verifying the correctness of old ones. Moreover, the possibility of automatically generating a number of viable algorithms for the solution of a given problem enables the selection of an optimal algorithm among a wider set of candidates. The optimality can be based on such parameters as completion time $T$, number of processors $P$, chip area, etc.[9]. Most of the existing synthesis methods tend to minimize the completion time.

Systolic systems generally are characterized by simple processing elements and regular and local communication pattern. However, the definition of a systolic system changes according to different authors. Here we shall refer to synchronous systems, i.e. systems with a global clock for the timing of all processing elements, and assume that all computations are data independent.

The first and probably most challenging part of the systematic design process is in the transformation of the high-level problem specification into a form better suited to VLSI implementation. Such a form can be, for example, a system of first-order recurrence equations, a uniform recurrence equation, or nested loops with constant data dependencies. Often, this transformation is obtained by using techniques similar to those used for software compilers: buffering of variables, addition of new variables, etc. However, it is not well understood how to select a good transformation especially for some complex non-numerical problems. Some authors assume that the problem is already given in the required form, and concentrate on how to map it into hardware.

A fundamental distinction between different approaches to the mapping problem is whether they use data dependence based transformations [1, 3, 8-13] or delay operators applied to the mathematical expression of the algorithm [5]. For a survey of the various methods see [2].

The transformational approach based on data dependencies has been successfully applied to a variety of algorithms characterized by constant data dependencies. For such algorithms linear time and space transformations of the index set into VLSI arrays have been derived [11-13]. The resulting designs have constant and regular data flow. However, a number of more complex problems with non-constant data dependencies require non linear transformations. A typical example is the optimal parenthesization problem, which uses dynamic programming.

A non-linear transformation for dynamic programming was indicated in [12]. However, the paper does not precisely describe how the transformation is obtained from the algorithm specification. Chen [1] presents a methodology for mapping algorithms expressed as systems of first order recurrence relations into systolic arrays. The synthesis procedure allows designs with non-uniform communication patterns. The mapping is done inductively, starting at the boundary conditions. By using this technique, various designs, corresponding to different communication patterns in the systolic array, are derived for dynamic

programming. The procedure, based on a point-by-point mapping, appears to be quite lengthy. In [10] a mathematical model, based on a sequence notation, is used to represent index transformations. The model provides a precise specification of systolic designs. It allows arbitrary interconnections in systolic networks and is not restricted to linear transformations. The paper does not give a constructive methodology to find the transformations.

This paper presents a systematic method for the design of VLSI algorithms. The method consists of transforming the high-level problem specification into a set of mutually dependent recurrence equations. To select the appropriate transformations we propose a two-step refinement procedure. The procedure first determines a coarse timing function of the computations in the original specification of the problem, based on a maximal set of constant data dependencies; then uses this function to guide the search for an index transformation. Ordered chains of dependent computations are identified in the algorithm, according to such function, and an index transformation is applied to each single chain. The index transformation must be compatible with the timing function, i.e. all the computations whose operands are available first will be performed first. Subsequently, the mapping of the obtained system of recurrence equations into a VLSI network is performed by applying linear time and space transformations separately to each recurrence subject to global constraints. The resulting design may have non-uniform data flow.

This paper is organized as follows. Section 2 describes a method which helps deriving from an abstract algorithm a set of mutually dependent recurrence equations. Section 3 illustrates the method by applying it to dynamic programming. In section 4 time-space transformations are used to map the new specification into a VLSI array.

## 2. Deriving a systolic algorithm from the high-level specification

In this section we discuss how to transform the high-level problem specification to adapt it to a VLSI architecture. The task of enhancing pipelining and local communication in an algorithm is generally accomplished by index transformations which involve adding indices to existing variables in the algorithm, or by renaming variables, or by introducing new variables. The aim of these transformations is to produce a new specification which is in *canonic form*.

*Definition.* A canonic form consists of a structured set of computations written as a recurrence relation or a nested loop. The set includes input statements, output statements, assignment statements, and conditional assignment statements. The recurrence relation or nested loop defines an index set $I^n=\{(i_1,\ldots,i_n) \mid l_1^1 \le i_1 \le l_1^2,\ldots,l_n^1 \le i_n \le l_n^2\}$, subset of the set $Z^n$ of the $n$-tuples of integers. We assume that the following conditions are satisfied:

CA1 - each variable in the algorithm is associated with an index vector $\bar{i}=(i_1,i_2,...,i_n)$, i.e. is an element of an $n$-dimensional array. In other words, there is a one-to-one correspondence between the $n$-tuples in $I^n$ and the dimensions of any array used in the algorithm.

CA2 - if $S$ is an assignment statement indexed by $(i_1,i_2,...,i_n)$, and a variable on the right side of $S$ is indexed by $(j_1,j_2,...,j_n)$, then each $i_k$ may depend only on $j_k$.

CA3 - a variable is used exactly once after it is generated.

It is not always possible to transform a given problem into canonic form. For problems which do not have such a representation we attempt to rewrite them into a form of many modules each being in canonic form, i.e. satisfying condition CA1-CA3.

The canonic form does not explicitly specify any ordering among the computations; the lexicographical ordering in $I^n$ is arbitrary and therefore irrelevant to our purposes. Rather, an implicit partial ordering of the computations is given by the data dependencies. The dependence vector of a variable is defined as the difference of the index vectors of computations where the variable is used and generated [7]. The data dependence vectors $\bar{d}_1,\ldots,\bar{d}_m$ associated to the variables of a recurrence can be represented as a matrix $D=[\bar{d}_1 \cdots \bar{d}_m]$, whose columns are labelled by the variable names. A variable may have many dependencies each corresponding to a different index vector; in this case there will be a column in the $D$ matrix for each pair *(variable, index vector)*, labelled by the pair itself. A partial ordering $>_D$ defined in $I^n$ by the data dependencies is such that $\bar{i} >_D \bar{i}'$ if $\bar{i}=\bar{i}'+\bar{d}_j$ for some $\bar{d}_j \in D$.

Transformations applied to derive a canonic form do not change the algorithm fundamentally, but only the data dependencies among the variables. The new data dependencies in the resulting specification of the problem are therefore not characteristic of the problem itself but of its parallel implementation. Indeed, as is well known, there are in general several ways to transform a given problem specification, according to the previous rules, each way producing a different set of data dependencies. However, not all the possible transformations lead to a feasible VLSI design. Moreover, different transformations may result in different performances. Consider the two following examples:

*Example 1.* The convolution problem is defined by : given a sequence $x_1,\ldots,x_n$ and a set of weights $w_1,\ldots,w_k$, determine the sequence $y_1,\ldots,y_n$ such that:

$$y_i \;=\; \textstyle\sum_{k=1,s} w_k * x_{i-k}$$

Broadcasting of $x$ and $w$ can be eliminated by adding one more index to all variables $x$, $w$, and $y$. At least two different index transformations can be applied which produce the two recurrences in canonic form below: the first is a backward recurrence, where the variable $y_{i,k}$ is defined in terms of $y_{i,k-1}$, and the second is forward recurrence, where the variable $y_{i,k}$ is defined in terms of $y_{i,k+1}$.

$$\begin{aligned} & 0 \le i \le n \ ; \ 0 \le k \le s \\ & w_{i,k} = w_{i-1,k} \\ & x_{i,k} = x_{i-1,k-1} \\ & y_{i,k} = y_{i,k-1} + w_{i,k} * x_{i,k} \end{aligned} \qquad (1)$$

$$\begin{aligned} & 0 \le i \le n \ ; \ 0 \le k \le s \\ & w_{i,k} = w_{i-1,k} \\ & x_{i,k} = x_{i-1,k-1} \\ & y_{i,k} = y_{i,k+1} + w_{i,k} * x_{i,k} \end{aligned} \qquad (2)$$

Data dependencies corresponding to the two recurrences introduce two different partial orderings in $I^2 = \{(i,k) \mid 0 \le i \le n;\ 0 \le k \le s\}$, which translate into two different schedules for the computations and consequently into different systolic designs.

*Example 2* . Recursive convolution

This problem can be expressed as: given a sequence of weights $w_1,..,w_k$, determine the sequence $y_1,..,y_n$ such that:

$$y_i \ = \ \sum_{k=1,s} w_k \ * \ y_{i-k}$$

Of the two recurrences which can be derived by using transformations similar to those used for the convolution problem, only the forward recurrence has to be considered for a systolic implementation. The backward recurrence uses data before they are generated therefore cannot result in any meaningful design.

For more complex problems, such as optimal parenthesization using dynamic programming, selecting a good initial transformation is not an obvious task and in fact straightforward transformations such as those applied to the convolution problem fail. It is clear that this part of the synthesis procedure sometimes requires creativity and programming experience. We suggest a way to assist the human designer in this crucial task. The method we propose here relies on identifying a set of constant data dependencies in the original formulation of the problem.

### A two-step procedure

We assume that the high level specification of a problem is written in the form of a nested loop with the index set $I^n$ defined by:

$$I^n = \{(i_1, \ldots, i_n) \mid l_1^1 \le i_1 \le l_1^2, \ldots, l_n^1 \le i_n \le l_n^2\}.$$

We assume that, unlike the canonic form, the loop contains a variable which is an $s$-dimensional array. More specifically, we let $s=n-1$ and assume that the loop contains an assignment statement of the form:

$$c(\bar{i^s}) = f(c(\bar{i^s} - \bar{d}_1^s), \ldots, c(\bar{i^s} - \bar{d}_m^s)) \qquad (3)$$

where: $\bar{i^s} = (i_1, i_2, \ldots, i_s)$ is an $s$-tuple of indices of the loop;

$\bar{d}_j^s = (a_{j,1}, .., a_{j,t-1}, i_t - i_n, a_{j,t+1}, .., a_{j,s})$ , $j=1,..,m$;

and where $a_{j,l}$ are integer constants. In other words, the index $i_t$ on the left side of (3) is replaced on the right side by the index $i_n$.

Each vector $\bar{d}_j^s$, $(j=1,..,m)$, represents a non constant data dependence for variable $c$, since its $t$-th component is a function of the two indices $i_t$ and $i_n$. We can expand $\bar{d}_j^s$ into a number of data dependence vectors, each corresponding to a specific value of index $i_n$ in the $t$-th component. Then, we associate to each pair (*variable ,index vector*)=$(c, \bar{i}_s)$ the set $D_{\bar{i^s}}^c$ of all the data dependence vectors obtained by expanding $\bar{d}_1^s,..,\bar{d}_m^s$.

Our strategy to select the initial index transformation consists of a two-step procedure. Let $I^s = \{(i_1,\ldots,i_s) \mid l_1^1 \le i_1 \le l_1^2, \ldots, l_s^1 \le i_s \le l_s^2\}$. First, determine from the high-level specification of the problem a coarse timing function $T: I^s \to Z$. This function will be used in the subsequent step of the procedure to guide the search for a schedule of computations indexed by $I^n$. We derive $T$ from a subset of the data dependencies of the algorithm, namely, the subset of constant data dependencies, thus, $T$ provides only a lower bound for an actual timing function for $I^s$. Furthermore, $T$ depends only on the implicit dependencies of the problem since it is derived before any arbitrary ordering of the computations is introduced. The set $D_{\bar{i^s}}^c$ of data dependencies is non constant in the computation space. However, the set $D^c$ defined as the intersection of $D_{\bar{i^s}}^c$ for all $\bar{i^s} \in I^s$ contains only constant data dependencies. For a nested loop with constant data dependencies, a linear (or quasi-affine) timing function can be determined by applying the transformational method described in [11,13]. Thus, if $D^c$ is not empty we can derive a linear timing function $T : I^s \to Z$ which is compatible with the set $D^c$, i.e. $\bar{i^s} >_{D^c} \bar{i'^s}$ implies $T(\bar{i^s}) > T(\bar{i'^s})$. In [11, 13] necessary and sufficient conditions for the existence of a linear timing function are given. In particular, it must be:

$$T(\bar{d}_i) > 0 \ \text{ for } \textit{each } \bar{d}_i \in D^c \qquad (4)$$

System (4) may have no solution or several solutions. In this latter case, the one which minimizes the total execution time (defined as the difference between the minimum and maximum value of $T$) is chosen.

It obvious that if $\tau$ is an actual timing function for $I^s$ then it must be $\tau(\bar{i^s}) \geq T(\bar{i^s})$ for each $\bar{i^s} \in I^s$. Moreover, because of the monotonocity of data dependencies in $D^c_{\bar{i^s}}$ , it must be $\tau(\bar{i^s}) > \tau(\bar{i'^s})$ if $T(\bar{i^s}) > T(\bar{i'^s})$.

The partial ordering defined by $T$ on the set of computations $I^s$ defines a partial ordering in a subset of $I^n$ based on the availability of operands. Consider the set $J^n \subset I^n$ consisting of the $n$-tuples $(\bar{i^s}, i_n)$ for any given $\bar{i^s} \in I^s$ and for $l_n^1 \leq i_n \leq l_n^2$. For any two such $n$-tuples, we introduce the relation $>_T$ defined by:

$$(\bar{i^s}, i_n') >_T (\bar{i^s}, i_n'') \quad \Longleftrightarrow$$

$$Max\{T(\bar{i^s}-\bar{d}_1'),\ldots, T(\bar{i^s}-\bar{d}_m')\} > Max\{T(\bar{i^s}-\bar{d}_1''),\ldots, T(\bar{i^s}-\bar{d}_m'')\}$$

where $\bar{d}_j'$ and $\bar{d}_j''$ $(j=1,..,m)$ are the data dependence vectors in (3) corresponding to values $i_n'$ and $i_n''$, respectively, of index $i_n$. Obviously, the relation $>_T$ is a partial ordering in $J^n$. Thus, $J^n$ can be decomposed into a number of chains, i.e. subsets whose elements are linearly ordered (relative to each other). Of course, there will be only one chain if the relation $>_T$ is linear to start with. Each chain consists of indexed computations which have to be carried out one after the other in a specific linear ordering. Computations belonging to different chains can be carried out independently. Among the many chain decompositions of the partially ordered set $J^n$, we choose the one in which the computations in a chain are also sorted (in either increasing or decreasing order) according to the index $i_n$. Let us denote by $s$ the number of such chains.

At this point, we are ready to restructure the given algorithm. We partition the computations indexed by $J^n$ into $s$ separate recurrences, each corresponding to a distinct chain. In each recurrence the ordering for index $i_n$ is chosen according to its ordering in the chain. Then, we transform each recurrence into canonic form using the three previous rules: 1) adding missing indices, 2) adding new variables, and 3) renaming old variables. In addition we also add statements between recurrences to correlate variables in distinct recurrences. In fact, a recurrence may use a variable generated in another recurrence. This last step may introduce non-constant data dependencies in the system.

In conclusion, the obtained new specification is expressed as a system of $s$ modules, each module being a recurrence equation in canonic form. Non-constant data dependencies may occur between variables of different modules.

## 3.An application to dynamic programming

Consider the dynamic programming technique applied to such problems as optimal parenthesization, and shortest path. Both problems can be expressed by the recurrence:

$$1 \leq i \leq n; i < j \leq n$$

$$c_{i,j} = \min_{i<k<j} f(c_{i,k}, c_{k,j}) \qquad (5)$$

with initial conditions:

$$c_{i,i+1} = c_i \quad 1 \leq i \leq n$$

for some function $f$. Note that no explicit ordering for the indices $i, j$, and $k$ is specified. If we choose the normal lexicographical ordering for the three indices and we apply some index transformation we can derive a canonic form from the above recurrence; however, the systolic implementation of it will have execution time $O(n^2)$ since it does not overlap the computations of $c_{i,j}$ for different $k$.

Let $I^3=\{(i,j,k) \mid 1 \leq i, j \leq n; i<k<j\}$ be the index set of the recurrence above; and let $I^2=\{(i,j) \mid 1 \leq i, j \leq n\}$ be the index set defined by variable $c$. Each pair $(c, (i, j))$ is associated with a distinct set of data dependencies (here represented in matricial form):

$$D^c_{(i\ j)} = \begin{vmatrix} 0 & \text{i-k} \\ \text{j-k} & 0 \end{vmatrix}$$

or in expanded form:

$$D^c_{(i\ j)} = \begin{vmatrix} 0 & \ldots & 0 & 0 & -1 & -2 & \ldots & \text{i-j+1} \\ \text{j-i+1} & \ldots & 2 & 1 & 0 & 0 & \ldots & 0 \end{vmatrix}$$

The intersection $D^c$ of all the set $D^c_{(i,j)}$ $(1 \leq i, j \leq n)$ is non empty and is given by:

$$D^c_{(i\ j)} = \begin{vmatrix} 0 & -1 \\ 1 & 0 \end{vmatrix}$$

We derive a timing function $T : I^2 \rightarrow Z$ compatible with $D^c$. Since $D^c$ contains only constant data dependencies, we can apply the methodology discussed in [11] to determine a linear timing function. Conditions (4) applied to the data dependence vectors in $D^c$ give:

$$T_1 > 0 \quad \text{and} \quad T_2 \leq -1$$

The least integer values that satisfy the above equations are:

$$T_1 = 0 \quad \text{and} \quad T_2 = -1.$$

Thus, the optimal time transformation is:

$$T(i,j) = j - i.$$

Next we consider the partial ordering $>_T$ in $J^3=\{(i,j,k) \mid i,j \textit{ are fixed} \text{ and } i<k<j\}$ defined by:

$$(i,j,k') >_T (i,j,k'') \quad \Longleftrightarrow$$

$$Max\{\, T(i,k'), T(k',j)\} \;>\; Max\{\, T(i,k''), T(k'',j)\}$$

Notice that the minimal elements with respect to $>_T$ are:

$(i, j, (i+j)/2)$ if $i+j$ is even or

$(i, j, (i+j-1)/2)$ and $(i, j, (i+j+1)/2)$ if $i+j$ is odd.

By repeatedly finding minimal elements after removing the previous minimal elements from the set we obtain a decomposition of $J^3$ in the two chains below (here we only write the third component of the index vectors):

{if (i+j) is even}

$(i+j)/2, (i+j)/2-1, ..., i+1;$

$(i+j)/2+1, (i+j)/2+2, ..., j-1.$

{if (i+j) is odd}

$(i+j-1)/2, (i+j-1)/2-1, ..., i+1;$

$(i+j+1)/2, (i+j+1)/2+1, ..., j-1;$

We can now rewrite (5) into a form where the execution ordering of index $k$ is specified according to the above chains. The new specification of the problem consists of two recurrences: the first recurrence is a forward recurrence where the index $k$ varies from $(i+j)/2$ to $i+1$ (or from $(i+j-1)/2$ to $i+1$ if $i+j$ is odd); and the second is a backward recurrence where $k$ varies from $(i+j)/2$ to $j-1$ (or from $(i+j+1)/2$ to $j-1$ if $i+j$ is odd) . To transform each recurrence into canonic form some further manipulation is necessary. We first add missing indices to variables on both sides of (5) and then introduce new recurrence variables to eliminate broadcast of a variable to different destinations. We use different sets of variables for the two recurrences. Each recurrence initializes some of its variables to values generated by the other recurrence. Now equations (5) can be converted into the following system of mutually dependent recurrence equations:

```
        for $i$ :=1 to $n-1$ do $a''_{i,i+1,i+1} := c_{i,i+1}$;  $c_{i,i+1,i+1} := c_{i,i+1}$;
        for $l$ := 2 to $n-1$ do
      for $i$ := 1 to $n$ do begin
            $j := i+l$;
            if $(i+j)$=$even$) then begin
A1:             $k :=(i+j)/2$; $a'_{i,j,k} = a''_{i,j-1,k}$ ;
A2:             if $k= i+1$ then $b'_{i,j,k} := c_{i+1,j,j}$ else $b'_{i,j,k} := b'_{i+1,j,k}$ ;
                $c'_{i,j,k} := f(a'_{i,j,k}, b'_{i,j,k})$; $c''_{i,j,k} := c'_{i,j,k}$
                end
            else begin    {i+j=odd};
                $k :=(i+j-1)/2$; $a'_{i,j,k} := a'_{i,j-1,k}$ ;
                if $k= i+1$ then $b'_{i,j,k} := c_{i+1,j,j}$ else $b'_{i,j,k} := b'_{i+1,j,k}$ ;
                $c'_{i,j,k} := f(a'_{i,j,k}, b'_{i,j,k})$
                $k := (i+j+1)/2$;
A3:             if $k := j-1$ then $a''_{i,j,k} := c_{i,j-1,j-1}$ else $a''_{i,j,k} := a''_{i,j-1,k}$ ;
A4:             $b''_{i,j,k} := b'_{i+1,j,k}$ ;
                $c''_{i,j,k} := f(a''_{i,j,k}, b''_{i,j,k})$;
                end
            for $k := \lceil (i+j-1)/2 - 1 \rceil$ downto $i+1$ do begin
                $a'_{i,j,k} := a'_{i,j-1,k}$ ;
                if $k= i+1$ then $b'_{i,j,i+1} := c_{i+1,j,j}$ else $b'_{i,j,k} := b'_{i+1,j,k}$ ;     module 1
                $c'_{i,j,k} := h(c'_{i,j,k+1}, f(a'_{i,j,k}, b'_{i,j,k}))$;
                end;

            for $k := \lfloor (i+j+1)/2 +1 \rfloor$ to $j-1$ do begin
                if $k= j-1$ then $a''_{i,j,k} := c_{i,j-1,j-1}$ else $a''_{i,j,k} := a''_{i,j-1,k}$ ;        module 2
                $b''_{i,j,k} := b''_{i+1,j,k}$ ;
                $c''_{i,j,k} := h(c''_{i,j,k-1}, f(a''_{i,j,k}, b''_{i,j,k}))$:
                end;
A5:         $c_{i,j,j} := h(c'_{i,j,i+1}, c''_{i,j,j-1})$;
            end.
```

From the above specification we extract distinct sets $D_1$ and $D_2$ of local data dependencies for the two modules.

$$D_1 = \begin{array}{|ccc|} c' & a' & b' \\ 0 & 0 & -1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{array} \qquad D_2 = \begin{array}{|ccc|} c'' & a'' & b'' \\ 0 & 0 & -1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{array}$$

Non-constant dependencies between variables of distinct recurrences are defined by statements A1 to A5 in the algorithm. We will refer to such dependencies as global dependencies.

## 4.Mapping the algorithm into hardware

Once the algorithm has been converted into the new form, the mapping into a VLSI array can be accomplished in two steps:

1) Finding for each individual module in the algorithm representation a separate timing function which is compatible with the local data dependencies and also satisfies the constraints imposed by the global dependencies.

2) Finding a space mapping for each module into the processors of a physical network which is compatible with the timing function and satisfies global constraints.

Assume that each processor of a VLSI array is assigned a label $l \in L^{n-1} \subset Z^{n-1}$ . Furthermore, the connection pattern of the network is described by a set of vectors $\Delta = [\delta_1, \delta_2, \ldots, \delta_s]$ which specify the interconnections among the processors. Precisely, $\delta_i$ is the difference of the integer labels of adjacent cells in the network.

The space mapping is a mapping from the set of computations to the set of processors

$$S : I^n \rightarrow L^{n-1}$$

which maps simultaneous computations into distinct processors. Determining a solution for $S$ is equivalent to find a solution to the diophantine equations:

$$SD = \Delta K \qquad (6)$$

for which the matrix $\begin{bmatrix}\tau \\ S\end{bmatrix}$, $\tau$ being the time function, is nonsingular. In (6) $K$ is an integer matrix with positive elements. The equations may not have any solution or have several solutions. If no feasible solution is found, the design procedure is repeated by starting with a different timing function or else a different physical network. If several solutions are possible, the one which is optimal according to some criterion is chosen. A criterion can be, for example, the minimum number of required processors. These issues are discussed in [3].

Referring again to the dynamic programming algorithm, we first seek linear time transformations $\lambda$ and $\mu$ for module 1 and 2, respectively. Furthermore, let $\sigma$ be the timing function for computation in A5 outside the two modules. The linearity requires that for the dependence vectors of the modules it must be:

$$\lambda\,(\bar{d}) > 0 \quad \text{for } \bar{d} \in D_1 \quad \text{and} \quad \mu\,(\bar{d}) > 0 \quad \text{for } \bar{d} \in D_2$$

that is:

$$\lambda_1 \leq -1 \qquad \lambda_2 \geq 1 \qquad \lambda_3 \leq -1$$
$$\mu_1 \leq -1 \qquad \mu_2 \geq 1 \qquad \mu_3 \geq 1.$$

Constraints specified by A1-A5 lead to the following equations:

$$\begin{gathered} \lambda(i, j, (i+j)/2) > \mu(i, j-1, (i+j)/2) \\ \lambda(i, j, i+1) > \sigma(i+1, j, j) \\ \mu(i, j, j-1) > \sigma(i, j-1, j-1) \\ \mu(i, j, (i+j+1)/2) > \lambda(i+1, j, (i+j+1)/2) \\ \sigma(i, j, j) \geq \max[\lambda(i, j, i+1), \mu(i, j, j-1)] \end{gathered}$$

It easy to check that an optimal solution to the above system is given by:

$$\lambda_1 = -1 \qquad \lambda_2 = 2 \qquad \lambda_3 = -1$$
$$\mu_1 = -2 \qquad \mu_2 = 1 \qquad \mu_3 = 1$$
$$\sigma_1 = -2 \qquad \sigma_2 = 1 \qquad \sigma_3 = 1.$$

Hence:

$$\lambda(i,j,k) = -i+2j-k$$
$$\mu(i,j,k) = -2i+j+k$$
$$\sigma(i,j,j) = -2i+2j.$$

The next step is to find a mapping of the computations indexed by $I^3$ into the processors of a VLSI array. We consider a triangular array labelled by $L^2 = \{(x,y)\} \subset Z^2$. The interconnections among cells are specified by the matrix:

$$\Delta = \begin{vmatrix} 0 & 0 & 1 \\ 0 & -1 & 0 \end{vmatrix}$$

The mapping function $S : I^3 \rightarrow L^2$ of the computations in the triangular array is obtained with a construction similar to the one for the timing functions. The same space function is determined for the two modules and is given by:

$$S(i,j,k) = (j,i).$$

The resulting design is identical to the one first introduced in [4]. The systolic array and the action of a cell are depicted in figure 1.

## 5.Conclusions

We have suggested a methodology to assist a human designer into the difficult task of designing a VLSI algorithm starting from a sequential specification of a problem. Among the many possible transformations which can make parallelism explicit in a program the method helps selecting a feasible and optimal sequence of transformations. The methodology appears useful for complex nonnumerical problems for which standard restructuring techniques seem inadequate. The class of obtainable designs is not restricted to designs having constant data flow.

## Abstract

We illustrate that the verification of systolic architectures can be carried out using techniques developed in the context of verification of programs. This is achieved by partitioning the original problem into three parts, namely proving the correctness of the data representation, of the individual processing elements, and of a composition of a number of such processors. By expressing a processing element as a function on a stream of data we are able to utilize standard proof techniques from programming language theory. This decomposition leads to relatively straightforward proofs of the properties of the systolic architecture. We illustrate the techniques via a substantial example, namely the proof of the correctness of a linear-time systolic architecture for computing the gcd of polynomials. Although this architecture has been designed a few years ago, a formal proof of correctness has not hitherto appeared in the literature.

## I Introduction

In the last few years there has been much interest in the use of formal techniques for the design and analysis of VLSI circuits. Special formalisms have been invented for expressing transformations and specifications of such circuits. One important aspect of the analysis of circuits is the correctness problem. In this paper we address the correctness problem for an important class of parallel architectures, namely systolic arrays. This problem is decomposed in such a manner that formal techniques from programming language theory can be used in a straightforward manner. The particular techniques we use were invented in the context of proving the correctness of data representations [3] and semantics of functional languages [4].

The individual processors in systolic arrays act synchronously (at least they can be conceptually viewed thus, even though the actual implementation may be asynchronous) on streams of data tokens. As a result their operation can be divided into a three-step *read-execute-write* cycle, where the execute phase does not branch on the *availability* of data values. It has been shown [4] that under such conditions the action of such a process can be described completely by a *stream function*. The action of the entire network is therefore merely the composition of these individual functions. The verification problem is thus reduced to the problem of verifying that the composition of a caerain number copies of a function computes as specified. We shall illustrate the technique by proving the correctness of a linear systolic architecture for computing the greatest common divisor (GCD) of two polynomials [1]. Due to lack of space, we present here only a brief outline of the proof. The interested reader is referred to [8] for full details.

The rest of this paper is organized as follows. In the following section (Sec II) we briefly describe the architecture of the chip. We also express each processor in the array as a stream function, provide a representation mapping from the domain on which the chip operates(i.e. streams of numbers) to the domain of polynomials, and give a representation invariant. The following section, (Sec III) then formulates the actual verificaton problem as three subproblems and addresses each in turn. Finally in Sec IV we compare our technique with other existing techniques for verifying systolic architectures.

## II Description of the gcd chip

The basis of the gcd-chip is Euclid's algorithm which depends on the following lemma. If A and B are two non-zero polynomials as shown below,

$$\begin{aligned} A &= a_i x^i + \ldots + a_1 x + a_0 \\ B &= b_j x^j + \ldots + b_1 x + b_0 \end{aligned}$$

then their gcd satisfies the following invariant.

$$\mathrm{gcd}(A,\ B) = \begin{cases} \mathrm{gcd}((A - [a_i/b_j]x^{i-j} * B),\ B) & \text{if } i \geq j \\ \mathrm{gcd}(A,\ (B - [b_j/a_i]x^{j-i} * A)) & \text{if } j \geq i \end{cases}$$

This serves as the basis for a gcd-preserving transformation that also reduces the degree of one of the polynomials by at least one. It is successively applied to the original pair of polynomials until one of them is reduced to the zero polynomial, at which point the other one is the desired gcd. Let us view a polynomial as a sequence of coefficient-power pairs in decreasing order of power. The first term has a nonzero coefficient, and thus its power is the degree of the polynomial. If $p_1$ and $p_2$ are two such sequences we can express Euclid's

This research was sponsored in part by the Office of the Naval Research under contract N00014-83-K-0317, and in part by a University of Utah fellowship. Travel and other support was obtained from an IBM faculty development grant.

algorithm as in Fig II-1. In our proof of correctness we shall show that the gcd architecture computes exactly this function.

```
gcd(p1, p2) =
if p1 = [0, 0] then p2
elseif p2 = [0, 0] then p1
elseif deg(p1) ≥ deg(p2) then
  gcd((p1-[Q(p1,p2), (deg(p1)-deg(p2))]*p2), p2)
else
  gcd(p1, (p2-[Q(p2,p1), (deg(p2)-deg(p1))]*p1))

where
  deg(p) = second(first(p)) is the degree of p;

  Q(p1, p2) = first(first(p1))/first(first(p2))
is the ratio of the leading coefs of p1 and p2;
and '-' and '*' are operations on polynomials;
first (and second) is a function that
returns the first (second) element of a list.
```

**Figure II-1:** *Euclid's algorithm*

The Kung-Brent architecture consists of 2*m-1 processors cascaded linearly. Each processor has three data input (and output) channels, and one control line `start`. Two of the data channels, `a` and `b` carry streams of numbers, and the third, `d` carries a single integer (aligned with the signal on the `start` line). The processor begins a new cycle when it receives a start bit on the `start` line. Depending on whether or not `d` is non-negative the processor determines whether stream A or stream B is to be reduced (say `A`). It then computes the coefficient `q` (= $a_1/b_1$, while delaying the other stream `B` by one time unit. After this it cycles through the rest of the input stream (i.e. until a new start bit appears) replacing each `a` element by $a_i-q*b_i$, and passing stream `B` unaltered (except for the delay). We shall consider the processor operating on only one pair of polynomials. From the description of each processor, the equivalent stream function (called *reduce*, see Fig II-2) can easily be determined, using the technique described in [7].

```
reduce(sA, sB, d) =
if first(sA)=0 or (first(sB)≠0 ∧ d≥0) then
 [f(rest(sA),rest(sB),first(sA)/first(sB))^0,sB,d-1]
else
 [sA,f(rest(sB),rest(sA),first(sB)/first(sA))^0,d+1]

where f is defined as
  f(s1, s2, q) = if s1 = [] then []
else
  (first(s1)-q*first(s2))^f(rest(s1), rest(s2), q)
  Note: ^ is an infix cons operator
```

**Figure II-2:** *The function reduce*

In order to prove the correctness of the gcd chip we must now demonstrate that the function *reduce*, applied 2*m-1 times to input streams of length m yields the gcd of the polynomials that the input streams represent. Before formulating this problem we must set up some basics. Firstly, we must give a mapping, *rep* from the data-domain on which the chip (i.e. *reduce*) operates (treams) to the abstract domain of interest (polynomials). Secondly, we must specify a representation invariant, *R* that must be satisfied by elements of the data domain. This is done as follows. We define *rep* in terms of another function *prep* which takes an integer *d* and a single stream of numbers *s* (which has no leading zeroes) and yields a polynomial.

```
prep(s, d) =
    if d = 0 then
        if s=[] then [0,0] else [first(s), 0]
    elseif s=[] then [0,d]^prep(s, d-1)
    else [first(s), d]^prep(rest(s), d-1)
```

Using this we now define *rep* (Fig II-3). `AllZero(s)` is a predicate asserting that all elements in s are zero, *StripTrailingZeroes*(s) is a function that removes all trailing zeroes from a stream s (provided `AllZero(s)` is false) and *Final*(i, s) is the stream consisting of the last i elements of a stream s.

```
rep(sA, sB, d) =
if AllZero(sA) then
  [[0,0], prep(StripTrailingZeroes(sB),
                    length(StripTrailingZeroes(sB))-1)]
elseif AllZero(sB) then
  [prep(StripTrailingZeroes(sA),
          length(StripTrailingZeroes(sA))-1), [0,0]]
elseif first(sA)=0 then rep(rest(sA), sB, d-1)
elseif first(sB)=0 then rep(sA, rest(sB), d+1)
else
  rep'(StripTrailingZeroes(sA),
          StripTrailingZeroes(sB), d)

where
rep'(s1, s2, d)=
if d > length(s1) - length(s2) then
  [prep(s1, length(s2)+d-1),
    prep(s2, length(s2)-1)]
elseif d = length(s1) - length(s2) then
  [prep(s1, length(s1)-1), prep(s2, length(s1)-1)]
elseif d < length(s1) - length(s2) then
  [prep(s1, length(s1)-1),
    prep(s2, length(s1)-d-1)]
```

**Figure II-3:** *The representation mapping, rep*

The representation invariant consists of four conjuncts $R_1$, $R_2$, $R_3$ and $R_4$ which are defined as follows.

```
R1 ≡ length(sA) = length(sB)              (= n, say)
R2 ≡ (first(sA)≠0 ∨ first(sB)≠0)
#i(R3) ≡ d≥0 ⇒
    (n≥d ∧ AllZero(Final(d, sB))) ∨ AllZero(sB)
R4 ≡ d<0 ⇒
   (n≥-d ∧ AllZero(Final(-d, sA))) ∨ AllZero(sA)
```

## III Problem decomposition and proof

With this machinery in place, the actual proof of correctness is achieved by demonstrating that *reduce* satisfies the following conditions.

- It must preserve the invariant $R$ on every invocation, i.e.

$$R(s_A, s_B, d) \Rightarrow R(reduce(s_A, s_B, d)) \qquad (1)$$

- It must preserve the gcd of the polynomials obtained by applying *rep* to its input and output streams, i.e.

$$gcd[rep(reduce(s_A, s_B, d))] = gcd[rep(s_A,s_B,d)] \qquad (2)$$

- The computation defined by *reduce* "terminates", i.e. if the length of the original streams is m the exactly 2*m-1 applications of *reduce* (denoted by $reduce^{2*m-1}(s_A, s_B, d)$) cause one of the polynomials to become the zero polynomial[1]. This means that

$$first(rep(reduce^{2*m-1}(s_A, s_B, d))) = [0,0]$$
$$\vee\ second(rep(reduce^{2*m-1}(s_A, s_B, d))) = [0,0] \qquad (3)$$

The proof of Theorem 1 involves fairly straightforward manipulation after substituting the definition of *reduce* in the equation. Next, proving that the function *reduce* preserves the gcd of the polynomials involves a case by case analysis on the first elements in the streams $s_A$ and $s_B$. Although the prof is somewhat long it is fairly simple conceptually. Finally, to prove Theorem 3 we also perform a similar casewise analysis. We first show that if one of the polynomials that $[s_A, s_B, d]$ represent is the zero polynomial, then further application of *reduce* leaves the streams (and hence the polynomials they represent) unchanged. Then we show that associated with each $[s_A, s_B, d]$ is an integer[2], N which decreases by exactly one on every application of *reduce*. When N becomes zero one of the polynomials is the zero polynomial. The interested reader is referred to [8] for full details.

## IV Conclusions

We have presented by means of an example how well-known techniques from programming language theory can be profitably applied to the verification of systolic architectures. An additional contribution of this paper is the proof of correctness of a hitherto unproved systolic array. Other researchers have addressed the problem of reasoning about systolic architectures [2, 5, 6]. In Chen's approach space-time recursion equations are set up and their fixed point [9] yields the function describing the network. By using our approach we do not need to explicitly reason about the time component. Successive time instants are represented by successive appearances of tokens on a stream. Melhem [5] describes a formalism involving graphs with colored arcs which is very similar to ours. The processing elements are also modelled as (essentially) stream functions, though they are referred to as operators. The overall network behavior is obtained by solving a system of *difference equations.* Purushothaman [6] also has a similar approach, where the verification problem is also reduced to the solution of recurrence equations. In both these methods the equations are set up using the token-wise behavior of the individual processing elements, and standard techniques for manipulating functions are not exploited. Their use of difference/recurrence equations implies that both, the data representation and processor behavior issues have to be handled simultaneously. These issues are cleanly separated in our approach.

## Acknowledgments

The authors would like to thank Kevin Karplus for helpful criticism of an early draft and Richard Fujimoto and Ashok Samal for comments on the presentation.

**Abstract** In this paper, a design methodology for synthesizing efficient parallel algorithms and architectures from problem definitions specified in the language **Crystal** is presented. First, transformations on a problem definition to programs with *bounded order* and *bounded degree* are introduced. This stage of transformations aims to reduce the dominant costs in the underlying hardware which might be incurred by a direct parallel implementation of the problem definition. At the second stage, pipelining is automatically incorporated into an algorithm so that the hardware resources can be most effectively utilized. The methodology allows the derivation of systolic algorithms and architectures in a unified framework based on **Crystal.** Since **Crystal** is a general purpose language for parallel proramming, new synthesis techniques and insights into problems can be integrated readily within the existing framework.

## 1. Introduction

VLSI technology provides a natural medium for parallel processing, from the level of switching elements, to logic gates, to functional and control units, and to architectures and algorithms. To expoit its potential fully, parallelism must be used at increasingly higher levels. Design automation, consequently, must go beyond the level of taking as givens architectural level specifications, and should head towards compiling or synthesizing efficient parallel algorithms and architectures. The technology, on the other hand, constrains the way in which parallel computation can be organized. Dominant costs at the technological level often have profound implications in the designs at algorithmic and architectural levels. Clearly, to achieve an efficient design, one must take advantage of what the technology can offer, and minimize the costs associated with the constraints it imposes upon the design.

In this paper, we describe a design methodology that takes into account the dominant costs in the underlying technology and minimizes such costs to yield efficient parallel algorithms and architectures. The design process starts with a problem definition specified in the language **Crystal** [4]. The definition is interpreted as a parallel algorithm, however naive and inefficient it might be. From this naive algorithm, the dominating costs it might incur in the underlying parallel hardware, such as that of communications and fan-ins and fan-outs, are examined. We then improve the algorithm by a series of transformations that results in a *bounded order* and **bounded degree** program which has reduced hardware costs. Once such a program is obtained, it goes through another stage of transformation, called *space-time mapping*, by which pipelining is automatically incorporated into the algorithm and the hardware resources are fully utilized. Algorithms are classified as either uniform or non-uniform because space-time mapping for uniform algorithms can be obtained by an expedient procedure.

Throughout this paper, the methodology is applied to the dynamic programming problem, which turns out to be a uniform algorithm. The well-known systolic algorithm of Guibas, Kung and Thompson [7] and others are generated as a result. The rest of this paper is organized as follows: in Section 2, a mathematical definition of dynamic programming is given. In Section 3, its interpretation as a parallel algorithm is described. In Section 4, transformations for reducing the number of fan-ins and fan-outs are presented. In Section 5, transformations that reduce long-range communications are illustrated. In Section 6, space-time mapping for uniform algorithm is described. A general inductive method for finding space-time mapping for non-uniform algorithms can be found in [5]. In Section 7, optimization of control signals is illustrated. Finally, some related work is discussed in Section 8.

## 2. A General Definition of Dynamic Programming

A large class of optimization problems can be solved by dynamic programming. The definition of such problems can be posed in a general form where $C(i,j)$ is some cost function which is to be minimized.

$$C(i,j) = \begin{cases} s > 0 \rightarrow \min\limits_{i<k<j} \{F(C(i,k), C(k,j))\} \\ \qquad \text{where } F \text{ is some function on the costs} \\ s = 0 \rightarrow C_i \text{ for some individual cost} \end{cases}$$

$$\text{where } s = j - i - 1, \tag{2.1}$$

and $i$ and $j$ are integers in the range $0 < i < j \leq n$, for some constant $n$.

## 3. Parallel Interpretation of Algorithms

The straightforward definition given in Equation (2.1) is

0190-3918/86/0000/0776 $01.00 © 1986 IEEE

in the form of a **Crystal** recursion equation with *recursion variables* $i$ and $j$. It can be interpreted as a parallel algorithm as follows: Each pair $(i,j)$ in Equation (2.1) is interpreted as a process in an ensemble of parallel processes denoted by the set $P_1 \overset{\text{def}}{=} \{(i,j) : 0 < i < j \leq n\}$. The local processing at each process $(i,j)$ is, in this example, the function $\min_{i<k<j}\{F(x_k, y_k)\}$ that takes $j - i - 1$ pairs of arguments. The communication between processes is specified, for instance, by the pairs $(i,k)$ and $(k,j)$ appearing on the right-hand side of Equation (2.1) to indicate that the computation of $C(i,j)$ at process $(i,j)$ needs the results from processes $(i,k)$ and $(k,j)$.

The ensemble of processes and its data flow can be depicted by a DAG (Directed Acyclic Graph) as shown in Figure 1. It consists of nodes, where each node corresponds to a process $(i,j)$ in $P_1$, and directed edges, each of which comes out of a node whose corresponding process appears on the right-hand side of Equation (2.1), and goes into a node whose corresponding process appears on the left-hand side of the equation. The directed edges of the DAG define the data dependency relation of the algorithm. We say that a process **u** immediately precedes **v** ($\mathbf{u} \prec \mathbf{v}$), or **v** immediately depends on **u** ($\mathbf{v} \succ \mathbf{u}$), if there is a directed edge from **u** to **v**. The transitive closure "$\overset{*}{\prec}$" of this relation, called "precede", is a partial order, and there is no infinite decreasing chain from any node **v**, nor is there an infinite number of processes that immediately precede **v**. Those nodes that have no incoming edges are called *sources.*

Processes are parallel in nature. A computation starts at the sources which are properly initialized, and is followed by other processes each of which starts execution when all of its required inputs, or dependent data become available. The parallel execution of the naive dynamic programming definition starts with all processes such that $s = 0$, followed by processes with increasing $s$ as illustrated in Figure 1.

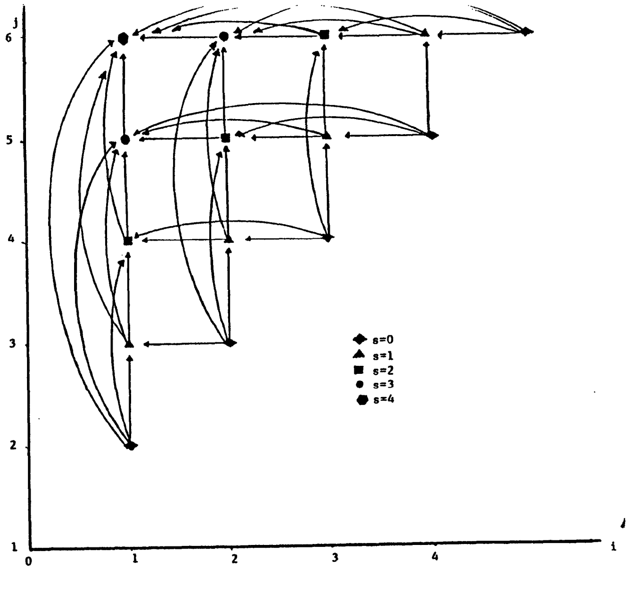

**Figure 1:** The DAG describing the data dependency of dynamic programming.

An immediate, very naive implementation of the parallel interpretation uses one processor for each process, and altogether $O(n^2)$ parallel processors are needed. The number of time steps needed to compute the result is at best $n - 1$ since any $C(i,j)$ cannot be computed until $C(i,j-1)$ and $C(i+1,j)$ are computed.

## 4. Problems with Large Number of Fan-ins and Fan-outs

Due to the inherent physical constraints imposed by the driving capability of communication channels, power consumptions, heat dissipations, memory bandwidth, etc., it is reasonable to assume that data can only be sent or received simultaneously to or from a small number of destinations or sources. Putting such constraints in algorithmic terms: the number of "fan-ins" and "fan-outs" of a datum must be small, where *fan-in degree* of a datum is defined to be the number of data items on which it depends, and *fan-out degree* is the number of data items dependent upon it. If what we are interested in are practical and efficient algorithms, the fan-in and fan-out degrees should be taken into account in measuring the complexity.

It can be easily seen that the fan-in degree of $C(i,j)$, which appears on the left-hand side of Equation (2.1), is $2s$, where $s \overset{\text{def}}{=} j - i - 1$. Conversely, for any value appearing as $C(i,k)$ on the right-hand side of Equation 2.1, that value is needed by $C(i,j)$ for $j = k+1, \ldots, n$ (there are $n - k$ such terms). The same value also appears as $C(k,j)$ in the equation and it is needed by processes $(i,j)$ for $i = 1, \ldots, k-1$ (there are $k - 1$ such terms). Since both $s$ and $k$ grow with the problem size $n$, the number of fan-ins and fan-outs therefore grows linearly with the size of the problem.

To avoid the high cost incurred at the hardware level, the large fan-in and fan-out degrees must be reduced. In the following transformations, the original fan-in and fan-out degrees are reduced from $O(n)$ to a constant while the complexity of the original algorithm is maintained the same as before.

### 4.1. Reducing fan-out degrees

The idea used in reducing the fan-out degree is quite simple:

**Proposition 4.1.** *Let $z(l)$ for $u \leq l \leq v$ where $u$ and $v$ are integers and $u < v$ be $v - u + 1$ variables to which a value $x$ shall be assigned, i.e., $z(l) = x$ for $u \leq l \leq v$ (where the fan-out degree of $x$ is $v - u + 1$). Then the assignments of these variables can be performed instead by*

$$z(l) = \begin{cases} l = u \rightarrow x \\ l > u \rightarrow z(l-1) \end{cases} \qquad (4.1)$$

*or by*

$$z(l) = \begin{cases} l = v \rightarrow x \\ l < v \rightarrow z(l+1) \end{cases} \qquad (4.2)$$

*for $u \leq l \leq v$*

*where the fan-out degrees of $x$ and $z(l)$ for $u \leq l \leq v$ are 1.*

To decrease the fan-out degree of $C(i,k)$, let the variables at processes $(i,j)$ for $k \leq j \leq n$ to which $C(i,k)$ will be assigned be denoted by $a(i,j,k)$. Similarly, let the variables at process $(i,j)$ for $1 \leq k < i$ to which $C(k,j)$ is to be assigned be denoted by $b(i,j,k)$. Applying Equation (4.1) of the proposition to $a(i,j,k)$ and Equation (4.2) to $b(i,j,k)$, we obtain

$$
\begin{aligned}
a(i,j,k) &= \begin{cases} j = k \to C(i,k) \\ j > k \to a(i,j-1,k) \end{cases} \\
b(i,j,k) &= \begin{cases} i = k \to C(k,j) \\ i < k \to b(i+1,j,k) \end{cases} \qquad (4.3) \\
&\text{for } 1 \le i < k < j \le n.
\end{aligned}
$$

Now the $n-k$ fan-out degree of $C(i,k)$ to all processes $(i,j)$, where $k < j \le n$, is reduced to 1, and so is the $k-1$ fan-out degree of $C(k,j)$ to all processes $(i,j)$ for $1 \le i < k$. We may now replace the high fan-out degree values $C(i,k)$ and $C(k,j)$ on the right-hand side of Equation (2.1) by the low fan-out degree values $a(i,j,k)$ and $b(i,j,k)$:

$$
C(i,j) = \begin{cases} s > 0 \to \min\limits_{i<k<j} \{F(a(i,j,k), b(i,k,j))\} \\ s = 0 \to C_i. \end{cases} \qquad (4.4)
$$

### 4.2. Reducing the fan-in degrees

The reduction of fan-in degree of a value computed by a process relies on the associtivity of the operation being computed.

**Definition 4.1.** An operation "$\bigoplus$", where $z = \bigoplus_{u<l<v} x(l)$, on $v-u-1$ arguments, is associative if it can be replaced by the composition of the following sequence of binary associative opertions "$\oplus$" on variables $z(l)$, $u < l < v$:

$$
z(l) = \begin{cases} l = u+1 \to x(u+1) \\ u+1 < l < v \to z(l-1) \oplus x(l) \end{cases} \qquad (4.5)
$$

and $z = z_{v-1}$.

Similarly, the same operation can be achieved by a different sequence using both binary and ternary associative operations.

**Proposition 4.2.** *If "$\bigoplus$" is an associative operation on $v-u-1$ arguments $x(l)$ for $u < l < v$, where $z = \bigoplus_{u<l<v} x(l)$, then it can be replaced by a sequence of binary and ternary operations on variables $z(l)$, for $m < l \le v$ of the following form:*

$$
z(l) = \begin{cases} l = m \to x(m) \oplus x(u+v-m) \\ m < l < v \to z(l-1) \oplus x(l) \oplus x(u+v-l) \\ l = v \to z(l-1) \end{cases} \qquad (4.6)
$$

*where* $m = \lceil \frac{v+u}{2} \rceil$

*and* $z = z_v$.

Since the operation "min" for computing $C(i,j)$ is associative, let the high fan-in degree value $C(i,j)$ at process $(i,j)$ be computed instead by the sequence $c(i,j,k)$ for $m < k < j$, where $m \overset{\text{def}}{=} \lceil \frac{i+j}{2} \rceil$. Now apply Proposition 4.2 to Equation (4.4), and it is transformed to

$$
c(i,j,k) = \begin{cases} s = 0 \to C_i \\ s > 0 \to \\ \quad \begin{cases} k = m \to \min(F(a(i,j,k), b(i,j,k)), \\ \qquad\qquad F(a(i,j,i+j-k), b(i,j,i+j-k)) \\ m < k < j \to \\ \qquad \min(c(i,j,k-1), F(a(i,j,k), b(i,j,k)), \\ \qquad\qquad F(a(i,j,i+j-k), b(i,j,i+j-k)) \\ k = j \to c(i,j,k-1), \end{cases} \end{cases} \qquad (4.7)
$$

and $C(i,j) = c(i,j,j)$ for all $(i,j) \in P_1$.

The application of Proposition 4.2 is motivated by the following: Due to the data dependency, the value $F(a(i,j,k), b(i,j,k))$ for $i < k < j$ cannot be computed before at least $max(k-i, j-k)$ time steps. A pair with the least delay is the one with $k = \lfloor \frac{i+j}{2} \rfloor$ and/or $k = \lceil \frac{i+j}{2} \rceil$, where the delay is about half of the interval size. Consequently, the most efficient sequence of binary or ternary operations will start with this pair, and will be followed by other pairs in the order of increasing amount of delay.

## 5. Communcations and Bounded-order Recursion Equations

The following two equations

$$
\begin{aligned}
a(i,j,k) &= \begin{cases} j = k \to c(i,k,k) \\ j > k \to a(i,j-1,k) \end{cases} \\
b(i,j,k) &= \begin{cases} i = k \to c(k,j,j) \\ i < k \to b(i+1,j,k) \end{cases} \qquad (5.1) \\
&\text{for } 1 \le i < k < j \le n,
\end{aligned}
$$

are obtained from Equation (4.3) by substituting $C(i,k)$ with $c(i,k,k)$, and substituting $C(k,j)$ with $c(k,j,j)$. The system of

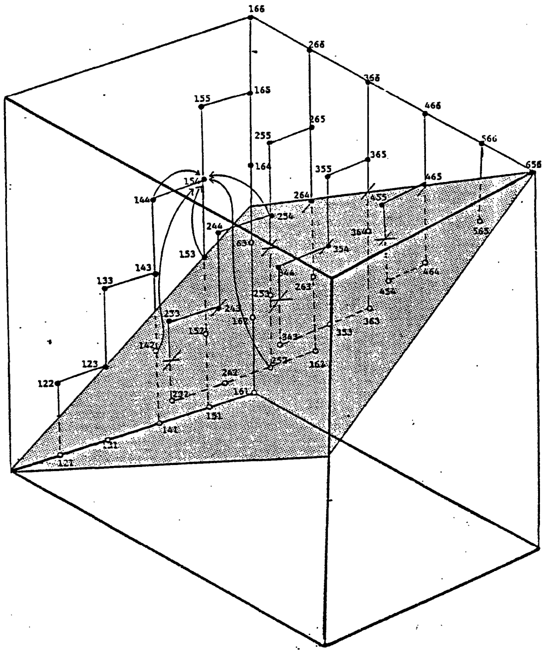

**Figure 2:** Process structure $P_2$ in which the fan-in and fan-out degreess are constant, but in which there are still long range communications

recursion equations consisting of Equations (5.1) and Equation (4.7) is a new algorithm for dynamic programming. The new ensemble of processes $P_2 \overset{\text{def}}{=} \{(i,j,k) : 0 < i < k < j \leq n\}$ is now three dimensional, as shown in Figure 2. The added one dimension and the increased number of processes are for the purpose of decreasing fan-in/fan-out degrees. A remaining criterion for a good parallel algorithm is that all communications between processes defined by a system of recursion equations should also be local. A few definitions are called for:

**Definition 5.1.** The path length between two processes $\mathbf{v} \overset{\text{def}}{=} (v_1, \ldots, v_m)$ and $\mathbf{u} \overset{\text{def}}{=} (u_1, \ldots, u_m)$ is defined to be $|v_1 - u_1| + \cdots + |v_m - u_m|$.

**Definition 5.2.** A communication between two processes $\mathbf{u}$ and $\mathbf{v}$, where $\mathbf{u} \prec \mathbf{v}$, is local if their path length is bounded by a fixed constant.

**Definition 5.3.** The *order* of a system of recursion equations is defined to be the maximum path length between any pair of processes $\mathbf{u}$ and $\mathbf{v}$, where $\mathbf{u} \prec \mathbf{v}$.

Similar to the high fan-in and fan-out degrees, the extra delay introduced by the communications of the high-order terms in the equations can undermine the efficiency of an algorithm. We therefore require that the order of a system of equations be either constant or grow very slowly with respect to the problem size.

### 5.1. Localizing communications by domain contraction

Note that Equation (4.7) contains terms $a(i,j,i+j-k)$ and $b(i,i+j-k,j)$, which in turn immediately depends on processes $a(i,j-1,i+j-1-k)$ and $b(i+1,j,i+1+j-k)$ by Equations (4.3). The order of the system of equations is therefore $2(|k+1-\frac{i+j}{2}|)$ for $i < k < j$, which grows with the problem size $n$. To eliminate the high order terms, further transformations are required.

The path length $2(|k+1-\frac{i+j}{2}|)$ between two communicating processes is a linear function of $i$, $j$ and $k$. The goal is to transform this linear function into a constant one. The most obvious choice is to set $k = \frac{i+j}{2}$, in which case the path length becomes 2. Geometrically, we can see that the coordinates of the high order terms above are symmetric to those of the low-order terms $a(i,j,k)$ and $b(i,j,k)$, with respect to the plane $k = (i+j)/2$, shown in Figure 2 as a shaded plane. The algebraic transformation now corresponds to the contraction of the original domain of processes by one half along the plane, so that $(i,j,k)$ and $(i,j,i+j-k)$ become a single process $(i,j,k)$.

Let processes $(i,j,k)$, such that $m \leq k \leq j$, be referred to as being in the upper half of the process structure $P_2$. Similarly, let those processes, such that $i \leq k \leq, m'$ be referred to as being in the lower half of $P_2$.

Let the new process structure be the upper half of $P_2$, i.e., $P_3 \overset{\text{def}}{=} \{(i,j,k) : 0 < i < j \leq n \text{ and } m \leq k \leq j\}$, as shown in Figure 3. The data streams $a$ and $b$ of those processes originally residing in the lower half must be given new names so that they can be differentiated from those of the processes originally in the upper half. To achieve this, let $d$ and $e$ be new data streams to replace $a$ and $b$ for the processes of the lower half as shown in Figure 3.

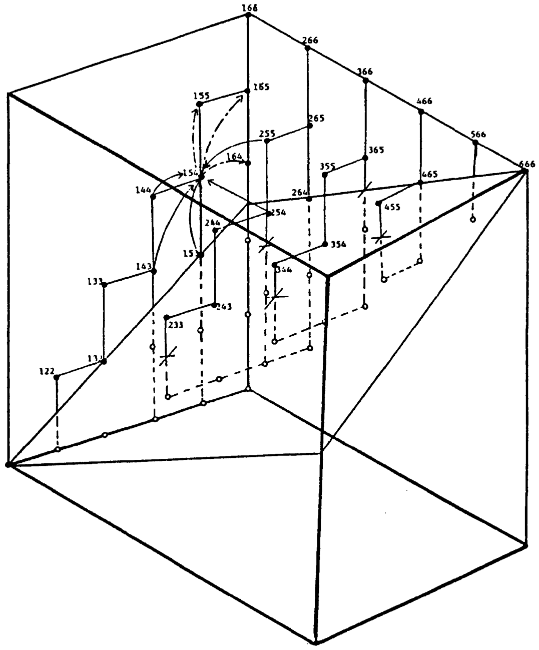

**Figure 3:** Process structure $P_3$, in which all data dependencies are local

### 5.2. Algebraic manipulation to obtain low order equations

First, Equation (5.1), defined for $(i,j,k)$, $i \leq k \leq j$, is now split into two set of equations, one for the case $m \overset{\text{def}}{=} \lceil \frac{i+j}{2} \rceil \leq k < j$ where $(i,j,k)$ resides in the upper half of $P_2$ and the other for the case $i < k \leq m' \overset{\text{def}}{=} \lfloor \frac{i+j}{2} \rfloor$ where it resides in the lower half. Since, for those processes $(i,j,k)$ that reside in the lower half, $a$ and $b$ will be renamed by $d$ and $e$, we must be aware of the case when a process $(i,j,k)$ is in the lower half of $P_2$ while process $(i,j-1,k)$ might be in the upper half, such as in the case when $k = m'$ and $i+j$ is even (or $s \overset{\text{def}}{=} j-i-1$ is odd). Another case to watch for is when $(i,j,k)$ is in the upper half while $(i+1,j,k)$ might be in the lower half; it occurs when $k = m$ and $i+j$ is even (or $s$ is odd). Two equations in (5.1) are now split into four equations, where the above two cases are singled out:

upper half:

$$a(i,j,k) = \begin{cases} j = k \rightarrow c(i,k,k) \\ m \leq k < j \rightarrow a(i,j-1,k). \end{cases}$$

lower half:

$$a(i,j,k) = \begin{cases} (k = m') \wedge (odd(s))) \rightarrow a(i,j-1,k) \\ \qquad\text{(upper half)} \\ (k = m') \wedge (even(s))) \rightarrow a(i,j-1,k) \\ i < k < m' \rightarrow a(i,j-1,k). \end{cases} \tag{5.2}$$

upper half:

$$b(i,j,k) = \begin{cases} (k = m) \wedge (odd(s)) \rightarrow b(i+1,j,k) \\ \qquad\text{(lower half)} \\ (k = m) \wedge (even(s)) \rightarrow b(i+1,j,k) \\ m < k < j \rightarrow b(i+1,j,k). \end{cases}$$

lower half:

$$b(i,j,k) = \begin{cases} k = i \to c(k,j,j) \\ i < k \le m' \to b(i+1,j,k). \end{cases}$$

Next, every $a(i,j,k)$ in the lower half is replaced by $d(i,j,i+j-k)$, where $(i,j,i+j-k)$ is now the upper half. Similarly, every $b(i,j,k)$ in the lower half is replaced by $e(i,j,i+j-k)$.

$(i,j,k)$ lower half

$$d(i,j,i+j-k) = \begin{cases} (k = m') \wedge (odd(s))) \to a(i,j-1,k) \\ \qquad \text{(upper half)} \\ (k = m') \wedge (even(s))) \to \\ \quad d(i,j-1,i+(j-1)-k) \\ i < k < m' \to d(i,j-1,i+(j-1)-k). \end{cases}$$

$(i,j,k)$ lower half

$$e(i,j,i+j-k) = \begin{cases} k = i \to c(k,j,j) \\ i < k \le m' \to e(i+1,j,(i+1)+j-k). \end{cases} \tag{5.3}$$

Finally, a "substitution of variable" is performed on the above two equations, which replaces $i+j-k$ by $k'$:

$$d(i,j,k') = \begin{cases} (k' = m) \wedge (odd(s))) \to a(i,j-1,i+j-k') \\ (k' = m) \wedge (even(s))) \to d(i,j-1,k'-1) \\ m < k' < j \to d(i,j-1,k'-1). \end{cases}$$

$$e(i,j,k') = \begin{cases} k' = j \to c(i,j,j) \\ m \le k' < j \to e(i+1,j,k'+1). \end{cases} \tag{5.4}$$

Since $k'$ is a bounded variable, replace it by $k$ throughout Equations (5.4).

### 5.3. Resulting System of Equations

The resulting algorithm is the following system of recursion equations:

$$a(i,j,k) = \begin{cases} j = k \to c(i,k,k) \\ m \le k < j \to a(i,j-1,k) \end{cases}$$

$$d(i,j,k) = \begin{cases} (k = m) \wedge (odd(s))) \to a(i,j-1,k-1) \\ (k = m) \wedge (even(s))) \to d(i,j-1,k-1) \\ m < k < j \to d(i,j-1,k-1) \end{cases}$$

$$b(i,j,k) = \begin{cases} (k = m) \wedge (odd(s)) \to e(i+1,j,k+1) \\ (k = m) \wedge (even(s)) \to b(i+1,j,k) \\ m < k < j \to b(i+1,j,k) \end{cases}$$

$$e(i,j,k) = \begin{cases} k = j \to c(i,j,j) \\ m \le k < j \to e(i+1,j,k+1) \end{cases}$$

$$c(i,j,k) = \begin{cases} s = 0 \to C_i \\ s > 0 \to \\ \quad \begin{cases} k = m \to \min(F(a(i,j,k),b(i,j,k)), \\ \qquad\qquad F(d(i,j,k),e(i,j,k)) \\ m < k < j \to \\ \quad \min(c(i,j,k-1), F(a(i,j,k),b(i,j,k)), \\ \qquad\qquad F(d(i,j,k),e(i,j,k)) \\ k = j \to c(i,j,k-1) \end{cases} \end{cases} \tag{5.5}$$

## 6. Space-time Mapping to Incorporate Pipelining

From the algorithm (5.5) derived above, we further improve the efficiency of the algorithm by incorporating pipelining automatically. From the stand-point of implementation, a process **v** in a system of recursion equations will be mapped to some physical processor $s$ during execution, and once the process is terminated, another process can be mapped to the same processor. In fact, such re-use of the resource is the essence of ***pipelining.*** We call each execution of a process by a processor an ***invocation*** of the processor. Let $t$ be an index for labeling the invocations so that the processes executed in the same processor can be differentiated, and let these invocations be labeled by strictly increasing non-negative integers. Then for a given implementation of a program, each process **v** has an alias $[s,t] \overset{\text{def}}{=} f(\mathbf{v})$, telling when (which invocation) and where (in which processor) it is executed. The key to an efficient parallel implementation of an algorithm is to find an appropriate one-to-one function $f$ that maps a process **v** to its alias $[s,t]$ such that $t$ will be non-negative and $t_2 > t_1$ if $\mathbf{v}_1 \prec \mathbf{v}_2$, where $[s_1,t_1] \overset{\text{def}}{=} f(\mathbf{v}_1)$ and $[s_2,t_2] \overset{\text{def}}{=} f(\mathbf{v}_2)$.

### 6.1. Data dependency vectors

To find such a mapping, we require that the domains of the recursion variables of a **Crystal** program be vector spaces, and that the appropriate vector addition and scaler vector product be defined. Though each of the recursion variables $i$ and $j$ in Equation (2.1) assumes an integer value, its domain can be extended to the set of rationals. For instance, an $m$ dimensional process structure is now embedded in an $m$-dimensional vector space over the rationals. From now on, we may refer to the $m$-tuple of values of recursion variables identified with a process as a vector. As suggested by [12], a data dependency vector plays an important role in mapping algorithms to parallel processors. Since the vector addition is defined and the data dependency of two vectors takes on an exact meaning, a data dependency vector can be formally defined:

**Definition 6.1.** A ***data-dependency vector*** is the difference $\mathbf{v} - \mathbf{u}$ of vector **v** and vector **u**, where $\mathbf{u} \prec \mathbf{v}$ (**u** immediately precedes **v**).

### 6.2. Basis communication vectors

As described above, each program defines a set of data dependency vectors. On the other hand, each network topology defines a set of ***basis communication vectors.*** For instance, in an $n$-dimensional hypercube, a processor has $n$ connections to its nearest neighboring processors. Each of the $n$ communication vectors (one for each connection), has $n+1$ components. The first $n$ ones indicate the movement in space and the last one indicate movement in time, which is always positive (counting invocations). These $n$ communication vectors, together with the communication vector $[0,0,\ldots,0,1]$, representing the processors's communication of its current state to its next state, form the basis communication vectors. In an $n$-dimensional network, there can be more than one set of basis communication vectors. Taking a two-dimensional hexagonal network as an example, a diagonal connection has a communication vector $[1,1,1]$. The set of vectors $\{[1,0,1],[0,1,1],[1,1,1]\}$ serves as bases as well as the set $\{[1,0,1],[0,1,1],[0,0,1]\}$. For any $n$-dimensional network which has nearest neighbor connections and is regularly connected and indefinitely extensible, all possible sets of basis communication vectors can be obtained by the enumeration of its symmetry groups Lin and Mead [10].

### 6.3. Uniformity of a parallel algorithm

The concept of uniformity is introduced to characterize parallel algorithms so that an expedient procedure can be applied to a *uniform algorithm* to find the space-time mapping from processes to processors. Let $\mathbf{d}_i$, $1 \le i \le k$ denote the data dependency vectors appearing in a program.

**Definition 6.2.** A uniform algorithm is one in which a single set of basis vectors $\mathbf{b}_j$, $1 \le j \le m$, can be chosen so as to satisfy the mapping condition that every data dependency vector $\mathbf{d}_i$ appearing in the algorithm can be expressed as a linear combination of the chosen basis vectors with non-negative coordinates, in other words, there exists $\mathbf{b}_j$ and $\alpha_j \geq 0$, $1 \le j \le m$, such that

$$\mathbf{d}_i = \alpha_1 \mathbf{b}_1 + \alpha_2 \mathbf{b}_2 + \cdots + \alpha_m \mathbf{b}_m, \text{ for } 1 \le i \le k.$$

### 6.4. Motivation for the mapping condition

The mapping condition is motivated by the possibility of using as the space-time mapping a linear transform from the basis data dependency vectors to the basis communication vectors. Each basis communication vector $\mathbf{e}_j$ corresponds to a nearest neighbor communication on a network of processors, and its time component is always 1. When the mapping between the two sets of basis vectors is determined, then the communication vector $\mathbf{c}_i$ to which a data dependency vector $\mathbf{d}_i$ corresponds is also determined, i.e., $\mathbf{c}_i = \sum_{j=1}^{m} \alpha_j \mathbf{e}_j$ if $\mathbf{d}_i = \sum_{j=1}^{m} \alpha_j \mathbf{b}_j$.

If a data dependency vector has a term with a negative coordinate $\alpha_{j1}$ in its linear combination, then $\alpha_{j1}\mathbf{e}_j$ represents a communication that takes negative time steps, a situation that is not feasible in any physical implementation. In the case of a non-uniform program, more than one set of basis data dependency vectors must be chosen so as to satisfy the mapping condition, and the space-time mapping may become non-linear. In this case, the inductive mapping procedure becomes necessary.

Examples of using such a simple procedure to find linear mappings of processes to parallel architectures for matrix products, LU decomposition, array multipliers, etc., can be found in [2, 3]. Most of the systolic algorithms reported in the literature can be obtained this way, and new systolic algorithms are discovered due to the ability to generate systematically all possible sets of basis communication vectors.

### 6.5. A uniform dynamic programming algorithm

Let $\mathbf{d}_i$, $i = 1, 2, \ldots, 5$ denotes the data dependency vectors of Systems 5.5:

$$\mathbf{d}_1 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \mathbf{d}_2 \stackrel{\text{def}}{=} \begin{pmatrix} -1 \\ 0 \\ -1 \end{pmatrix}, \mathbf{d}_3 \stackrel{\text{def}}{=} \begin{pmatrix} -1 \\ 0 \\ 0 \end{pmatrix}, \qquad (6.1)$$
$$\mathbf{d}_4 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}, \mathbf{d}_5 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}$$

Let the following vectors be the chosen basis data dependency vectors:

$$\mathbf{z}_1 \stackrel{\text{def}}{=} \begin{pmatrix} -1 \\ 0 \\ -1 \end{pmatrix}, \mathbf{z}_2 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \mathbf{z}_3 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix},$$

and let matrix $Z$ be defined as $Z \stackrel{\text{def}}{=} (\mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3)$, then

$$\mathbf{d}_i = Z\mathbf{a}_i, \text{ where}$$
$$\mathbf{a}_1 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \mathbf{a}_2 \stackrel{\text{def}}{=} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \mathbf{a}_3 \stackrel{\text{def}}{=} \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix},$$
$$\mathbf{a}_4 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}, \mathbf{a}_5 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.$$

Note that every component of $\mathbf{a}_i$ is non-negative, thus System 5.5 of dynamic programming is a uniform algorithm. Choose the set of basis communication vectors as

$$\mathbf{c}_1 \stackrel{\text{def}}{=} \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix}, \mathbf{c}_2 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}, \mathbf{c}_3 \stackrel{\text{def}}{=} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \text{ and } C \stackrel{\text{def}}{=} (\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3). \qquad (6.2)$$

The linear mapping $T$ from the basis dependency vector to the basis communication vector is then

$$T = CZ^{-1} = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ -2 & 1 & 1 \end{pmatrix}.$$

**Proposition 6.1.** *The space-time mapping from each process $(i, j, k)$ in $P_3$ of System (5.5) to an invocation of a processor $[x, y, t]$ is a linear mapping $T$, in the matrix notation where each process and invocation is written as a column vector, or written in a functional notation as*

$$[x, y, t] = f(i, j, k) = [-i, j, -2i + j + k] \text{ where}$$
$$-n \le x < -1, 1 < y \le n, 2 \le t < 2(n-1).$$

*The inverse mapping from the image of $f$ to the process structure, denoted by $f^{-1}$, is*

$$(i, j, k) = f^{-1}(x, y, t) = (x, y, 2x - y + t),$$

*specifying which process is being executed at a particular time step $t$ of processor $(x, y)$.*

Similarly, other space-time mappings can be derived from other sets of basis communication vectors which are given below in a matrix notation with each basis communication vector written as a column vector:

$$\begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \\ 1 & 1 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & 0 \\ 1 & 1 & 1 \end{pmatrix}.$$

The set of basis communication vectors in Equation (6.2), or in each of the above sets of vectors, results in a different systolic architecture, as demonstrated below.

### 6.6. Space-time Recursion Equations (STREQ)

A system of *space-time recursion equations* (STREQ), which describes a target systolic architecture or algorithm can be obtained from an original program and a space-time mapping by algebraica manipulation. The following STREQ that describe the resulting design are obtained by substituting the inverse mapping $f^{-1}$ of $i$, $j$, and $k$, the mappings $[x_l, y_l, t_l]$, $l = 1, 2 \ldots, 5$ of dependency vectors $\mathbf{d}_l$, into the original system of recursion equations, and by renaming $\hat{a}(x,y,t) = a(i,j,k)$, $\hat{b}(x,y,t) = b(i,j,k)$, $\hat{c}(x,y,t) = c(i,j,k)$, $\hat{d}(x,y,t) = d(i,j,k)$, and $\hat{e}(x,y,t) = e(i,j,k)$. Note that as a result, the substitution of the predicates $s = 0$ becomes $z = 1$, where $z \overset{\text{def}}{=} y - x$, $k = m$ becomes $t = \lceil\frac{3(y-x)}{2}\rceil = \lceil\frac{3z}{2}\rceil$, $k = j$ becomes $t = 2z$, $m < k < j$ becomes $(\lceil\frac{3z}{2}\rceil \leq t < 2z)$, etc.

$$\hat{a}(x,y,t) = \begin{cases} t = 2z \to \hat{c}(x,y,t) \\ \lceil\frac{3z}{2}\rceil \leq t < 2z \to \hat{a}(x,y-1,t-1) \end{cases}$$

$$\hat{d}(x,y,t) = \begin{cases} (t = \lceil\frac{3z}{2}\rceil) \wedge (even(z))) \to \hat{a}(x,y-1,t-2) \\ (t = \lceil\frac{3z}{2}\rceil) \wedge (odd(z))) \to \hat{d}(x,y-1,t-2) \\ \lceil\frac{3z}{2}\rceil < t < 2z \to \hat{d}(x,y-1,t-2) \end{cases}$$

$$\hat{b}(x,y,t) = \begin{cases} (t = \lceil\frac{3z}{2}\rceil) \wedge (even(z)) \to \hat{e}(x+1,y,t+1) \\ (t = \lceil\frac{3z}{2}\rceil) \wedge (odd(z)) \to \hat{b}(x+1,y,t-2) \\ \lceil\frac{3z}{2}\rceil < t < 2z \to \hat{b}(x+1,y,t-2) \end{cases}$$

$$\hat{e}(x,y,t) = \begin{cases} t = 2z \to \hat{c}(x,y,t) \\ \lceil\frac{3z}{2}\rceil \leq t < 2z \to \hat{e}(x+1,y,t+1) \end{cases}$$

$$\hat{c}(x,y,t) = \begin{cases} z = 1 \to C_x \\ z > 1 \to \\ \quad \begin{cases} t = \lceil\frac{3z}{2}\rceil \to \\ \quad \min(F(\hat{a}(x,y,t),\hat{b}(x,y,t)), F(\hat{d}(x,y,t),\hat{e}(x,y,t)) \\ (\lceil\frac{3z}{2}\rceil \leq t < 2z) \to \\ \quad \min(\hat{c}(x,y,t-1), F(\hat{a}(x,y,t),\hat{b}(x,y,t)), \\ \quad F(\hat{d}(x,y,t),\hat{e}(x,y,t)) \\ t = 2z \to \hat{c}(x,y,t-1) \end{cases} \end{cases} \tag{6.3}$$

## 7. Target Systolic Architecture

### 7.1. Processor and time requirements

The design consists of a triangular array of $(n-1)(n-2)/2$ processors which complete the computation in $2(n-2)$ time steps, as indicated by the range of $x$, $y$ and $t$ in Proposition 6.1. Notice that the space-time mapping has achieved the goal of decreasing the complexity of processor requirement from $O(n^3)$ of the naive interpretation of System (5.5), to $O(n^2)$ in the new algorithm by only increasing the time complexity with a constant factor, in this case, 2. Thus we see pipelining in the resulting algorithm and the successful sharing of a single processor among $O(n)$ processes.

### 7.2. I/O and storage requirements

In the resulting algorithm, if any of the space components of a process on the left-hand side of a Equation, which is the identifier of a processor, differs from that on its right-hand side (the identifier of another processor), then the corresponding datum is an input to the processor, such as $\hat{a}[x, y-1, t-1]$ in Equation (6.3), which is from the processor below it and which takes 1 time step to arrive. If the processor identifiers on both sides of an equation are the same, then the corresponding datum is a stored value such as $\hat{c}[x, y, t-1]$ in Equation (6.3).

The space-time mapping in Proposition 6.1 yields the well-known systolic architecture for dynamic programming [7]. It can be seen in Figure 4 that a process $(i,j,k)$ is mapped to processor $(-i,j)$ at time step $t = -2i + j + k$. Such an invocation may have inputs from invocations both at time $t-1$ and $t-2$, corresponding to the fast registers and the slow registers described in [7]. All signals controlling the loading and unloading between registers of different speed can be systematically derived by techniques of compiler optimization as described below.

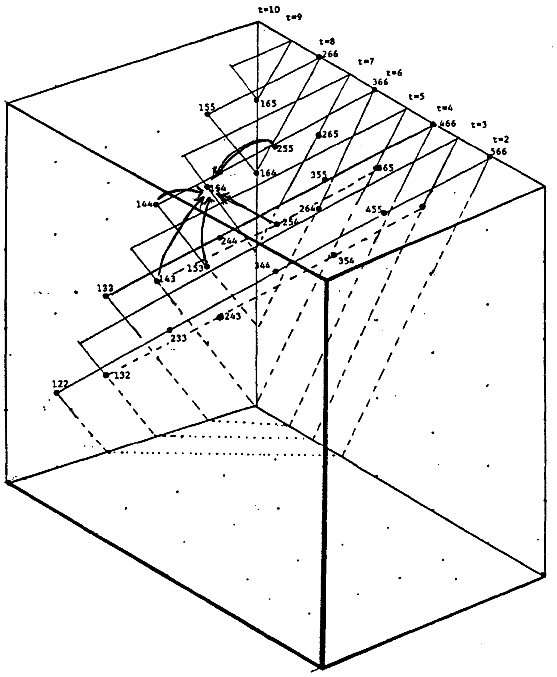

Figure 4: A series of parallel planes indicates the time steps of the space-time mapping. Processes on the same plane are mapped to the same invocation number $t$. (The processor number of a process in this case is its projection onto the bottom plane with the sign of $x$ changed).

### 7.3. Control requirements

The predicates in the STREQ are implemented differently depending on different target implementation media. In a multiprocessor machine, the "processor id" $(x,y)$ can be stored and an "invocation counter" keeps track of $t$ until conditions such as $t = 2z$ is satisfied. In a VLSI implementation, however, it is too costly to store these integers and dedicate hardware to perform the tests. The following optimization of STREQ becomes necessary.

### 7.4. Optimization performed on STREQ

A better design can be obtained by replacing the expensive computations of the predicates by transferring a one-bit control signal, as illustrated by [7]. For a predicate that is independent of $t$, there is no concern, since it can be hardwired into the design. For any predicate that is dependent on $t$, it must be substituted by one that is independent of $t$. Since a communication always both moves in space and takes time to complete, it can be used to "compute" expressions of the space-time recursion variables. For instance, an expression $t = x - 1$ can be computed by a data stream which carries the value "true" and "false".

$$q(x,t) = \begin{cases} (t=0) \wedge (x=1) \rightarrow true \\ \quad \text{(establish the truth initially for the test)} \\ (t>0) \wedge (x=1) \rightarrow false \\ (t>0) \wedge (x>1) \rightarrow q(x-1, t-1) \end{cases}$$

It can be easily seen that such signal can be used to compute any predicates that is linear with respect to the recursion variables. Of all the control signals, the one to implement the test of predicate $t = \lceil \frac{3z}{2} \rceil$ is of particular interest. The predicate contains a piece-wise linear expression, and the resulting signal travels in those processors with even $s$ in half the speed as they do in those processors with odd $s$. This particular type of signal is described incorrectly as a linear signal that moves "two cells every three time units" in [7] as opposed to the above-mentioned piece-wise linear signal.

Central to an optimizing compiler for parallel systems is the making of trade-offs between communications and computations, which can be carried out symbolically in quite an elegant fashion, as illustrated here.

## 8. Related Work

Many attempts in pursuit of systematic methods for designing systolic computations have appeared in the literature. In the classification of systolic designs from the geometric point of view, Lin and Mead [10] classify systolic arrays using symmetry groups, but there is no attempt made to obtain new designs. Cappello and Steiglitz [1] view systolic designs as affine transforms from combinational designs, however, their method does not give clues to finding the appropriate transforms.

Moldovan [12, 13] notes that data dependency vectors are what suggest clues to potential linear transforms. Miranker and Winkler [11] describe a similar method, and they have observed that all 2-dimensional regularly connected arrays can be embedded in a hexagonal array, called a universal array. Quinton [14] starts with a specification called a system of uniform recurrence equations and applies affine and linear transforms to obtain a systolic array. The class of systolic computations that can be described by uniform recurrence equations is limited to those that have only one of their data streams dependent upon other data streams. Li and Wah [8] describe a method that first finds an appropriate placement of one of the input streams and then perform the linear transforms. Delosme and Ipsen [6] describe how to implement a hyperbolic Cholesky solver by a linear transformation from a system of recurrences.

All of the above four methods use (quasi-)linear or affine mappings from a restricted class of algorithms to a new design. The class of designs that can be obtained by these methods are thus subject to restrictions such as uniform recurrent (a more restrictive definition than the uniformity defined in this paper), synchronous, regular, having uniform data flow, etc. The capabilities of these methods are, at best, equal to the mapping procedure for the uniform algorithms described above. However, instead of using a simple, constant time procedure consisting of enumerating the basis communication vectors by subgroup enumerations and finding mappings between the two sets of basis vectors, they find linear mappings by searching through the space of possible linear transforms or input placements. The search requires a time at least polynomially of the size of the problem [8]. None of these methods is able to deal with the problem of the large number of fan-ins and fan-outs.

Li and Wah [9] have classified the problems that can be solved by dynamic programming into several classes and have proposed systolic processors for solving them. The formulation given in this paper corresponds to the most general class — in their terminology, the polyadic-nonserial class. In their treatment, however, the issue of synchronization and timing, which makes the systolic design in [7] particularly interesting, is not addressed.

## 9. Concluding Remarks

The objective of this work is the seeking of parallel programs that effectively utilize underlying technologies. Due to the complexity that might arise in dealing with hundreds of thousands of autonomous parallel processing elements, we find design methodology for this process necessary in order to take the enormous burden off the designers. Program synthesis, at the very basic level, relies on a formal notation for describing the problem, and henceforth on manipulating the descriptions to yield efficient parallel programs. This paper describes two stages of transformations of programs described in the parallel language **Crystal**. The first stage proceeds from a definition of a problem to a program that has fixed fan-in and fan-out degrees and uses only local communications. The second stage incorporates pipelining into this program by space-time mapping. Optimization of control signals is also illustrated.

It is essential that the language **Crystal** be amenable to algebraic manipulation; hence, techniques developed for algorithm transformation can be carried out formally, and potentially by an automatic process. The procedure of space-time mapping for uniform algorithms and the test for the existence of a linear mappings are computational attractive and their complexities are independent of the problem sizes.

# APPLICATION OF PARALLEL PROCESSING TO FAULT SIMULATION

Dr. Prabhu Goel, Dr. Chi-Lai Huang, and Robert E. Blauth

Gateway Design Automation Corporation
Littleton, MA 01460

## Abstract

As an alternative to using special-purpose hardware to accelerate the fault simulation process for digital logic design, a new approach is proposed to perform fault simulation using multiple workstations or processors in parallel. By dividing the faults equally among those processors, it is possible to achieve a linear performance improvement for circuits of 5,000 gates and up. The empirical results obtained from implementation of this approach on ELXSI-6400 super mini-computers and Apollo workstations corroborates the expectation.

## 1. Overview

The increasing complexity of digital systems has forced digital designers to use sophisticated computer-aided design (CAD) tools. One of the most widely used ([1]) class of CAD tools is digital logic simulators which are used both for verifying the behavior of conceptual designs of digital systems and for developing tests for digital systems. These simulators are commonly referred to as verification simulators or fault simulators ([2]) depending upon the intended application.

There has been an increasing trend ([3][4][5]) towards applying parallel processing to accelerate logic simulators. Usually, a special hardware engine is proposed and built to implement the simulator algorithm. Hardwiring or microcoding one specific algorithm may increase the performance from ten to one hundred times. The major drawbacks to this approach are the extra hardware cost and the difficulty of interfacing with other tools. Sometimes the performance gained through one step may be lost in the whole design procedure. In this paper, we shall describe one method of applying parallel processing to achieve acceleration of fault simulation. Our method permits us to use a large number of low cost general purpose computers in a parallel processing mode to achieve very high speed fault simulation at very low cost compared to the use of hardware accelerators or expensive mainframe computers. As distinguished from the application of other parallel processing techniques ([3][4][5]) applied to digital simulation, our technique exploits general purpose computers rather than special purpose hardware. Empirical results show that even with a large number of processors, we are able to achieve nearly linear acceleration of fault simulation as a function of the number of processors. With "N" processors, each operating at 1 Mips, we can achieve close to the performance obtainable from a single processor with a processing power of "N" Mips.

## 2. Status of Fault Simulators

Fault simulators are used for developing manufacturing and field service tests with a particular view to detection and diagnosis of defects in digital systems. They are used for evaluating the effectiveness of candidate tests in screening digital systems for defects. The same simulators can also be used for developing diagnostic information that is used in conjunction with the tests to help locate defects caused in manufacturing or defects that develop in the field. The diagnostic information developed from the use of fault simulators can then be used in the repair of defective products as well as in the adjustment of the manufacturing process.

Defects in digital systems can be quite varied ([6]), e.g. shorts, opens, pinholes in oxide, improper alignments, etc.. However, it becomes impractical to simulate this diversity of defects when applying a fault simulator to digital systems of any reasonable complexity. The classical stuck fault model is most commonly used in conjunction with fault simulators since single stuck faults are relatively easy to simulate and empirical evidence suggests that this model is highly effective in practice when applied to digital systems. Since a large number of single stuck faults can exist in a digital system, the computer resources needed to simulate these faults for very large digital systems can be excessive ([14]).

Innovations in fault simulation algorithms have made it practical to apply fault simulation to digital systems consisting of tens of thousands of logic gates. Starting with serial fault simulation ([7]) involving simulation of one single stuck fault at one time, there has been an evolution of techniques that permit simulation of several faults at one time. Parallel fault simulators ([8]) enable a fixed number of faults to be simulated in parallel, typically 31 faults at one time for a computer with 32 bit words. Deductive ([9]) and concurrent ([10]) fault simulators permit simultaneous simulation of a much larger number of faults even more efficiently ([14]) than with parallel fault simulators.

More recently there have been significant developments in application of statistical ([11]) and approximate ([12]) methods to achieve additional speed-up in the fault simulation process. There is clear recognition of the value of approximate and statistical methods of fault simulation in the design and test of digital systems. However, the issue of whether or not one needs accurate fault simulation is very much open ([13]) and subject to both intense controversy as well as to the application at hand and, as such, will not be further elaborated upon in this paper.

Digital systems being designed today are large enough to create compute-time bottlenecks for accurate fault simulation ([14]) even on the most advanced computers. Rigorous design for testability techniques help to significantly alleviate the problem bottlenecks. In spite of this, few large digital systems are being designed with testability enforced rigorously. Hence, there is a continuing need to accelerate fault simulators.

## 3. Acceleration of Fault Simulation

Special purpose computers ([3][4][5]) have been developed expressly for accelerating verification simulation and extended to accelerate fault simulation as well. These special purpose computers, commonly referred to as hardware accelerators, are just beginning to enter the marketplace for fault simulation. Current hardware accelerators exploit special purpose hardware as well as micro-code to directly implement the

0190-3918/86/0000/0785 $01.00 © 1986 IEEE

simulation algorithms.

Another way to improve simulation speed is to use several general purpose processors to execute the same simulation algorithm. Rather than each processor simulating a piece of the algorithm, each processor can apply the complete algorithm on separate pieces of data. For logic simulation, each processor can simulate part of the circuit ([3]). However, it is not practical to obtain a linear performance improvement with an increasing number of processors by this method since there is no way to ensure an even distribution of simulation events across the multiple processors. In fact, the inter-processor communication overhead can quickly overtake the benefits realized from parallelism. A second approach is to let parallel processors simulate the entire circuit with independent subsets of the stimulus vectors. This is feasible only when the set of stimulus vectors is such that independent subsets of stimulus vectors can be identified with each subset not dependent on the circuit state created by preceding stimulus vectors. In general, without explicit designer assistance, it would be infeasible to attempt this form of stimulus vector partitioning for sequential logic circuits. In combinational logic circuits however, each stimulus vector can be viewed as being completely independent of the preceding stimulus vectors. Hence, the technique of parallel processing of vectors is quite viable for combinational logic circuits. In a recent publication ([15]), this technique has been applied by exploiting the bit-wise parallelism inherent within all general purpose processors. In ([15]), 256 stimulus vectors at a time are simulated in parallel with serial fault simulation to achieve significant speed-up in accurate fault simulation for large combinational logic circuits. The same publication also cited an application of the same approach to verification simulation of scan design logic which, for most verification purposes, can be treated in a manner similar to combinational logic circuits.

Fault simulation lends itself to multi-processing even more so than verification simulation. Besides a plurality of gates and stimulus vectors, fault simulation also has another dimension - a plurality of faults. The time used by a fault simulator can be summarized by the following formula:

$$T=TP+TG\bullet P+F\bullet TF\bullet P/2$$

where:

TP is the time spent for the model building and the post-processing,

P is the total number of patterns to be simulated,

TG is the average time to simulate the good machine for one pattern,

F is the total number of faults to be simulated,

TF is the average time to simulate one faulty machine for one pattern.

Here we assume that a fault will be dropped from further simulation if it is detected in one pattern. By assuming all faults are detected uniformly in these P patterns, a fault will be simulated only P/2 patterns on average.

Usually TF is about 0.01 to 0.1 of TG for a concurrent fault simulator. For a circuit of 5,000 gates, there are about 10,000 stuck-at faults to be simulated. Hence, the third factor in the equation is about 50 times the second for this circuit. This ratio will be increased proportionally with the size of the circuit.

In a multi-processor computer, each processor can simulate a subset of the total faults set. At the end of the simulation, one processor can merge the data generated by the other processors and produce the combined simulation results for viewing by the designer. During simulation time, very limited communication is needed between the parallel processors. In this way, each processor will spend about 1/Nth of the third factor on faulty machine simulation. As such, one would expect to achieve an almost linear performance improvement with increased numbers of parallel processors, even up to hundreds of processors for a 50,000-gate fault simulation. Results achieved by us from a practical implementation of these concepts corroborates the expectation.

## 4. AIDSSIM-A: Accelerated Fault Simulation With Parallel Processing

AIDSSIM ([16]) is a concurrent fault simulator which has been used in the industry for several years. Based on AIDSSIM, a new multi-processor fault simulator, AIDSSIM-A has been implemented on ELXSI super mini-computers and on a multi-processor Apollo Domain network. The basic algorithm can be summarized as follows:

Step 1.
The main processor, called parent processor, accesses model and stimulus vectors for the circuit to be simulated.

Step 2.
The parent processor activates several children processors while passing along the circuit information.

Step 3.
Each processor (both parent and child) selects an independent non-overlapping subset of the total fault set; only one fault subset is to be simulated by one processor.

Step 4.
During fault simulation of each subset of faults, the corresponding processor creates the simulation data that is written out to unique files.

Step 5.
As each processor finishes simulating the stimulus vectors and its unique fault subset, it signals the parent processor and returns summary information to the parent while terminating its own processing.

Step 6.
The parent processor merges the simulation data created by each of the children and produces the final result.

Since fault simulators spend the majority of their time in the simulation of Step 4, the algorithm provides an almost linear reduction in elapsed time by using several processors running in parallel. Whether the algorithm can achieve the full linear performance acceleration depends on the effectiveness of the host multi-processing computer in reducing the communication overhead. The ELXSI-6400 ([17]) is a super-minicomputer with closely-coupled processors. In contrast, Apollo computers ([18]) are microcomputers linked with a relatively slower speed inter-processor communication network. In spite of significant architectural differences, both the ELXSI and the Apollo systems show an almost linear performance gain with increasing number of processors while running AIDSSIM-A.

We have experimented with different approaches to partitioning the total fault set into subsets for parallel processing but have not observed any striking difference from one to the other. The results reported in this paper have been achieved by a fault set partitioning that is quite arbitrary and is done as follows. The fault set is assumed to have an arbitrary order. Each successive group of "n" faults is assigned by associating one fault to each of the "n" processors.

## 5. AIDSSIM-A Implementation and Results on an ELXSI-6400

ELXSI-6400 is a multi-processor system with up to ten processors. The system can support up to 192 M-bytes of real memory. Four billion bytes of virtual memory are available per processor. Its GIGABUS, a synchronous, 64-bit data bus operating at 320 M-bytes per second, allows data sharing among processors with a minimum overhead. With cache memory, ELXSI-6400 allows memory segments to be shared among processors without any noticeable overhead. Taking this into consideration, AIDSSIM-A implementation on the ELXSI shares the circuit model's data structure between the multiple processors. Only the single parent processor is used to perform good machine simulation over a small number of consecutive stimulus vectors. The good machine simulation result for each group is saved in common memory for access by all the children processors. When there is not enough memory space to hold good machine simulation data for the next group of stimulus vectors, the parent processor will enter a wait state. The parent processor's wait state is exited only when the children processors have processed the good machine data for a previous group, thereby making memory available for the new group. When a child processor finishes processing with the current good machine data, the child will also enter a wait state until new good machine data is available from the parent. Provision of shared memory to hold good machine data for up to 10 stimulus vectors reduces the number of wait states for each processor. Further, to minimize wait states for the children processors, the parent processor is made to run faster than all children processors by having the parent simulate only half the number of faults simulated by the children processors.

We have processed several circuits on an ELXSI-6400 computer. Figure 1 shows the results for a circuit containing 6600 gates. There are 23741faults; 8404 faults are equivalence faults. After 104 test stimulus vectors, 16031 faults are detected. The fault coverage is 67.52%. Our results are reported from an ELXSI-6400 with 32 M-bytes of main memory and 4 processors. Note that the results go up to 9 processors. We used virtual processors to go beyond the 4 processors on the machine that was available to us. The total processor (cpu) time is the summation of the individual processors' times. Note that the total time increases only about 10% from one processor to nine processors. As can be seen, the average processor time decreases inversely with the number of processors. There is about a 25% difference between the fastest and the slowest processors running independent fault subsets. The effective elapsed time reduction has to be determined from the run time associated with the slowest of the parallel processors.

## 6. AIDSSIM-A On Apollo

Apollo computers are based on the Motorola 68010/68020 microprocessors as well as on proprietary bit-slice processors. They are linked by the high-speed Apollo Domain network which allows communication data rates of up to 10 M-bits per second. Hundreds of Apollo computers can be linked in a network.

Due to the slower communication speed on an Apollo network, (compared to an internal bus on an ELXSI-6400), the AIDSSIM-A implementation on the Apollos does not transfer data between parent and children processors during the simulation step (Step 4). At the beginning of the simulation, the parent processor will send the model and fault data to all the children processors. Each processor will have its local model data structure, but the stimulus vectors file is shared. At the end of simulation, the parent processor accesses the simulation result files of children processors and produces the final result.

The circuit used to produce results shown in Figure 1 was also processed with AIDSSIM-A on an Apollo network with six processors. The results are shown in Figure 2. The Apollo processors used are DN460 or DN660, each ranging from 4 M-bytes to 16 M-bytes of physical main memory. Since only six processors were available, AIDSSIM-A results in Figure 2 are limited to a maximum of six processors. As can be seen, the total processor (cpu) time undergoes relatively small change as we increase the number of processors. For the circuit used, we determined the communication overhead to be about 5 to 10 seconds per processor. The average processor time also decreases inversely with increasing number of processors.

## 7. Conclusions and Future Extensions

AIDSSIM-A has demonstrated that fault simulation can be accelerated almost linearly with an increasing number of processors in a multi-processing environment. A major advantage of this technique is in permitting the exploitation of a large number of low cost processors to provide a powerful cost/performance alternative to the use of special purpose processors or hardware accelerators. We further intend to gather data from running circuits with one hundred thousand gates. Since Apollo networks permit hundreds of processors in the network, it will be quite interesting to see how AIDSSIM-A performs with a very large number of processors. More work is required to permit recovery from the failure of one or more processors being used in the network or in a multi-processing environment. It would also be desirable to dynamically determine the existing/projected workload on various processors in a network and allow for migration of the processing workload from high utilization processors to those processors which have low current utilization by other users. In an environment where some of the processors being operated in parallel are of unequal compute power, it will be necessary to change the allocation of fault subsets and allow for the slower processors to be synchronized with the faster processors without slowing down the latter.

## *ABSTRACT*

**Since its birth two decades ago, the Petri Nets theory has been widely applied to system modeling. In particularily, Petri Nets are highly suitable for modeling and analyzing distributed systems due to its inherent property of concurrency. This paper describes an algorithm which can slice out all concurrency sets of a Petri Nets model. The concurrency set is defined as the set of paths in different processes which should be executed concurrently. Determining the concurrency sets of a concurrent or distributed system model is very significant in performing analysis. The time complexity of the algorithm is $O((n/N)^N)$. Here n is the number of transitions of the model and N is the number of processes of the model. An example of the application of the algorithm in testing distributed software systems is also presented.**

## I. INTRODUCTION

Petri Nets is a well-known theory concerned with the concurrency or parallelism property of different kinds of systems in the area of computer science and other related fields [1]. As the application of Petri Nets are continously emerging, many variations and extensions of Petri Nets have also been developed, such as Modified Petri Nets [2], Discrete Time Stochastic Petri Nets [3], extended Petri Nets [4], etc. Certainly, they provide more powerful tools in modeling and analyzing a variety of systems.

In general, the problem of analyzing a concurrent system is to analyze the interactions among different processes in the system. For the Petri Nets model, the problem is the analysis of the dynamic relations among the transitions in different processes. Typically, firing the transitions in one process can affect the execution of transitions in other processes. For example, in Figure 1, there are two paths in process 1: P11=(t11, t12, t14), P12=(t11, t13, t14) and two paths in process 2: P21=(t21, t22, t23), P22=(t21, t23, t24). P11 and P12, P21 and P22 are mutual-exclusion paths, i.e. execution of one path will suspend another path. In Figure 1, if path P12 in process 1 is expected to be executed, the path P21 in process 2 should be executed concurrently, otherwise the transition t13 will never be enabled. We define the set of paths in different processes which should be executed concurrently as *concurrency set.* Therefore, P12 and P21 are in same concurrency set. Identifying concurrency sets in Petri Nets models is critical to the analysis of these models.

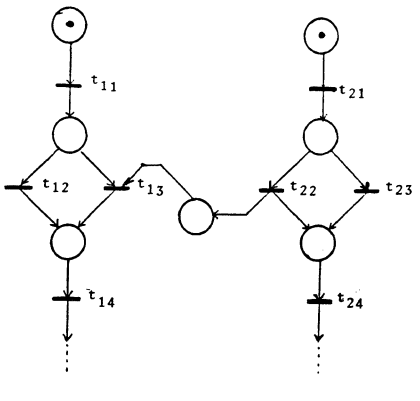

Figure 1. A concurrency set

Upon the modeling of a distributed software system, several processes can be executed concurrently on different processors. In regard to the testing problem, we want to select a set of input data to execute these processes concurrently in order to verify the correctness of the program [5]; for example, to detect deadlock. Because there may exist more than one path in each process, we have to determine which paths should be executed concurrently (i.e. in the same concurrency set). To date, few research results have been reported in this area.

In section II, a slicing algorithm is presented. The algorithm is able to slice out all concurrenccy sets by examining the Petri Nets model. The complexity of the algorithm is discussed in Section III. An example is given in Section IV. Finally, Section V presents the concluding remarks.

## II. SLICING ALGORITHM

Before describing our slicing algorithm, we need the following definitions.

***Definition 1:*** In a Petri Nets model, if transition t is in Process i and I(t), input place of t, is in process j or O(t), output place of t, is in Process k, i ≠ j or i ≠ k, then t is termed a *communication transition.*

***Definition 2:*** A path in a process which contains one or more communication transitions is termed a *communication path.*

***Definition 3:*** For Process i and Process j, if there exists t in Process i, such that O(t) is in Process j, then Process i and Process j are *interrelated,* or Process i has a *relation* with Process j.

***Definition 4:*** A *concurrency set* is a set of communication paths, which are selected from some interrelated processes and can be executed concurrently.

The slicing algorithm can slice out all concurrency sets in a Petri Nets model. In this algorithm, we first find a base path which covers at least one communication transition and put it into the concurrency set S. We mark those transitions in other processes which have relations with this base path. Then we scan each process to select a path which covers all the marked transitions. This path may generate new communication transitions which have relations with it in either the previous (been-scanned) processes or the succeeding (not-scanned yet) processes. If this path does not involve any new communication transitions having relations with the previous processes or these transitions are already in the concurrency set, then we put this path into the concurrency set and mark those transitions having relations with the succeeding processes. Otherwise, if this path involves new communication transitions having relations with a previous process, say x, then we have to give temporary marks to these related transitions and backtrack to process x to find a new path to cover both marked and temporarily marked transitions. If we can find such a path, then we replace the one already in the concurrency set by

0190-3918/86/0000/0789 $01.00 © 1986 IEEE

this new path and mark again the transitions in other processes. Otherwise, we erase temporary marks and try to find a new path other than the old one which was already in the concurrency set. Afterwards, we restart the scanning process from x, until all processes have been scanned and a concurrency set has been found. This procedure is repeated until all communication transitions are included in certain concurrency sets.

Here we should consider a special case in which there is no concurrency set in the model. For example, in Figure 2, transition $t_{j1}$ and $t_{j2}$ are mutually exclusive. There exists only one path which includes $t_{j1}$ in $process_j$. $t_{j1}$ has a relation with $t_k$ in $process_k$ and $t_k$ has a relation with $t_{j2}$ in $process_j$. When we backtrack to $process_j$ we can find neither a path which covers both $t_{j1}$ and $t_{j2}$ nor a new path which covers $t_{j1}$. In this case, the algorithm should terminate. Otherwise it will enter an infinite loop.

Details of the algorithm now follow.

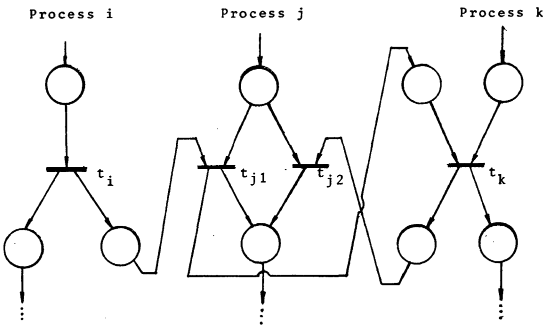

Figure 2. A special case: there is no concurrency set.

***Input:*** P[1], P[2], ..., P[N] : Process 1 to Process N.
CS = { t| t ∈ T, t is a communication transition}

***Output:*** S[1], S[2], ..., S[I] : A set of concurrency sets.

***Variables:*** M = { t| t∈T, t has a mark}
TM = { t| t∈T, t has a temporary mark}
WS = { t| t∈CS and t is in current process being scanned}
N = number of processes in the model.

```
Algorithm_Slicing (P[1],...,P[N],CS : in; S[1],...,S[I] : out)
  for j <-- 1 to N do if There exist more than one path in P[j]
                          then changable[j] <-- true
                          else changable[j] <-- false;
  I <-- 0;  terminate <-- false;
  while CS ≠ ∅ and terminate = false do
      I <-- I+1;      S[I] <-- ∅;
      M <-- ∅;        TM <-- ∅;
      WS <-- ∅;   WS <-- WS U {t}; /* pick up a t from
      CS which belongs to P[1] */

      Procedure_findpath (P[1], WS : in; PA : out);
      /* input process P[1], WS to find a path PA in P[1]
      which covers all communication transitions in WS. If
      there is no such path, PA = ∅ */

      S[I] <-- S[I] U PA;
      M <-- M U {t|t∈P[x], x=1 and t has relation with
      PA};

      Procedure_scanning (P[1], ..., P[N] : in; CS, M,
      TM, S[I] : in&out);
      /* scanning all processes according to the base path
      to find a concurrency set */

      CS <-- CS - CS∩S[I]
  end while
end slicing
```

The procedure *findpath* is to find a path in the given process such that this path can cover all communication transitions in WS. WS is the working set which contains the marked communication transitions in the process to be dealt with. The *Procedure_findpath* is not complicated. Here we will not give a detailed description.

The procedure *scanning* is central to the algorithm. Executing this procedure once, we can get a concurrency set. The following is the *Procedure_scanning:*

```
Procedure_scanning (P[1], ..., P[N] : in; CS, M, TM, S[I]
: in&out)
  i <-- 2;     flag <-- true;
  while i < N  and  terminate = false do
      if flag = true
          then WS <-- P[i]∩M;
              if WS ≠ ∅
                  then Procedure_findpath (P[i], WS
                  : in; PA : out)
                  else i <-- i + 1
          else PA <-- ∅
      end if
      if WS ≠ ∅ and PA = ∅
          then i <-- No. of nearest changable process;
              flag <-- false;
      if WS ≠ ∅ and PA ≠ ∅
          then if (there is no t in previous processes which
          have relations with PA)
                  or (these t are in S[I])
                  then S[I] <-- S[I] U PA;
                      i <-- i + 1;
                      M <-- M U {t|t∈P[x] (x>i), and
                      t has relation with PA};
                      flag <-- true
                  else TM <-- TM U {t|t∈P[x] (x<i) and
                  t has relation with PA};
                      i <-- the least No. of process x
                      (x<i) which has relation with
                      PA;
                      S[I] <-- S[I] - all paths in
                      processes j, j>i;
                      flag <-- false
              end if
      end if
      if flag = false
          then WS <-- P[i]∩(M U TM);

              Procedure_findpath (P[i], WS : in; PA
              : out);

          if PA = ∅
              then TM <-- TM - TM∩P[i];
                  if there is no new path which
                  covers WS
                      then terminate <-- true
                      else flag <-- true
              end if
      end if
  end while
end scanning.
```

## III. TIME COMPLEXITY

*Algorithm_Slicing* is basically a backtracking algorithm. Finding a concurrency set consists of slicing out N paths from N processes. Because there would be several paths in each process, say k, the total combinations of these paths is $k^N$. The backtracking in this algorithm is necessary to find a new path combination. Hence the worst case is that the algorithm tries all possible combinations.

If there are n transitions in the Petri Nets model and N processes, we assume that n transitions are evenly distributed in N processes. That is, each process has n/N transitions. Now the problem is how to determine the number of paths in each process. Let us consider the situation in Figure 3. In the upper half, each place has two output transitions and in the lower half part, each pair of transitions has one output place. Thus the number of paths in this model equals the number of transitions at the $m_{th}$

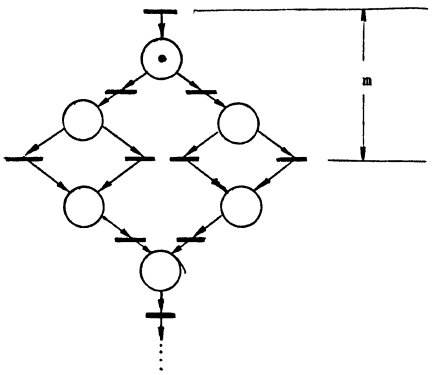

Figure 3. Maximum munber of paths in a Petri Net model

level. Let x denote the number of transitions in this model. We take this model as consisting of two binary trees. Thus we have the equation:

$$2(2^{m} - 1) - 2^{m-1} = x \qquad (1)$$

$2^{m} - 1$ is the number of transitions in a binary tree with depth m. $2^{m-1}$ is the number of transitions at the $m_{th}$ level. Solving equation (1):

$$\begin{aligned}
&2^{m+1} - 2 - 2^{m-1} = x\\
&2^{m-1}(2^{2} - 1) = x + 2\\
&2^{m-1} = (x + 2)/3\\
&m - 1 = lg(x + 2)/3\\
&m = lg(x + 2)/3 + 1
\end{aligned}$$

Thus the number of paths (i.e. number of transitions in the $m_{th}$ level) is:

$$2^{m-1} = 2^{(lg(x+2)/3+1)-1} = 2^{lg(x+2)/3} = (x + 2)/3$$

number of paths with x transitions = (x + 2)/3 (2)

The number of paths in a process calculated by equation (2) is at least more than the general case, because we assume each process has one entry and one exit.

Now we can continue to discuss the time complexity of our algorithm. Since each process has n/N transitions, the number of paths in each process is (n/N + 2)/3, so that the worst case is:

$$[(n/N + 2)/3]^{N}$$

Thus the time complexity
$T(n) = [(n/N + 2)/3]^{N} = O((n/N)^{N})$.

***Discussion:***

There are two factors affecting the time complexity. One is n, the total number of transitions, and the other is N, the number of processes. If N has been given (i.e. N is a constant), then T(n) becomes simpler. The time increases as n becomes larger. But in another case, the problem will be more complicated. That is, if n has been given, the complexity varies as the ratio n/N changes. Therefore, N will affect the complexity considerably. Now let us analyze the complexity function $(n/N)^{N}$

Let $y = (n/N)^{N}$

$$\begin{aligned}
(\,ln\, y)' &= (N\, ln\, n/N)'\\
y'/y &= (N\, ln\, n/N)'\\
y' &= (N\, ln\, n/N)'y\\
&= [\,ln\, n/N + N(-n/N)/(n/N)](n/N)^{N}\\
&= (\,ln\, n/N - 1)(n/N)^{N}
\end{aligned}$$

Let y = 0, that is $(\,ln\, n/N - 1)(n/N)^{N} = 0$

Because in our problem $0<N<n$, so $(n/N)^{N} = 0$

$$\begin{aligned}
&(\,ln\, n/N - 1) = 0\\
&ln\, n/N = 1\\
&n/N = e\\
&N = n/e
\end{aligned}$$

when $N < n/e$ $y' > 0$ i.e. $(n/N)^{N}$ is increasing as N is getting larger,

$N > n/e$ $y' < 0$ i.e. $(n/N)^{N}$ is decreasing as N is getting larger.

Figure 4 shows the curve of the complexity function $(n/N)^{N}$ (when n is given).

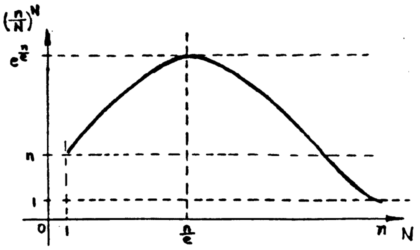

Figure 4. Thc curve of the complexity function

For example, if n = 100, $T(100) = (100/N)^{N}$ The following table gives the time comlexity at different values of N.

| N | 5 | 10 | 20 | 25 | 37 | 40 | 50 |
|---|---|---|---|---|---|---|---|
| $(n/N)^{N}$ | $3.2x10^{6}$ | $1.0x10^{10}$ | $9.45x10^{13}$ | $1.13x10^{15}$ | $9.47x10^{15}$ | $8.2x10^{15}$ | $1.13x10^{15}$ |

Table 1. Example values of the complexity function

When N = 100/e = 36.79, $((n/N)^{N})' = 0$.

Because N is an integer, we consider N = 37 as an extreme value. From Table 1, we can find that when N < 37, $(n/N)^{N}$ is increasing; and when N > 37, $(n/N)^{N}$ is decreasing.

## IV. AN EXAMPLE

In this section, we shall show how to apply our algorithm to the testing of a distributed software system. As mentioned in the INTRODUCTION section, in order to generate test data for the system, we should first determine which parts of the system must be executed during the testing. There may exist a set of concurrency sets in the system model. We have to determine these concurrency sets, before we can generate different sets of input data to execute these concurrency sets.

Figure 5 gives an example of a distributed software system modeled on Petri Nets. There are three processes in the system. Now we apply our slicing algorithm to this Petri Nets model to obtain all concurrency sets.

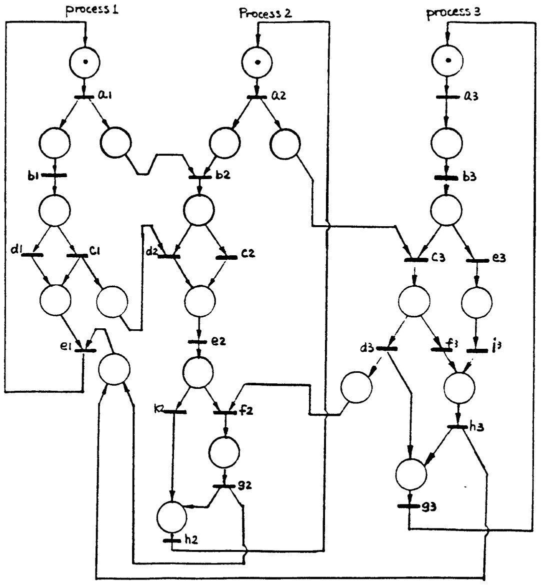

Figure 5. A system model in Petri Nets

*Input* : P[1], P[2], P[3]
CS = {a1, c1, e1, a2, b2, d2, f2, g2, c3, d3, f3}
All three processes are changable.

1. First select the base path (a1, b1, c1, e1) in process 1.
   S = { (a1, b1, c1, e1) }

2. mark communication transitions in process 2.
   M = { b2, d2}; WS = { b2, d2}

3. Find a path in process 2 to cover WS.
   { a2, b2, d2, e2, k2, h2 }
   Because this path only has a relation with process 3, we put it into S1 :
   S1 = { (a1, b1, c1, e1), (a2, b2, d2, e2, k2, h2) }
   mark C3 in process 3.
   M = { b2, d2, c3 }, WS = { c3 }.

4. Find a path in process 3 to cover WS :
   { a3, b3, c3, d3, g3 }
   Because this path has the relation with transition f2 in process 2 and f2 is not in S1, we go back to process 2 and give a temporary mark to f2 :
   TM = { f2 }, WS = { b2, d2, f2 }.

5. Find a new path in process 2 to cover WS :
   { a2, b2, d2, e2, f2, g2, h2 }
   Because this path has the relation with e1 in process 1 but e1 is in S1, so put this path into S1 and delete the old one.

   S1 = { (a1, b1, c1, e1), (a2, b2, d2, e2, f2, g2, h2) }
   mark transition c3 in process 3 :
   M = { b2, d2, c2 }, WS = { c3 }.

6. Find a path in process 3 to cover WS :
   { a3, b3, c3, d3, g3 }
   Because the transition f2 has a relation with this path is in S1 , we put this path into S1 :
   S1 = { (a1, b1, c1, e1), (a2, b2, d2, e2, f2, g2, h2), (a3, b3, c3, d3, g3) }.

7. Now we have found a concurrency set S1. Delete all communication transitions in S1 from CS :
   CS = { f3 }.

Repeat this procedure: select base path in process 3:
( a3, b3, c3, f3, h3, g3 );
We can easily get another concurrency set S2:
S2 = { (a1, b1, d1, e1), (a2, b2, c2, e2, f2, g2, h2), (a3, b3, c3, f3, h3, g3)}

Now CS = $\emptyset$, the algorithm terminates. There are two concurrency sets S1 and S2 in this Petri Nets model.

## V. CONCLUSION

A slicing algorithm of concurrency modeling based on Petri Nets is presented in this paper. Its application has been discussed and an example of an application in distributed software testing is given. The time complexity of the algorithm is also analyzed. This slicing algorithm will be a very useful tool for analyzing distributed systems modeled in Petri Nets.

Abstract--Simulation, which is very often compute bound on uniprocessor computers, is an excellent candidate application for parallel processing. This paper describes the implementation of a simple military simulation on the BBN Butterfly parallel computer. The entity centered nature of the problem will be described, followed by an overview of the model that represents the essential characteristics of similar full scale simulations. Implementation issues on the Butterfly and performance will be given, with particular attention to scaling up to the 124 node size of the available machine.

## 1. Background

The performance problem in military simulation is illustrated by the CORBAN (Corps Battle Analysis) simulation, which runs only about twice as fast as real time for a large scenario [1]. Since the period simulated is measured in days, this is too slow for operational use in decision aids. This is very unlikely to be achieved at reasonable cost without resort to parallelism. The effort reported in this paper investigated the potential for speedup by using a small, simple simulation having similar structure to CORBAN, implemented on the Butterfly computer. A full report on the effort has been prepared [2].

The CORBAN simulation represents ground combat and some aspects of air combat, including perception, attrition, movement, and decisionmaking processes [3][4]. A simulated scenario includes many entities, each representing a military unit, which may have a variety of types of weapons. Each such entity may only engage enemy units which it can detect.In addition, combat simulations include decisionmaking algorithms and movement algorithms that cause entities to change location and hence the combat relationships among them. A time stepped approach is used in CORBAN, so that each $\Delta t$ every unit perceives, shoots, makes decĩsions, and moves. Entities directly observe and modify state variables of each other. This style of programming maps well onto a shared memory parallel computer such as the Butterfly where all state variables can be maintained in global memory. [5]

## 2. The Butterfly Computer

The Butterfly is a shared memory parallel computer having up to 256 nodes, each within an 8 Mhz 68000 microprocessor, a 2901 bit slice node controller, and 1 Mbyte of memory. Instructions referencing memory located locally take about 1 1/2 microseconds, while those referencing memory on another node take about 5 microseconds. References to other nodes are through an omega, or "Butterfly," network topology from which the machine takes its name. Each link has a capacity of 32 mbits/sec. The machine is programmed by the user as an MIMD (Multiple Instruction stream, Multiple Data stream) shared memory machine [6].

## 3. The Simulation

With a parallelism approach that processes entities on different processors, potential for problems occurs where more than one entity may access the same data simultaneously during perception, combat processes, movement. Decisionmaking is a function internal to an entity, so it has no intrinsic requirement to reference other entities. Only the perception, combat, and movement functions were included in this simple simulation since they are the problem areas. This simulation named "Zipscreen," was written in C with the addition of parallel constructs available through the BBN "Uniform System" package which supports allocation of global memory blocks and scattered matricies, and parallel process generation [7].

The data structures of the program are shown in Figure 1. As in CORBAN, units are represented by blocks of data of varying length, which contain a number of common attributes in the "unitsb" structure and a list of assets in the concatenated "asitem" structures. Units are accessed using the "unarry" array. Each asset item specifies the type and quantity of each asset. The variable "hexloc" specifies an octal hex location address. These index into the array "phexar" which contains pointers to the linked list of units for each hex. The hex address "newhex" is the new hex a unit moves to during a time step.

The program structure is illustrated in Figure 2. The "runsim" routine cycles through all of the time steps. The "GenOnIndex" is a mechanism provided by the Butterfly "Uniform System" to initiate a task for each unit. The "ciunit" routine calls "percev," the perception routine, to generate a target list of adjacent enemy units. The "hxadd" function is used to generate the hex addresses to be searched. If

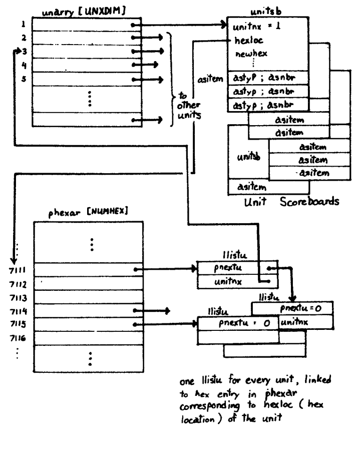

Figure 1. Data Structures

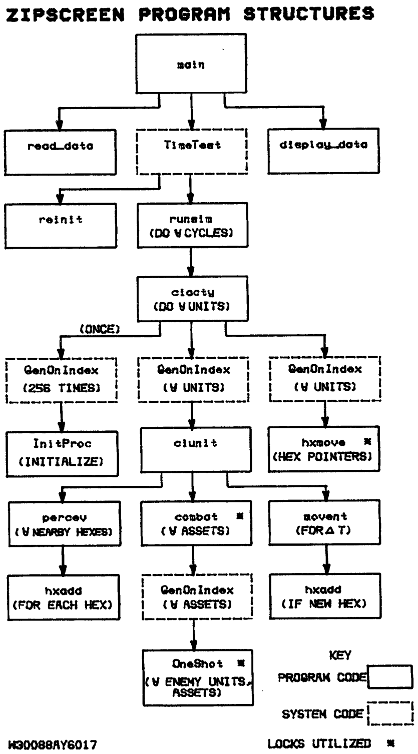

Figure 2. Parallel Program Structures

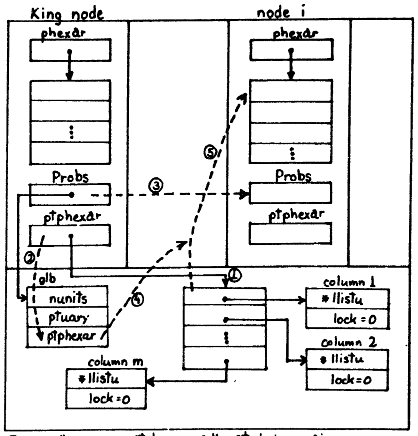
targets are found, the subroutine "combat" is called. The movement routine then updates the unit's position. After "ciunit" is completed for all units, "hxmove" is called for all units to update the occupancy lists. The combat routine makes separate calculations of effects for each of the weapons in the unit's asset list. A separate task, "OneShot," is spawned for each asset. Each weapon then calculates attrition against each asset of each target unit. The "movent" routine causes each unit to move at a constant speed in the direction "hexdir." When the unit moves into another hex, "hexdir" is added to the hex address "hexloc" to determine the new hex location "newhex." The original data structure for hex access had to be modified to use the "AllocateScatterMatrix" function of the Uniform System. For the hex pointer array, "phexar," the columns correspond to the hex numbers. A second element in the column is used for the lock. The matrix column pointer array is duplicated on all of the processors. Figure 3 illustrates how this is done.



① scatterarray ptphexar allocated in main
② ptphexar inserted into glb by ciacty
③ Probs, The pointer to glb, passed via GenOnIndex
④ ptphexar retreived from glb by InitProc at node i
⑤ column pointers copied to local array by block move in InitProc

Figure 3. Distribution at ScatterMatrix Pointers

## 4. Performance and Conclusions

The original simulation, with no parallelism, required 29.81 seconds for a run with 99 units for five time steps. When parallelism was added for units but the machine was constrained to use only one processor, the run time was 30.59 seconds, a 3.4% increase in run time. Later, with concurrent processing of assets, the single processor run time increased to 31.00 seconds, for a total of 3.5% overhead. A version of the simulation that did not include movement was developed and run on the large 124 node butterfly. Figure 4 shows the results. The results are sensitive to the amount of combat. With an earlier scatter algorithm that permitted only 62 of the 800 units to engage in combat, efficiency for 124 nodes was still relatively high at 56%.

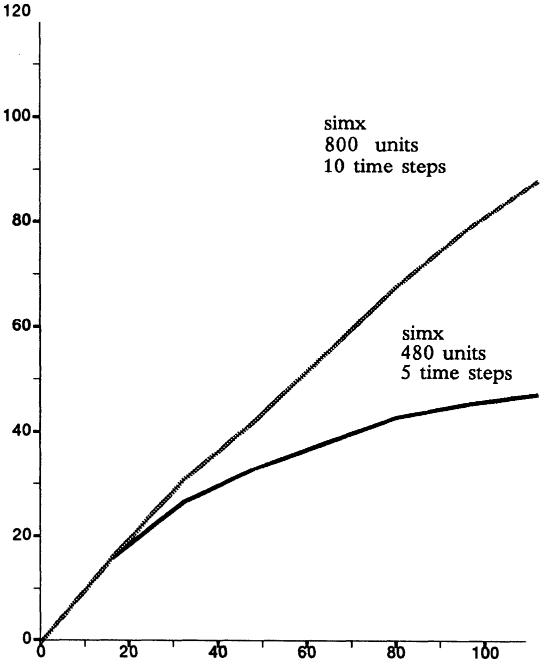


Figure 4. Zipscreen Performance on the Butterfly

In later histogramming, movement processing was found to consume a very small amount of the computational resources. Figure 4 also illustrates speedup curves using the most complete version of the simulation. Note that for the 480 unit case on 124 processors, removal of initialization processing raises the 124 node efficiency to 45%. Typical CORBAN runs range from about 500 to 1000 units. These two cases bound the range of performance that might be achieved without the use of optimized scheduling. Histograms indicated that load balancing was the dominant cause of inefficiency.

The Butterfly computer running the Zipscreen simulation demonstrates the feasibility of parallel combat simulations of the type similar to CORBAN, having entity centered, time stepped architecture. Good scaling with additional processors was demonstrated for up to 124 processors, with efficiency limited by the task breakdown implied by data.

An effort is currently underway to demonstrate parallel simulation on a larger, more detailed scale by implementing a subset of the CORBAN simulation on the BBN Butterfly and a hypercube architecture simulation. These projects are being pursued by the US Army Ballistic Research Laboratory, Los Alamos National Laboratory and The BDM Corporation, under the sponsorship of the Defense Advanced Research Projects Agency.

## 5. Acknowledgements

The simulation demonstration effort described here was largely pursued as part of a one-week Butterfly training course in August 1985. The BBN personnel rendered valuable assistance. This effort was sponsored by the Defense Advanced Research Projects Agency.

# A TECHNIQUE FOR SIMULATING SIMD SIGNAL PROCESSING ALGORITHMS ON THE PASM PARALLEL PROCESSING SYSTEM

**Edward C. Bronson**
**James T. Kuehn**[†]
**Leah H. Jamieson**

**School of Electrical Engineering**
**Purdue University**
**West Lafayette, IN 47907 USA**

**Abstract** -- This paper describes a new technique to analyze data-independent SIMD algorithms to obtain performance measures of their execution on a parallel processing system. The execution time of an SIMD algorithm is the greatest amount of time required by the control unit and any one processing element to complete execution. The operations performed by the control unit and this single processing element constitute the longest processing path or critical path through the parallel algorithm. A procedure is described to extract the critical path and to simulate the execution of the critical path on an SIMD control unit and a single processing element. This is a general technique that combines a complete parallel architecture hardware model with serial processing tools to obtain very detailed SIMD algorithm performance information. The simulation studies presented here are for SIMD signal processing algorithms written in Parallel-C and executed on the PASM parallel processing system.

## I. Introduction

An SIMD machine typically consists of a *control unit (CU),* an interconnection network, and *N processing elements (PEs)* where each PE is a processor-memory pair. The CU broadcasts instructions to the PEs and all enabled PEs execute the same instruction at the same time. *Masking* operations can be performed by the CU to enable or disable any set of PEs within the machine. The execution time of an SIMD algorithm is the greatest amount of time required by the CU and any one PE to complete execution of the algorithm. The operations performed by the CU and this single PE constitute the longest processing path or *critical path* through the parallel algorithm. Performance measures of a parallel algorithm such as execution time, throughput, utilization, and speedup can be determined by extracting the critical path and simulating a CU and a PE executing it. This paper describes a new technique to extract, compile, and simulate the critical path of an SIMD algorithm.

Many parallel processing systems are currently being designed or are under development. During the early stages of these systems parallel hardware and a complete set of parallel software tools are often not available. The simulation technique presented here is important because the critical path through the algorithm is a serial program and thus can be processed and simulated using existing serial processing tools. Simulation of the critical path permits analysis of all major components of an SIMD algorithm including enabling and disabling PEs, interprocessor communications, and CU operations. This technique is being used to design a real-time distributed speech understanding system [1].

Section II discusses the PASM architecture which is used as a model in this paper, the SIMD signal processing algorithms to be analyzed, and aspects of the Parallel-C programming language in which the algorithms are coded. Section III details the critical path analysis procedure. As an example of this procedure, Section IV presents the analysis of a fast Fourier transform algorithm.

## II. Architecture and Algorithms

### PASM Parallel Processing System

*PASM* [10] is a partitionable SIMD/MIMD system which can be structured as one or more independent SIMD and/or MIMD machines. This dynamically reconfigurable multiprocessor system is being designed at Purdue University to serve as a research tool in speech and image processing applications. PASM consists of *N* PEs, *Q Microcontrollers (MCs),* a partitionable multistage interconnection network, multiple secondary storage units, and additional processors for job scheduling and I/O.

N/Q PEs are associated with each MC to form an *MC-group.* An SIMD machine *partition* of MN/Q PEs is formed by combining the efforts of M MC-groups. The MCs act as CUs for their PEs in SIMD mode. The PASM operating system will schedule and protect system resources to support a multi-user environment. A prototype of the PASM parallel system with $N = 16$ PEs and $Q = 4$ MCs is being constructed. The design uses the Motorola MC68010 microprocessor [5] as the computation engine of the PE, MC, and support processors.

### Parallel-C Signal Processing Algorithms

Many common signal processing algorithms used in speech and image processing such as fast Fourier transforms *(FFTs),* digital filtering, power spectrum estimation, convolution, and histogramming [7, 8] have very regular data-independent control structures. It is this type of algorithm that this work addresses.

The SIMD signal processing algorithms are written in Parallel-C [4], an extension to the C programming language [3]. Parallel-C provides a "high-level" medium to describe a parallel algorithm without excessive emphasis on the details of the machine's hardware. The language extensions for SIMD mode processing include the definition of parallel variables, functions, and expressions; a scheme for accessing parallel variables by using *selectors;* and extended control structure semantics. Selectors are special variables which are used to define the set of PEs that will perform a parallel operation. As in serial C, scalar variables, functions, and operations may also be defined. Variables are declared in Parallel-C by the new keywords *parallel*, *scalar*, and *selector.*

[†] current address: Institute for Defense Analyses - Supercomputing Research Center, 4380 Forbes Blvd., Lanham, MD 20706 USA

0190-3918/86/0000/0796 $01.00 © 1986 IEEE

Algorithms in Parallel-C can be written for whatever number of processors seems "natural" without regard for the number of physical processors that may actually be available at run time.[‡] If the algorithm's ***extent of parallelism*** exceeds the physical machine size, multiple ***virtual processing elements (VPEs)*** can be emulated on each real ***physical processing element (PPE)*** to create a ***virtual machine size (VMS)*** equivalent to the extent of parallelism. For each VPE emulated within a PASM PPE, a ***virtual microcontroller (VMC)*** is emulated within the associated ***physical microcontroller (PMC)***. If the extent of parallelism in an algorithm is $E$ but only $H$ PPEs are available in hardware, the operating system will map E/H VPEs into each real PPE and E/H VMCs into each PMC. Therefore, each of the M MC-groups in the machine partition emulates E/H virtual MC-groups.

Conceptually, the ME/H MC-group emulations described above are separate processes, M of which are scheduled to run at a time. These processes are forced to perform a ***context switch*** at certain synchronization points in the algorithm to ensure correct emulation of the SIMD machine. For example, consider a synchronized SIMD inter-processor communication step in which all source VPEs write data to destination VPEs through the interconnection network. All VPEs must send data to their destinations before any is allowed to retrieve the data. A synchronization point is required in the network transfer routine to force each virtual MC-group to context switch. When E/H context switches have occurred all VPEs can continue.

## III. Analysis Procedure

The execution time of an algorithm is obtained by extracting the critical path from the Parallel-C source program, compiling the resulting serial C program, assembling the code, adding the PASM library functions, and simulating the algorithm.

### Critical Path Extraction

The source code of an algorithm written in Parallel-C describes each scalar and parallel operation and the appropriate masking information. The Parallel-C Critical Path *(PCCP)* preprocessor accepts the Parallel-C source program and converts it into an equivalent critical path C program using the PASM hardware machine size (Q MCs, N PEs) and the machine partition size (M MCs, MN/Q PEs) to specify the conversion. The critical path conversion process mimics some of the operations that would be performed by a Parallel-C compiler.

PCCP extracts the critical path of an algorithm by transforming each Parallel-C input line into its critical path equivalent. As variables are declared, PCCP maintains a list of each variable name and type while converting the declaration into equivalent C language notation. Scalar variable declarations remain the same except for the elimination of the *scalar* keyword. Parallel variable declarations are converted into normal C language variables. Selector variables are not declared in the critical path code. PCCP uses the variable information to differentiate between scalar and parallel expressions and to analyze parallel variable selector information.

A Parallel-C expression containing only scalar variables is equivalent to its critical path counterpart and no changes are necessary. Conversion of an expression containing parallel variables requires several steps. Initially, selector information is extracted from the expression. The selector information within a parallel statement specifies the MC masking operations required to execute the statement. It is necessary for the MC to perform masking operations only if the new selector differs from the selector of the previously executed parallel statement. The number of selectors, the selector type (select a fixed group of VPEs or a group of VPEs that varies depending on the value of a program variable), and the surrounding algorithm control structure may also indicate the necessity to perform MC masking operations. PCCP tracks selector information and generates special instructions for the MC to perform masking when required. After generating the masking information the parallel expression is converted by removing all selector information.

The PCCP preprocessor performs all of the operations of the standard C preprocessor [3]. This permits the inclusion of special optimized algorithm macros and assembly language code to improve algorithm performance. The preprocessor also permits the selective elimination of sections of Parallel-C source code from the final program. With the exception of the expressions that translate into MC control instructions, removing source code permits a closer dissection of the execution times of the operations which comprise the algorithm such as masking operations time, operating system overhead, and the time for inter-processor communications.

### Simulation

The resulting serial C source program text is prepared for simulation by an MC68010 C compiler, assembler, and linker-loader. PASM library functions to perform C startup, initialization, mathematics, interconnection network, PE masking, and context switching operations are linked to the algorithm code.

The output of the linker-loader is an object file and is interpreted by the simulator. The simulation program is used to simulate the CU and a PE executing the critical path of the parallel algorithm. The simulator is a general purpose uni/multi-processor hardware description and simulation program. It allows the modeling of a wide variety of machine interconnection structures and processing models.

To obtain the algorithm critical path execution time the critical path VPE and associated VMC are simulated. When the machine partition size is less than the extent of parallelism, the critical path execution time must be multiplied by E/H to obtain the complete algorithm execution time. This is accurate because the overhead of the operating system to perform context switching is included in the PASM library functions and hence in the critical path simulation results.

## IV. Example Algorithm Analysis

As an example of the detailed algorithm performance measures obtainable by the critical path extraction technique, the analysis results for a 512-point complex decimation-in-time FFT algorithm are presented. The PE model used in this simulation uses the Motorola MC68010 microprocessor and MC68881 floating-point coprocessor as the execution unit [5, 6]. A multistage cube interconnection network [9] is used.

Parallel SIMD algorithms to perform FFTs have been described in [2]. The principal components of the algorithm include computation steps called ***butterfly operations,*** interconnection network transfers, PE masking

[‡] This approach can be used for an operating system implementation in which multiple jobs may be active simultaneously and the available resources cannot be predicted at compile time. In real-time systems, programs would be coded for a specific number of processors and would be compile-time bound to those processors.

operations, and algorithm control. The structure of the 512-point algorithm consists of 9 stages each containing 256 butterfly operations. Each butterfly operation requires 2 complex floating point additions and 1 complex floating point multiplication. The extent of parallelism in the algorithm is 256 PEs. The complex data, D(i), $0 \leq i < 512$, is distributed 2 data items per VPE. At the start of the algorithm VPE i contains D(i) and D(i + 256). At algorithm completion VPE i contains data item br(2i) and br(2i + 1) where br(i) indicates the bit-reverse of i. The algorithm is optimized by pre-calculating the FFT twiddle factors, masking operation constants, and interconnection network transfer settings.

Figure 1 is a graph of the cumulative execution times of the operations that comprise the algorithm as a function of the number of PPEs within the machine partition. Starting from the bottom of Figure 1, each solid line indicates the algorithm execution time resulting from the addition of the labeled operation to the operations graphed below. The top curve on the graph was obtained by simulating the complete FFT algorithm. The second curve from the top was obtained by using PCCP to eliminate the code that performs the operating system functions. The difference between the top two curves is the operating system execution time. The difference between the next two curves is the execution time of the butterfly operations. Additional performance measures such as overhead ratio, speedup, and throughput [11] can be obtained by combining these execution time results. Processor utilization [11] can be inferred by using PCCP to eliminate portions of the algorithm corresponding to each PE mask setting, obtaining the execution time for the remaining PEs, and comparing these times to the execution time of all PEs.

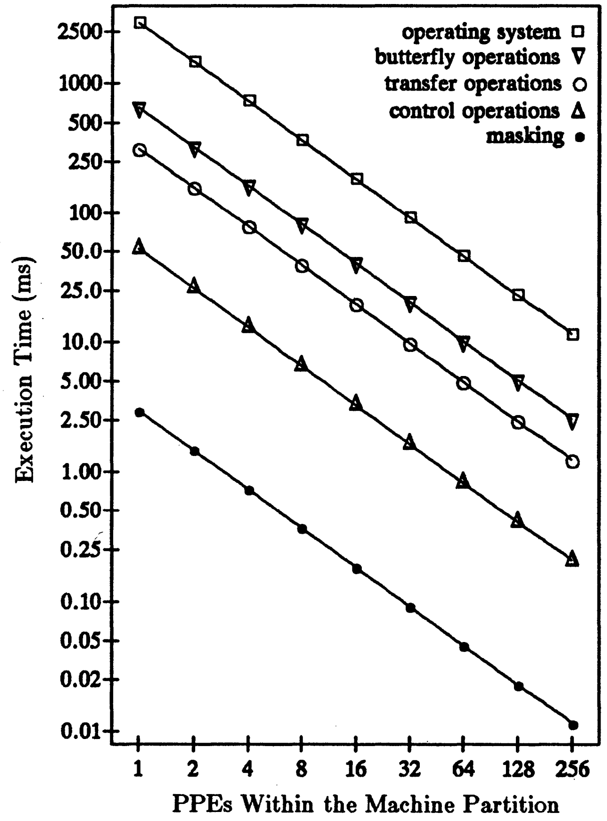

Figure 1 The cumulative execution times for the operations that comprise a 512-point complex fast Fourier transform algorithm.

## V. Summary

A new method to obtain execution time related performance measures of certain data-independent SIMD algorithms running on a parallel processing system has been described. Performance measures such as execution time, speedup, throughput, and utilization can be obtained by extracting the critical path from a Parallel-C algorithm and simulating its performance. The critical path analysis procedure is described and the analysis of an FFT algorithm is presented.

The technique allows detailed analysis of parallel algorithms at an early stage in the development cycle of a parallel system while the software and hardware tools are still under construction. Analysis of the critical path permits a more detailed algorithm analysis than is possible by purely analytical techniques because it includes actual compiler and operating system overhead details such as register allocation, function call overhead, high-level language initialization, context switch overhead, and specific details about the hardware implementation. Although PASM has been used as the specific model in this work, critical path analysis is a general technique and can be applied to other SIMD architectures executing a Parallel-C-like high-level language.

# MULTI GRID ALGORITHMS IMPLEMENTED ON EGPA MULTIPROCESSOR

J. Volkert and W. Henning

Universität Erlangen-Nürnberg
Institut für Mathematische Maschinen
und Datenverarbeitung (III)
Martensstr. 3 / D-8520 Erlangen / F.R.G.

## Abstract

This paper presents the numerical solution of partial differential equations for simulation of physical phenomena on a class of multiprocessors, called EGPA-systems. The used multigrid methods are well-suited for the considered EGPA systems. An implementation example is given. Communication mechanisms are explained. The results are discussed in respect to efficiency and speed up. At last a view at the future work is taken.

## Introduction

For many years only computer scientists have been interested in multiprocessors consisting of more than just a few elements. But with the appearance of the Hypercube, such a system is commercially available. In the field of vector-computers the trend to multiprocessors is also discernible. Till now, these supercomputers were offered with only a small number of processors, but the number is continuously increasing.

At the University of Erlangen-Nürnberg, West-Germany, multiprocessors have been investigated for several years. We are particularly interested in a certain class called EGPA (Erlangen General Purpose Array). Since we presented the features of such systems in former papers [1-3] we will only give a short description of the EGPA architecture in chapter II. The main part of this paper deals with software aspect.

Two EGPA systems were realized. The first one, a small prototype (5 processors), was built in the late seventies. In chapter III we will have a short look at the other system which is presently running and consists of 21 processors.
