# Preface

In this decade, the field of parallel processing has exploded! This conference provides clear proof: in the early 1980's on the order of 100 to 125 papers were submitted annually; in contrast, over 400 papers were submitted this year. Such growth is both gratifying and challenging. On the one hand, it indicates a high and growing level of interest in parallel processing techniques and technologies. The resulting parallel systems are sorely needed to provide computing resources for ever more demanding applications in science, medicine, commerce, and industry.

On the other hand, such growth also challenges the logistics implicit in organizing the conference. Consider, for example, the paper selection process: (1) papers are submitted to the program co-chairs, (2) the co-chairs reassign some papers to other program areas (based on the co-chairs' mutually agreed definitions of the subject areas), (3) at least three reviews are solicited for each paper, (4) as the program selection date approaches, additional reviews are solicited (on a "crash" basis) for those papers with fewer than three reviews, (5) each program co-chair makes a tentative selection of papers and organizes them into potential sessions, (6) the three co-chairs merge their tentative programs, coalescing overlapping sessions, deleting orphan papers (those good papers that don't quite fit with others to form cohesive sessions), and continue to raise the acceptance standards to meet the conference size constraints, and finally (7) acceptance and rejection letters are sent to the authors. The difficulty of this process increases in proportion to the number of submissions, and in inverse proportion to the paper acceptance rate.

For many conferences, a typical paper acceptance rate is 60% to 70%, in our case, we were limited by the conference facilities and by the desire that the proceedings be portable to a 45% acceptance rate. While such a low rate indicates that the papers that comprise this proceedings are of extremely high quality, it also indicates that many good papers had to be rejected. The impact is probably more profound on new entrants to the field and foreign (i.e., non-native English speaking) authors than upon experienced authors, which may give the appearance that the field has become "in-bred". This year's program committee has tried to avoid any such prejudice, but given our limitations, the program can only be viewed as a best approximation to the rapidly evolving state of the art of parallel processing in 1986.

It has been our privilege to have received support from a large and dedicated assembly of reviewers as listed on the next page. Without their rapid assistance, the conference could not occur. It is also a pleasure to identify the secretaries that have handled the various filing, copying, correspondence, and countless other chores required to develop the program. Our sincere thanks go to: Jenine Abarbanel, Vicki Adame, Lauren Hall, Alice Harris, Shirin Mistry, and Elaine Smiles. The continuous support and encouragement of the Conference General Chairman, Professor Tse-yun Feng has been most gratifying. Most of all, we thank the authors for taking the time and effort to share their work with the parallel processing community.

# AN AUTOMORPHISM OF A CLASS OF INTERCONNECTION NETWORKS

WOEI LIN

*Department of Electrical Engineering*

*University Park, PA 16802*

## ABSTRACT

A class of interconnection schemes, commonly referred to as multistage interconnection networks, is proposed as a means, providing simultaneous connections among processing elements in multiprocessor systems. In this paper, we present an automorphism, with which the logical structure of the interconnection networks can be changed. We show that the resulting logical structure of a network is isomorphic to its physical structure. For the purpose of demonstration, three popular networks are examined: baseline network, omega network and indirect n-cube network.

## I. INTRODUCTION

A class of multistage interconnection networks have been proposed, and many of them have been implemented for providing simultaneous, reconfigurable connections among processing elements in multiprocessor systems. These networks include baseline network[1]-[3], flip network[4], omega network[5], and many others[6]-[8]. Advantages of these networks include cost effectiveness, logarithmic communication delay, modular expansibility, and partitionabilit. The primary goal of this work is to show that for each network of this class, there exist a multiplicity of logical network structures, which are isomorphic to its physical network structure. More specifically, we will present a one-to-one correspondence, which turns out to be an automorphism, changing logical structures of these networks. To illustrate this idea, three popular multistage interconnection networks are chosen for demonstration: baseline network, indirect n-cube network and omega network.

The rest of this work is organized as follows. In Section II, we will describe the integration of the networks, including network components and general network configuration. In Section III, we will present the definition of a one-to-one correspondence. Section IV contains the proofs, showing that this correspondence is an automorphism with respect to the three networks.

## II. PRELIMINARIES

### 2.1 Configuration of Networks

The multistage interconnection networks to be examined are characterized by three attributes: (1) switching element, (2) arrangement of switching elements, and (3) permutation pattern between stages of switching elements.

(1)Switching element. These networks employ a 2x2 crossbar switch as a buliding block, as shown in Figure 1. This 2x2 switching element has two inputs and two output, denoted $X_1$, $X_2$, $Y_1$, and $Y_2$. It has the capability of connecting the input $X_1$ to either the output $Y_1$ or the output $Y_2$, depending on the value of some routing bit of the input $X_1$. If the routing bit is 0, the input is connected to the output $Y_1$, and if the routing bit is 1, the connection is made to the output $Y_2$. Input $X_2$ of the switch behaves similarly with a routing bit.

(2)Arrangement of switching element. These networks is composed of a logarithmic number of stages of switching elements; a network of size $N=2^n$ comprises n stages of switching elements. Furthermore, each stage comprises N/2 switching elements, as described above. Consequently, an interconnection network of such a configuration has *N network inputs* and *N network outputs* and contains $(N/2)\log_2 N$ switching elements.

(3)Permutation pattern between stages of switching elements. In a network, two adjacent stages of switching elements are cascaded by a set of N communication links, from the outputs of switching elements of the preceding stage to the inputs of switching elements of the succeeding stage. In a network of size N, there are $(\log_2 N)+1$ levels of communication links. Each level is associated with a specific permutation pattern. It should be noted that these networks, however, are different in the permutation patterns between stages of switching elements. In Section IV the permutation patterns of each individual network will be described.

### 2.2 Addressing of networks

To facilitate describing the configurations of these interconnection networks, a uniform addressing scheme is presented. As shown in Figure 2, in a network of size $N=2^n$, the network inputs are addressed in a sequence from 0 to N-1, from top to bottom. In a similar way, the network outputs are addressed from 0 to N-1. Recall that an interconnection network of size N, as described in the previous subsection, contains $n=\log_2 N$ stages of switching elements and n+1 levels of links. The addressing schemes of stages and switching elements are depicted as follows. These n stages are labeled in a sequence from 0 to n-1 with 0 for the leftmost stage and n-1 for the rightmost stage. Similarly, the levels of links are labeled in a sequence from 0 to n. In each stage, the N/2 switching elements are addressed from 0 to N/2-1, each of which can also be represented by an (n-1)-bit binary number of the form, $s_{n-1}s_{n-2}...s_1$. In each stage, each switching element is associated with four communication links; for a switching element labeled by $s_{n-1}s_{n-2}...s_1$, the upper link to the input $X_1$ is addressed by an n-bit binary number, $s_{n-1}s_{n-2}...s_1 0$, and the lower one to the input $X_2$ is addressed by $s_{n-1}s_{n-2}...s_1 1$. Similarly, the two links from outputs $Y_1$ and $Y_2$ are addressed by $s_{n-1}s_{n-2}...s_1 0$ and $s_{n-1}s_{n-2}...s_1 1$, respectively.

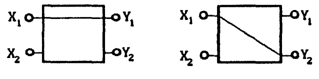
From topological point of view, these interconnection networks are different in their permutation patterns between stages of switching elements. To describe the permutation patterns of an interconnection network, the following notation will be adopted:

$$\gamma_i(Y)=X.$$

For a network of size $N=2^n$, $\gamma_i$ specifies the permutation of communication links of level i (from the outputs of stage i-1 to the inputs of stage i of switching elements). However, in the case of i=0, the input domain of $\gamma$ is the set of network inputs. Similarly, in the case of i=n, the output domain of $\gamma$ is the set of network outputs. For instance, if the permutation pattern of level i is a perfect shuffle permutation[12], then we have

$$\gamma_i(Y)=(2Y+\lfloor 2Y/N \rfloor) \bmod N,$$

for all the outputs of switching elements of stage i-1. That is, the output, Y, of stage i-1 is connected to the input, $((2Y+\lfloor 2Y/N \rfloor) \bmod N)$, of stage i.



Routing bit of $X_1$ is 0 Routing bit of $X_1$ is 1

## III. THE DEFINITION OF $\xi$

This is the purpose of this section to define a one-to-one correspondence, which turns out to be an automorphism, with respect to the multistage interconnection networks. Also, we will present two functions, which are used to rearrange the switching elements and the topology of the five networks.

**DEFINITION.** Let S be a set of n-bit binary numbers from 0 to $2^n-1$, or $S=(0,1,\dots 2^n-1)$. And let C be a constant, $0\leq C\leq 2^n-1$. $\xi_C$ is a mapping from S to S, and $\xi_C(X)=X\oplus C$, for every $X\epsilon S$.

With the definition above, we now present the statement of the problem to be investigated as follows.

**STATEMENT OF THE PROBLEM:** If we relabel the network inputs and outputs of a multistage interconnection network by $\xi_p$ and $\xi_Q$, respectively, then there exists a way of rearranging the switching elements and links such that the topology of the rearranged network is equivalent to that of the original network. That is, both of the two topologies are isomorphic.

To illustrate the statement above, an example is given in Figure 3. Consider a baseline network of size 16, whose network inputs and outputs are relabeled through $\xi_{11}$ and $\xi_6$, respectively. What we intend to show is that the two network topologies are isomorphic. For convenience, hereafter $\xi_{p:Q}$ denotes "apply $\xi_p$ to the network inputs and $\xi_Q$ to the network outputs of a multistage network."

Before presenting the proof that $\xi_{p:Q}$ is an automorphism onto the multistage interconnection network, we further introduce two functions, which will be used to rearrange switching elements and their associated links:

(1)MOVE $\mu_i$: This is a one-to-one correspondence, which is used to rename the switching elements of stage i, according to some mapping rule.

(2)TWIST $\tau_i$: This is used to interchange a pair of inputs or outputs of a switching element of stage i. Associated with $\tau_i$, there are two control bits $c_x$ and $c_y$, which are used to specify the interchange on the input side and the output side of a switching element, respectively. As illustrated in Figure 4, there are four possible operations of $\tau_i$ on a switching element:

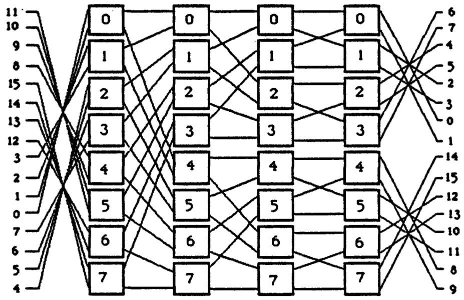

Figure 3. A baseline network whose network inputs and outputs are permuted by $\xi_{11:6}$.

1. *No-twist.* When $c_x=0$ and $c_y=0$, no operation is performed on the switching element;
2. *Left-twist.* When $c_x=1$ and $c_y=0$, the input side of the switching element is twisted 180° counterclockwise;
3. *Right-twist.* When $c_x=0$ and $c_y=0$, the output side of the switching is twisted 180° clockwise;
4. *Vertical-flip.* When $c_x=1$ and $c_y=1$, the switching element is flipped vertically.

## VI. THE AUTOMOPHISM OF NETWORKS

In this section, we prove that $\xi_{p:Q}$ is an automorphism onto the three multistage interconnection networks: baseline network, omega network, and indirect n-cube network. (However, only the proof for the baseline network is presented, and the other two proofs for the omega network and the indirect n-cube network are omitted.) Throughout the discussion, we assume that $X=x_{n-1}x_{n-2}\dots x_0$ is an input and $Y=y_{n-1}y_{n-2}\dots y_0$ is an output of a switchig element. For the reason of uniform notation, here we define that $\tau_{-1}(\mu_{-1}(Y))=\xi_P(Y)$ and $\tau_n(\mu_n(X))=\xi_Q(X)$; that is, network inputs are considered as the outputs of a virtual stage, Stage -1, and similarly network outputs are considered as the inputs of a virtual stage, Stage n.

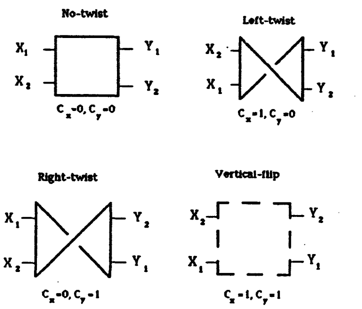

Figure 4. Four combinations of $\mu$ and $\tau$ on a switching element.

### 4.1 Baseline Network

The permutation patterns of a baseline network of size $N=2^n$ are defined by:

$$\gamma_i(Y)=x_{n-1}x_{n-2}\dots x_0 = \begin{cases} y_{n-1}y_{n-2}\dots y_0 & i=0,\\ y_{n-1}\dots y_{n-i+1}y_0y_{n-i}\dots y_1 & 1\leq i\leq n-1,\\ y_{n-1}y_{n-2}\dots y_0 & i=n. \end{cases} \qquad (1)$$

Let P and Q be two n-bit numbers, and $P=p_{n-1}p_{n-2}\dots p_0$, $Q=q_{n-1}q_{n-2}\dots q_0$. The function of $\mu_i$ is to move a switching element $(z_{n-1}z_{n-2}\dots z_1)$ of stage i to a new location

$$\begin{cases} (z_{n-1}z_{n-2}\dots z_1)\oplus(p_{n-1}p_{n-2}\dots p_1) & i=0,\\ (z_{n-1}z_{n-2}\dots z_1)\oplus(q_{n-1}\dots q_{n-i}p_{n-1}\dots p_{i+1}) & 1\leq i\leq n-2,\\ (z_{n-1}z_{n-2}\dots z_1)\oplus(q_{n-1}q_{n-2}\dots q_1) & i=n-1. \end{cases}$$

In terms of binary addresses of the communication links associated with switching elements of stage i, the function of $\mu_i$ can be explicitly described by

$$\mu_i(X)=\begin{cases} (x_{n-1}x_{n-2}\dots x_0)\oplus(p_{n-1}p_{n-2}\dots p_10) & i=0\\ (x_{n-1}x_{n-2}\dots x_0)\oplus(q_{n-1}\dots q_{n-i}p_{n-1}\dots p_{i+1}0) & 1\leq i\leq n-2\\ (x_{n-1}x_{n-2}\dots x_0)\oplus(q_{n-1}q_{n-2}\dots q_10) & i=n-1 \end{cases}$$

and

$$\mu_i(Y)=\begin{cases} (y_{n-1}y_{n-2}\dots y_0)\oplus(p_{n-1}p_{n-2}\dots p_10) & i=0\\ (y_{n-1}y_{n-2}\dots y_0)\oplus(q_{n-1}\dots q_{n-i}p_{n-1}\dots p_{i+1}0) & 1\leq i\leq n-2\\ (y_{n-1}y_{n-2}\dots y_0)\oplus(q_{n-1}q_{n-2}\dots q_10) & i=n-1. \end{cases} \qquad (2)$$

In addition, $\tau_i$ is defined by

$$\tau_i(X)=(x_{n-1}x_{n-2}\dots x_0)\oplus(0\dots 0p_i) \qquad 0\leq i\leq n-1$$

and

$$\tau_i(Y)=(y_{n-1}y_{n-2}\dots y_0)\oplus(0\dots 0q_{n-i-1}) \qquad 0\leq i\leq n-1. \qquad (3)$$

The equivalent function of $\tau_i$, as defined above, is to left-twist all the switching elements at stage i if $p_i=1$ and right-twist the switching elements if $q_{n-i-1}=1$. With $\tau_i$ and $\mu_i$ above, we now prove that there always exists an equivalence relationship between a baseline network and its rearranged network by $\xi_{p:Q}$.

**THEOREM 1.** $\xi_{p:Q}$, $0\leq P,Q\leq 2^n-1$, is an automorphism onto a baseline network of size $2^n$.

**Proof**: Our approach is to show that after the switching elements of stage i-1 are rearranged by $\tau_{i-1}$ and $\mu_{i-1}$, and the switching elements of stages i are rearranged by $\tau_i$ and $\mu_i$, the rules of (1) still hold for all the links of level i. Thus we have

$$\gamma_i(\tau_{i-1}(\mu_{i-1}(Y)))=\begin{cases} (y_{n-1}\oplus p_{n-1})(y_{n-2}\oplus p_{n-2})\dots(y_0\oplus p_0) & i=0,\\ (y_0\oplus q_{n-1})(y_{n-1}\oplus p_{n-1})\dots(y_1\oplus p_1) & i=1,\\ (y_{n-1}\oplus q_{n-1})\dots(y_{n-i+1}\oplus q_{n-i+1})(y_0\oplus q_{n-i}) & \\ \qquad (y_{n-i}\oplus p_{n-1})\dots(y_1\oplus p_i) & 2\leq i\leq n-1,\\ (y_{n-1}\oplus q_{n-1})(y_{n-2}\oplus q_{n-2})\dots(y_0\oplus q_0) & i=n. \end{cases}$$

Furthermore, we have

$$\tau_i(\mu_i(X))=\begin{cases} (x_{n-1}\oplus p_{n-1})(x_{n-2}\oplus p_{n-2})\dots(x_0\oplus p_0) & i=0,\\ (x_{n-1}\oplus q_{n-1})(x_{n-2}\oplus p_{n-1})\dots(x_0\oplus p_1) & i=1,\\ (x_{n-1}\oplus q_{n-1})\dots(x_{n-i+1}\oplus q_{n-i+1})(x_{n-i}\oplus q_{n-i}) & \\ \qquad (x_{n-i-1}\oplus p_{n-1})\dots(x_0\oplus p_i) & 2\leq i\leq n-1,\\ (x_{n-1}\oplus q_{n-1})(x_{n-2}\oplus q_{n-2})\dots(x_0\oplus q_0) & i=n. \end{cases}$$

As a result, we have $\gamma_i(\tau_{i-1}(\mu_{i-1}(Y)))=\tau_i(\mu_i(X))$, for all $0\leq i\leq n$. □

For instance, Figure 5 illustrates a rearranged baseline network of size 16 by $\xi_{11:6}$ and $\tau$ as well as $\mu$ as defined by (2) and (3). Note that the rearranged network is topologically equivalent to the baseline network.

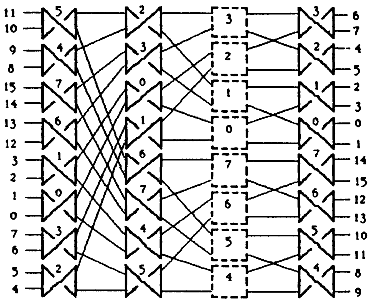

Figure 5. Configuration of a rearranged baseline network.

### 4.2 Omega Network

The permutation patterns of an omega network of size $N=2^n$ are described by:

$$\gamma_i(Y)=x_{n-1}x_{n-2}\cdots x_0 = \begin{cases} y_{n-2}y_{n-3}\cdots y_0\, y_{n-1} & 0\le i\le n-1, \\ y_{n-1}y_{n-2}\cdots y_0 & i=n. \end{cases} \qquad (4)$$

Let P and Q be two n-bit numbers, and $P=p_{n-1}p_{n-2}\cdots p_0$, $Q=q_{n-1}q_{n-2}\cdots q_0$. The function of $\mu_i$ is to move a switching element $(z_{n-1}z_{n-2}\cdots z_1)$ of stage i to a new location

$$\begin{cases} (z_{n-1}z_{n-2}\cdots z_1)\oplus(p_{n-2}p_{n-3}\cdots p_0) & i=0 \\ (z_{n-1}z_{n-2}\cdots z_1)\oplus(p_{n-i-2}\cdots p_0q_{n-1}\cdots q_{n-i}) & 1\le i\le n-2 \\ (z_{n-1}z_{n-2}\cdots z_1)\oplus(q_{n-1}q_{n-2}\cdots q_1) & i=n-1. \end{cases}$$

In terms of binary addresses of the communication links, $\mu_i$ can be described by

$$\mu_i(X)=\begin{cases} (x_{n-1}x_{n-2}\cdots x_0)\oplus(p_{n-2}p_{n-3}\cdots p_0 0) & i=0, \\ (x_{n-1}x_{n-2}\cdots x_0)\oplus(p_{n-i-2}\cdots p_0q_{n-1}\cdots q_{n-i}0) & 1\le i\le n-2, \\ (x_{n-1}x_{n-2}\cdots x_0)\oplus(q_{n-1}q_{n-2}\cdots q_1 0) & i=n-1. \end{cases}$$

and

$$\mu_i(Y)=\begin{cases} (y_{n-1}y_{n-2}\cdots y_0)\oplus(p_{n-2}p_{n-3}\cdots p_0 0) & i=0, \\ (y_{n-1}y_{n-2}\cdots y_0)\oplus(p_{n-i-2}\cdots p_0q_{n-1}\cdots q_{n-i}0) & 1\le i\le n-2, \\ (y_{n-1}y_{n-2}\cdots y_0)\oplus(q_{n-1}q_{n-2}\cdots q_1 0) & i=n-1. \end{cases} \qquad (5)$$

In addition, we define $\tau_i$ by

$$\tau_i(X)=(x_{n-1}x_{n-2}\cdots x_0)\oplus(0\ldots 0p_{n-i-1}) \qquad 0\le i\le n-1,$$

and

$$\tau_i(Y)=(y_{n-1}y_{n-2}\cdots y_0)\oplus(0\ldots 0q_{n-i-1}) \qquad 0\le i\le n-1. \qquad (6)$$

The equivalent function of $\tau_i$, as defined above, is to left-twist all the switching elements at stage i if $p_{n-i-1}=1$ and right-twist the switching elements if $q_{n-i-1}=1$. With $\tau_i$ and $\mu_i$ above, we now prove that there always exists an equivalence relationship between an omega network and its rearranged network by $\xi_{P:Q}$

**THEOREM 2.** $\xi_{P:Q}$, $0\le P,Q\le 2^n-1$, is an automorphism onto an omega network of size $2^n$.

### 4.3 Indirect n-Cube Network

In an indirect n-cube network of size $N=2^n$, the permutation patterns of n stages of links are defined by:

$$\gamma_i(Y)=x_{n-1}x_{n-2}\cdots x_0 = \begin{cases} y_{n-1}y_{n-2}\cdots y_0 & i=0, \\ y_{n-1}\cdots y_2y_0y_1 & i=1, \\ y_{n-1}\cdots y_{i+1}y_0y_{i-1}\cdots y_1y_i & 2\le i\le n-2, \\ y_0y_{n-2}\cdots y_1y_{n-1} & i=n-1, \\ y_0y_{n-1}y_{n-2}\cdots y_1 & i=n. \end{cases} \qquad (7)$$

Let P and Q be two n-bit numbers, and $P=p_{n-1}p_{n-2}\cdots p_0$ and $Q=q_{n-1}q_{n-2}\cdots q_0$. The function of $\mu_i$ is to move a switching element $(z_{n-1}z_{n-2}\cdots z_1)$ of stage i to a new location

$$\begin{matrix} (z_{n-1}z_{n-2}\cdots z_1)\oplus(p_{n-1}p_{n-2}\cdots p_1) & i=0, \\ (z_{n-1}z_{n-2}\cdots z_1)\oplus(p_{n-1}\cdots p_{i+1}q_{i-1}\cdots q_0) & 1\le i\le n-2, \\ (z_{n-1}z_{n-2}\cdots z_1)\oplus(q_{n-2}q_{n-3}\cdots q_0) & i=n-1. \end{matrix}$$

In terms of the binary addresses of communication links associated with switching elements of stage i, we have

$$\mu_i(X)=\begin{cases} (x_{n-1}x_{n-2}\cdots x_0)\oplus(p_{n-1}p_{n-2}\cdots p_1 0) & i=0, \\ (x_{n-1}x_{n-2}\cdots x_0)\oplus(p_{n-1}\cdots p_{i+1}q_{i-1}\cdots q_0 0) & 1\le i\le n-2, \\ (x_{n-1}x_{n-2}\cdots x_0)\oplus(q_{n-2}q_{n-3}\cdots q_0 0) & i=n-1, \end{cases}$$

and

$$\mu_i(Y)=\begin{cases} (y_{n-1}y_{n-2}\cdots y_0)\oplus(p_{n-1}p_{n-2}\cdots p_1 0) & i=0, \\ (y_{n-1}y_{n-2}\cdots y_0)\oplus(p_{n-1}\cdots p_{i+1}q_{i-1}\cdots q_0 0) & 1\le i\le n-2, \\ (y_{n-1}y_{n-2}\cdots y_0)\oplus(q_{n-2}q_{n-3}\cdots q_0 0) & i=n-1. \end{cases} \qquad (8)$$

In addition, we define

$$\tau_i(X)=(x_{n-1}x_{n-2}\cdots x_0)\oplus(0\ldots 0p_i) \qquad 0\le i\le n-1$$

and

$$\tau_i(Y)=(y_{n-1}y_{n-2}\cdots y_0)\oplus(0\ldots 0q_i) \qquad 0\le i\le n-1. \qquad (9)$$

The equivalent function of $\tau_i$, as defined above, is to left-twist all of the switching elements at stage i if $p_i=1$ and right-twist the switching elements if $q_i=1$. With $\tau_i$ and $\mu_i$ above, we now prove that there always exists an equivalence relationship between an indirect n-cube network and its rearranged network by $\xi_{P:Q}$

**THEOREM 3.** $\xi_{P:Q}$, $0\le P,Q\le 2^n-1$, is an automorphism onto an indirect n-cube network of size $2^n$.

## VI. CONCLUSION

**We have presented a one-to-one correspondence, $\xi_{P:Q}$, used to rename network inputs and outputs for a class of multistage interconnection networks. It is then proved that a renamed network is isomorphic to its parent network; that is, $\xi_{P:Q}$ is an automorphism. The class of multistage interconnection networks we have shown includes baseline network, omega network and indirect n-cube network. To illustrate that $\xi_{P:Q}$ is an automorphism, schemes of rearranging switching elements for each network are described and demonstrated in detail.**

# EFFECT OF ARBITRATION POLICIES ON THE PERFORMANCE OF INTERCONNECTION NETWORKS

**Laxmi N. Bhuyan**

## ABSTRACT

In performance evaluation of interconnection networks it is usually assumed that in case of conflicts a request is accepted with equal probability. This paper illustrates that this arbitration policy is discriminatory to remote or less frequent requests because they are rejected most of the time. The paper considers a favorite memory environment as an example and examines the network performance under various arbitration policies. Equal Acceptance, priority to favorite and non favorite request policies are examined by defining three probabilities of acceptance. The networks considered are crossbar, multiple-bus and multistage interconnection networks.

## 1. INTRODUCTION

A tightly coupled multiprocessor is usually categorized depending on the interconnection network (IN) that is used between the processors and memories [1]. Such IN's can be broadly divided into: (a) Crossbar (b) Multiple-bus (c) Multistage interconnection network (MIN). A crossbar interconnection allows all possible connections between the processors and memories [2]. When two or more processors try to access the same memory module only one of the requests is accepted and the others are blocked or rejected. A multiple-bus provides a fault-tolerant and cost effective interconnection between the processors and memories [3-5], but the number of simultaneous connections is dependent on the number of buses. When the number of buses is sufficient, a multiple-bus has the same performance as that of a crossbar. An MIN, on the other hand, is composed of several stages of switching elements (SE's) [6]. A conflict occurs when two or more requests contend for the same output of an SE. The cost and performance of such an IN is a reasonable balance between a shared bus and a crossbar. There is an extensive literature on the performance evaluation of these networks. All evaluations for synchronous multiprocessors measure Bandwidth (BW) which is defined as the number of memories remaining busy in a cycle.

The BW does not give us an idea about which requests are accepted and which are rejected. For equally likely case when a processor generates a request that is equiprobably directed to all the memories, it may not be essential to know the above details because all the processors perform similarly in the long term. However, when the processors request different memories with different probabilities, the equal acceptance (EA) rule appears discriminating because a processor with a remote request to a memory will be rejected most of the times. Rather, it should be given a priority over another processor which requests that particular memory more often. Hence, the previous analytical models of the BW do not reveal this important information that is so practical of the multiprocessor operation. As we know, no closed form solutions can be derived for general or arbitrary memory references. We will therefore restrict our analysis to favorite memory cases as depicted in Fig.1. For simplicity, we will restrict our analyses to $N \times N$ networks that connect $N$ processors to $N$ memories. Also, because of page restrictions some final equations will be given without derivations.

In Fig.1, a processor $P_i$ requests its favorite memory $MM_i$ with a probability of $m$ provided it generates a request. The processor requests all other $(N\text{-}1)$ memories with a probability of $1\text{-}m$. Assuming that those requests are uniformly distributed, the probability that a processor requests any one of those memories is $\frac{p_0(1\text{-}m)}{(N\text{-}1)}$, where $p_0$ is the probability of its request generation. When $m > \frac{1}{N}$, it is called a favorite memory case and by putting $m = \frac{1}{N}$, the analysis reduces to an equally likely case. The rate of request at a memory $MM_i$ is then $p_0.m$ due to its favorite processor $P_i$ and $\frac{p_0(1\text{-}m)}{(N\text{-}1)}$ due to any other processor provided there is no conflict in the $IN$.

## 2. ANALYSIS FOR CROSSBAR

The crossbar allows all processor requests to reach the memory modules. If more than one request reach a particular memory, one of them is accepted and the others are rejected. Which one is accepted depends on the arbitration policy of the controller. The rate of request $(p_f)$ at a memory $MM_i$ in an $N \times N$ crossbar is [7] :

$$p_f = 1 - (1 - p_0.m)(1 - p_0.\frac{1-m}{N-1})^{N-1}. \tag{1}$$

The BW, given by $N.p_f$, does not depend on the basis upon which the selection is made. The probability of favorite acceptance $(p_{fe})$ at a memory due to EA policy is given by:

$$p_{fe} = \frac{m.(N-1)}{N.(1-m)}.(1-(1 - p_0.\frac{1-m}{N-1})^N). \tag{2}$$

For large values of $N$, $\lim_{N\to\infty} p_{fe} = \frac{m}{1-m}(1-e^{p_0(m-1)})$. As an example, with $p_0 = 1$ and $m = 0.8$, $\lim_{N\to\infty} p_{fe} = 0.725$ The probability of nonfavorite acceptance,

$$p_{ne} = p_f - p_{fe}. \tag{3}$$

With $p_0 = 1$ and $m = 0.8$, $\lim_{N\to\infty} p_{ne} = 0.111$. Since most of the time a memory receives requests from its favorite processor, the requests from the other processors will be mostly unsuccessful in an EA policy. In a practical design a selection policy is fixed and is based on some priority structure. It is therefore reasonable to assign a priority to the non-favorite requests for higher values

This research is supported in part by NSF Grant No. DMC-8513041.

of $m$. Hence, whenever there is a nonfavorite request at $MM_i$, any request from $P_i$ will not be granted. We will assume that when more than one nonfavorite requests contend for a memory module, a random selection is made with an equal probability. A request from $P_i$ is granted only when there is no nonfavorite request. As a result the rate of request at a memory module due to its favorite processor is :

$$p_{fn} = p_0 \, m (1 - p_0 \frac{1-m}{N-1})^{N-1} . \tag{4}$$

The subscript $n$ stands for priority to nonfavorite requests. With $p_0 = 1$ and $m = 0.8$ , $\lim_{N \to \infty} p_{fn} = 0.655$. The rate of request at $MM_i$ due to other processors is

$$p_{nn} = p_f - p_0 \, m (1 - p_0 \frac{1-m}{N-1})^{N-1} . \tag{5}$$

With $p_0 = 1$ and $m = 0.8$ , $\lim_{N \to \infty} p_{nn} = 0.181$. The *Probability of Acceptance (PA)* of a request is the ratio of the average number of requests accepted to the number of requests generated per cycle. Thus

$$PA = \frac{BW}{p_0 * number \ of \ processors} = \frac{p_f}{p_0} . \tag{6}$$

We will define the *Probability of Favorite Acceptance (PFA)* as the ratio of the average number of favorite requests accepted to the number of favorite requests generated per cycle,

$$PFA = \frac{p_{fn} \ (or \ p_{fe} \ )}{p_0 . m} . \tag{7}$$

For the same example with $p_0 = 1$ and $m = 0.8$,

$$\lim_{N \to \infty} PFA = 0.906 \quad for \ EA \ policy.$$

$$= 0.819 \quad for \ priority \ to \ Nonfavorite \ requests.$$

Thus the *Probability of Non-favorite Acceptance* ,

$$PNFA = \frac{p_f - p_{fn} \ (or \ p_{fe} \ )}{p_0 \cdot (1-m)} \tag{8}$$

With $p_0 = 1$ and $m = 0.8$,

$$\lim_{N \to \infty} PNFA = 0.555 \quad for \ EA \ case.$$

$$= 0.905 \quad for \ priority \ to \ nonfavorite \ requests.$$

Hence by adopting priority to nonfavorite requests there is a remarkable improvement in $PNFA$ compared to the corresponding degradation in $PFA$ . The relationship between these probabilities is given by

$$PA = m \ . PFA + (1 - m) \ .PNFA \ . \tag{9}$$

It is noticed from the above examples that by allowing a priority to the nonfavorite requests, the degradation in $PFA$ is not substantial. Since the $PA$ remains the same, the $PNFA$ is increased to a large extent and for this particular example it jumps from 0.555 to 0.905 as calculated earlier. However, if $m$ is low, there will be a substantial degradation in the $PFA$ with priority to nonfavorite requests. Then $EA$ policy should be adopted. If priority is assigned to the favorite request, $PFA$ is unity for all values of $N$ and hence, the case is not considered.

## 3. ANALYSIS OF MULTIPLE-BUS

The BW analysis of multiple-bus architecture for the favorite memory case is given in [5]. There are $B$ buses in the system that connect $M$ processors to $N$ memories for $B \leq \min(M, N)$. A bus is connected to all the processors and memories. The arbiter (controller) cyclically allocates a bus to a memory that has an outstanding request. The BW of the multiple-bus structure is clearly a function of the number of buses $B$. When $B$ is equal to $min(M, N)$, the architecture has the same BW as that of a crossbar [5]. When the buses are insufficient, there will be bus conflicts in addition to the memory access conflicts. Hence, the multiple-bus controller can be designed as a cascade of a crossbar controller for resolving memory access conflicts and a bus controller to allocate buses to the memories. As a consequence, we can enumerate the following control policies.

1) Equal Acceptance - Equal Acceptance (EE)
2) Equal Acceptance - Nonfavorite (EN)
3) Nonfavorite - Equal Acceptance (NE)
4) Nonfavorite - Nonfavorite (NN)

For example, the EN policy states that EA rule is adopted for solving the memory access conflicts (crossbar controller) and Nonfavorite requests are given priority for the bus allocations. In case there are more than $B$ nonfavorite requests, $B$ of them are accepted with an equal probability. If there are less nonfavorite requests the extra buses are distributed to the favorite requests on an equally likely basis. This information is implicit in an arbiter policy and hence, is not explicitely mentioned in the above classification.

For simplicity, again, we will consider only $N \times N$ multiprocessor system. When the BW $BW_c$ of such a crossbar is less than or equal to $B$, the bus controller allows a bus to each of the selected requests and hence the system behaves as a crossbar. So for $BW_c \leq B$, the parameters derived in section II are true. For example, with $N$=16, $p_0 = 1$ and $m = 0.8$ , 14 buses are required for the multiple-bus architecture to have the same $BW$ as that of a crossbar. When $BW_c \geq B$, the bus controller plays a major role in deciding which of the requests should be allocated the buses. However, the bandwidth for the multiple-bus ($BW_m$) will remain equal to $B$ because of bus deficiency. The overall probability of acceptance is :

$$PA = \frac{Min(B, BW_c)}{p_0 . N} . \tag{10}$$

Hence, the following analyses are derived when $BW_m = B$.

(1) *Equal Acceptance - Equal Acceptance (EE) case*

The rate of request at a memory due to favorite requests is given by $p_{fe}$ in eq. (2). Hence $N.p_{fe}$ is the expected number of favorite requests out of $N.p_f$ requests accepted by the crossbar controller in total. With an EA policy at the bus controller, number of favorite requests allocated buses is $\frac{p_{fe}}{p_f} .B$. The total number of favorite requests generated at the processor side is $p_0 .m.N$. Hence,

$$PFA = \frac{p_{fe}}{p_f} \cdot \frac{B}{p_0 .m.N} . \tag{11}$$

And similarly

$$PNFA = \frac{p_{ne}}{p_f} \frac{B}{p_0 .(1-m)N} \tag{12}$$

where $p_f$ , $p_{fe}$ and $p_{ne}$ are given by equations 1, 2 and 3 respectively.

(2) *Equal Acceptance - Nonfavorite (EN) case*

Total number of nonfavorite requests accepted by crossbar controller is $p_{ne}.N$. They are all allocated buses subject to availability. Hence, the number of successful nonfavorite requests is $\min(p_{ne}.N, B)$. The number buses available for favorite requests is $B - min(p_{ne}.N, B)$
Then

$$PFA = \frac{B - min(p_{ne}.N, B)}{p_0.m.N} \qquad (13)$$

$$\text{and } PNFA = \frac{min(p_{ne}.N, B)}{p_0(1-m)N} \;. \qquad (14)$$

(3) *Nonfavorite - Equal Acceptance (NE) case*

All the nonfavorite requests are accepted by the crossbar controller. The rate of favorite request in this case is given by $p_{fn}$ in equation (4). With an equal acceptance of $p_{fn}.N$ favorite requests out of $p_f.N$ requests by the bus controller,

$$PFA = \frac{p_{fn}}{p_f} . \frac{B}{p_0.m.N} \;. \qquad (15)$$

The rate of request due to nonfavorite requests as selected by the crossbar controller is given by $p_{nn}$ in equation (5). With an EA policy by the bus controller,

$$PNFA = \frac{p_{nn}}{p_f} . \frac{B}{p_0.(1-m)N} \;. \qquad (16)$$

(4) *Nonfavorite - Nonfavorite (NN) case*

Here both the crossbar as well as the bus controllers give priority to nonfavorite requests while making selection. All the nonfavorite requests are allocated buses subject to availability and their number is given by $\min(p_{nn}.N, B)$. Rest of the buses are allocated to favorite requests. Hence,

$$PFA = \frac{B - \min(p_{nn}.N, B)}{p_0.m.N} \qquad (17)$$

$$\text{and } PNFA = \frac{\min(p_{nn}.N, B)}{p_0(1-m)N} \;. \qquad (18)$$

The $PFA$ and $PNFA$ for various selection policies, obtained for a $16 \times 16$ system, with $p_0 = 1$ and $m = 0.8$ , are plotted against the number of buses in Fig. 2 and 3 respectively. It can be observed in Fig. 2 that degradation in $PFA$ is not substantial by giving a priority to nonfavorite requests. Moreover, the $PFA$ linearly increases until it is saturated (after 14 buses) by the memory access conflicts. For $EN$ and $NN$ policies, buses are first allocated to nonfavorite requests. So the $PFA$ remains zero until more buses are available. In Fig. 3, the $PNFA$ increases linearly for $EE$ and $NE$ cases, but reaches saturation values quickly for other two policies. There is a substantial increase in $PNFA$ from 0.555 to 0.905 when priority is given to nonfavorite requests by the crossbar controller.

## 4. MULTISTAGE INTERCONNECTION NETWORKS (MIN's)

An MIN usually connects $N$ processors to $N$ memories through $\log_2 N$ stages of $2 \times 2$ switching elements (SE's). Each stage contains $\frac{N}{2}$ such SE's. Examples of such networks are Banyan, Omega, Cube and Baseline, etc. [6]. Although MIN's for $M \times N$, with $M \neq N$, systems have been proposed [8], we would limit our discussion to $N \times N$ systems for simplicity. We will assume that each processor can access its favorite memory through a straight connection of the switches on its path [7]. A $2 \times 2$ SE in an MIN may have a built-in priority structure to resolve the conflicts or it may choose one of the contending requests based on an EA policy. If a priority is given to straight connections, it may mean that more and more favorite requests will go through. However, nonfavorite requests are rejected most of the time, which should indeed be given priority over the favorite requests. We have analyzed the MIN performance for all the three different cases, namely : equal acceptance policy, priority to favorite requests and priority to nonfavorite requests. The analysis is an extension of our previous analysis for EA policy [7] and is not given here because of space restriction.

The BW obtained, with different priority assignment in a switch, are plotted in Fig. 4 for $p_0 = 1$ and $m = 0.8$ . The BW of an $MIN$ is affected by the switch arbitration policy unlike the crossbar or multiple-bus. When a priority is given to favorite requests, more and more requests are accepted giving rise to an increased BW. With a priority to nonfavorite requests more conflicts occur in the network and the BW reduces considerably. With decrease in the value of $m$ the BW is further reduced, but will be limited to an equally likely case. In an equally likely case, the priority assignment has no effect on the BW. The probability of acceptance (PA), probability of favorite acceptance (PFA) and probability of non favorite acceptance (PNFA) can be easily determined.

Unlike the crossbar or multiple-bus results, the PA of an MIN is different for different arbitration policies. This is evident from Fig. 4 because $PA = \frac{BW_0}{p_0.N}$ . The $PFA$ and $PNFA$ for different policies are drawn in Fig. 5 and 6 respectively against the size of the $MIN$ . As the size of the network increases, the probabilities reduce because of more and more conflicts. One can again observe that in a $1024 \times 1024$ network, with $p_0 = 1$ and $m = 0.8$ , there is about 40 % degradation in $PFA$ by adopting priority to nonfavorite requests (cross connection) compared to an $EA$ policy. However, the corresponding $PNFA$ increases by about 9 times in Fig. 6. The $PNFA$ is almost zero for large networks when priority is given to favorite (straight) connections.

## 5. CONCLUSION

The paper described the effect of various selection policies on the performance of crossbar, multiple-bus and MIN. The BW of crossbar and multiple-bus networks does not depend on the selection policy, but the probabilities of individual request acceptance do. It was shown that by giving a priority to remote or less frequent requests, the probability of their acceptance is dramatically improved. Unlike the above two networks, the selection policy in a $2 \times 2$ switch does affect the overall BW of an MIN. Although the BW decreases by giving priority to nonfavorite requests, it is an advisable policy because of the tremendous increase in PNFA. Overall, the paper described some interesting phenomena that were neglected before and are so practical for IN designs.

## ABSTRACT

This paper is concerned with demonstrating the topological equivalence between two classes of computer architectures that support parallel computation, viz. Cube-Connected Cycles network (CCC) and Homogeneous Circular Shuffle Network (HCSN). The latter is based on the Perfect Shuffle Connection. By developing a suitable and common notation for addressing processing elements and specifying interconnections in the two networks, it is shown that these are topologically equivalent. The implications of such an equivalence are described. Known properties and algorithms about HCSN networks, in respect of routing, and fault tolerance, thereby, immediately become applicable to CCC networks. It is also shown that a large class of algorithms that run on a CCC network can also be implemented, with slight modification, on an HCSN network.

## 1. INTRODUCTION

Within the context of parallel computation a number of computer architectures have been proposed. These include systolic arrays, associative processors, vector processors, SIMD machines with or without shared memory, and MIMD machines. Our interest here is with SIMD architectures that do not share memory. An SIMD machine consists of a number of identical Processing Elements (PEs) each with its own local memory. The PEs communicate with each other through an interconnection network. A variety of such networks have been proposed, and parallel algorithms to solve various problems on them have been developed. Hypercube, Mesh-Connected, Cube-Connected Cycles (CCC), Perfect Shuffle Connection (PSC) networks (see Figures 1, 2) are some of the networks that have been extensively studied (see references [1]-[3]). More recently, a Homogeneous Circular Shuffle Network (HCSN) was proposed and studied (see reference [4]). This network has PSC as its basis (see Figure 4).

This paper demonstrates topological equivalence between the CCC network and the HCSN network. We develop a notation for addressing PEs in each of the networks and for specifying interconnections between PEs (see Section 3). This topological equivalence has a number of implications for both HCSN networks as well as CCC networks. These relate to routing algorithms, fault tolerance and VLSI layout (see Section 4). It is also shown that the equivalence is more than simply topological, in that the algorithms that run on an HCSN network also run on a CCC network. However, algorithms that run on a CCC network may require minor modifications when implemented on an HCSN network.

## 2. THE CCC AND HCSN NETWORKS

A CCC is a network of identical PEs, where each PE has three interconnection ports. Each interconnection linking two PEs may be used for bi-directional transmission of operands. The CCC network has $N=2^k$ PEs, where $1 \leq k \leq r+2^r$, $r \geq 1$, and $r$ is the smallest integer. Here each PE is addressed as $m$, $0 \leq m < N$. A PE with an address $m$ is alternatively represented as a tuple $(l,p)$, such that $m=l*2^r+p$, $0 \leq p < 2^r$, $0 \leq l < 2^{k-r}$. $l$ and $p$ have $k-r$ bit and $r$ bit representations, respectively. The interconnection between the PEs is described as follows: each PE has three ports, namely $F$, $B$, and $L$. Thus $F(l,p)$ is the $F$ port of a PE numbered $(l,p)$, etc. The PE with address $(l,p)$ is connected to the three other PEs as follows:

$$(B(l,p),F(l,(p-1) mod\, 2^r)),\ 0 \leq l < 2^{k-r},\ 0 \leq p < 2^r \qquad (1(a))$$

$$(L(l,p),L(l+e*2^p,p)), \qquad (1(b))$$

where $e=1-2*bit_p(l)$, and $bit_p(l)$ is the $p$-th bit of $l$. The notation used is as follows: $(P,Q)$ indicates a bi-directional communication link between the ports $P$, and $Q$ of some PEs, while $<P,Q>$ indicates a uni-directional link from port $P$ to port $Q$. (Note: The connection from $F(l,p)$ to $B(l,(p+1) mod\, 2^r)$ is implied by (1(a)), above.) See Figure 2 for an example of a CCC network where $N=32$, $k=5$, and $r=2$. Preparata, et al. (see reference [2]) have proposed a VLSI layout for CCC networks. See Figure 3 for the layout of a CCC network where $N=64$, $k=6$, and $r=2$. Looking at the layout it is reasonable to generalize the CCC network by dropping the requirement that $N=2^k$. Instead, we assume $N=n \log n$ where $n$ is a power of 2, and $n \geq 2$. As a consequence, each PE in a CCC is numbered $(l,p)$, $0 \leq l < n$, $0 \leq p < \log n$, and the interconnections are

$$(B(l,p),F(l,(p-1) mod \log n)) \qquad (2(a))$$

$$(L(l,p),L(l+e*2^p,p)) \qquad (2(b))$$

where $e=1-2*bit_p(l)$.

The Perfect Shuffle Connection (PSC) is a network of $n$ PEs, where $n$ is a power of 2 and $n \geq 2$. Each PE has three ports $O$, $I$, and $L$. The PEs are numbered as $l$, $0 \leq l < n$. The interconnection is described as:

$$<O(l),I(2*l\ mod(n-1))>,\ 0 \leq l < n-1, \qquad (3(a))$$

† On leave from Department of Computer Science and Engineering, Indian Institute of Technology, New Delhi

0190-3918/86/0000/0008 $01.00 © 1986 IEEE

$$<O(n-1), I(n-1)> \qquad (3(b))$$

$$(L(l), L(l+1)),\ l\ mod\ 2=0,\ 0 \leq l < n. \qquad (3(c))$$

Based upon the PSC network, Tripathi and Huang (see reference [4]) have proposed a Homogeneous Circular Shuffle Network (HCSN). An HCSN network, parameterized by two numbers $(b, r)$, has $r$ columns with $b^{r-1}$ processors in each column, with a total of $r*b^{r-1}$ processors. We shall restrict $b=2$. Processors in an HCSN network are homogeneous with 2 input ports and 2 output ports. The interconnection pattern is a 2-shuffle connection described below in terms of addresses associated with input (and output) ports.

For a given column, the column-wide address of an input port (or an output port) is $x$, $0 \leq x < 2^r$, and given by its representation $(x_{r-1}, ..., x_0)$. The network-wide address of an input port (or an output port) $x$ in column $i$, $0 \leq i < r$, is $(a_{r-1}, ..., \mid a_i, \ldots, a_0)$, obtained by circularly left-shifting the column-address until the last tuple, $x_0$, is shifted into position $i$. The symbol "|" is put before $a_i$ to indicate the column of the input port (or the output port). Since, for various values of $a_i$, the notation refers to the two input ports (or output ports) of the same processor, the network-wide address of a processor in column $i$ is given by $(a_{r-1}, ..., a_{i+1}, \mid, a_{i-1}, ..., a_0)$. As an example, if the network-wide address of a processor $S$ is $(0, \mid, 1, 1)$, then its two input ports have addresses $I(0, \mid 0,1,1)$ and $I(0, \mid 1,1,1)$, while its output ports are addressed $O(0, \mid 0,1,1)$ and $O(0, \mid 1,1,1)$. See Figure 4 for an HCSN network where $b=2$, and $r=4$. The interconnection in an HCSN network may now be specified:

$$\left\langle O(a_{r-1}, ..., a_{i+1}, \mid a_i, a_{i-1}, ..., a_0), I(a_{r-1}, ..., a_{i+1}, a_i, \mid a_{i-1}, ..., a_0)\right\rangle. \qquad (4)$$

## 3. TOPOLOGICAL EQUIVALENCE

Before we demonstrate the topological equivalence between the CCC network with $n \log n$ PEs and the HCSN network, where $r = \log n$, the following comments are made:

(1) All interconnection links in a CCC network are bi-directional, while in an HCSN network the links are uni-directional, that is data may flow along a link from an output port of a processor to an input port of some processor.

(2) The notion of PEs in a CCC network and that of a processor in an HCSN network is somewhat different. In an HCSN network a processor may operate on two data objects that it receives at its input ports, and upon processing, produces two data objects at its two output ports. On the other hand, in a CCC network two PEs that are directly connected may communicate data with each other, and any processing on these data objects may be performed in either (or both) of the PEs.

To reconcile the two notions, we may take either of the approaches given below:

(A) Split each processor in an HCSN network into two PEs, each being associated with a pair of input port and output port. Further, the two PEs are connected to each other by a bi-directional link (see Figure 5(a)).

(B) Combine two neighboring PEs in a CCC network into one processor capable of operating on the data objects within the PEs (see Figure 5(b)).

We shall take the former approach. The resulting view of the HCSN network of Figure 4 is given in Figure 6. As such an HCSN network has $r = \log n$ columns, each containing $n = 2^r$ PEs. Thus an HCSN network has a total of $n \log n$ PEs. Further, it is easy to see that an HCSN network is an unfolding of a PSC network with $n$ PEs, the unfolding is to the extent of $\log n$ stages. The last stage is circularly connected to the first. The addresses associated with the PEs thus obtained from splitting processors in an HCSN network may now be obtained from the network-wide address of the corresponding input port (or output port). To show topological equivalence between a CCC network and an HCSN network, we rewrite the address of PEs in the HCSN network as $((a_{r-1}, ..., a_i, ..., a_0), c)$, where $c$ is the column number, and is equal to the index where the symbol "|" appeared in the original network-wide address. Each PE in an HCSN network has three ports, viz. $I$, $O$, and $L$. $I$ is an input port, $O$ is an output port, and $L$ is bi-directional. With this the interconnections in the HCSN network are described as:

$$<O(a, c), I(a, (c-1) mod \log n)>, \qquad (5(a))$$

$$(L(a, c), L(a + e * 2^c, c)), \qquad (5(b))$$

where $e = 1 - 2*bit_c(a)$.

The equivalence between the CCC network and the HCSN network is now evident. The CCC network and the HCSN network each have $n \log n$ PEs. That is, in the HCSN network there are $n$ PEs in each of the $\log n$ columns, while in a CCC network there is a hypercube of $n$ cycles each containing $\log n$ PEs. The processors in them are numbered as $(l, p)$, $0 \leq l < n$, $0 \leq p < \log n$. The interconnections are identical (see interconnections (2) and (5), above). The only difference is that in an HCSN network the interconnection from an output port to an input port of a PE is uni-directional.

## 4. IMPLICATIONS OF EQUIVALENCE

There are a number of implications of the above topological equivalence. First, a VLSI layout for an HCSN network is now evident. In fact, the layout of Figure 3 is a layout for the HCSN network of Figure 6, or equivalently that of Figure 4. The layout has an area $n*(n-1)$, or more precisely $O(N^2/\log^2 N)$. If the known layout for CCC networks is of minimum area, then the layout for HCSN networks is also optimal.

From the layout of Figure 3 it is evident that an HCSN network, and similarly a CCC network, has a recursive definition for certain values of n. Further, an HCSN network is symmetric not only with respect to a column (because of circular connection), but is also symmetric with respect to a PE within a column. The latter is a consequence of the fact that in a CCC network any cycle of PEs may be assumed to be at the origin of the hypercube. This symmetry allows one to make statements about the HCSN network assuming that a PE has an address (0,0) "without loss of generality", and enables one to provide new and simpler proofs for known results for HCSN networks in respect of routing algorithms and fault-tolerance analysis.

Properties that have been developed for the HCSN network now readily become applicable for CCC networks. One set of results known for the HCSN network are in respect of message routing using control tags (see reference [4]). A control tag, which is part of the message header, is a sequence of control numbers. The first remaining control number is extracted from the control tag upon receipt by a PE, and is used to select the outgoing route or link. The rest of the control tag is used to guide the routing following this PE. When the control tag is empty, the message is at its destination. Algorithms can now be obtained for routing data through a CCC network using a scheme discussed above. Further, it can be shown that the length of a control tag is no more than $2*\log n$ in a CCC network with $n \log n$ PEs. Also, results in respect of fault-tolerance of HCSN networks can be applied to CCC networks.

In view of the topological equivalence, an HCSN network may be treated as an implementation of a CCC network (provided bi-directional communication between $B$ and $F$ ports of a CCC network is not insisted upon), or vice versa. And, since a Perfect Shuffle Connection (PSC) network can always simulate an HCSN network, it is reasonable to expect that most algorithms for CCC networks are similar to those for PSC networks or even for Hypercube networks (see references [1], [2], and [5]).

The equivalence between HCSN networks and CCC networks is more than simply topological. For sure, any algorithm that runs on an HCSN network may be made to run on a corresponding CCC network. The reverse is, however, not true. The reason why such functional equivalence cannot be established is that, in a CCC network, transmission of data between PEs within a cycle is instead bi-directional. The latter implies a capability of processing data objects contained in neighboring PEs within a cycle.

Preparata, et al. (see reference [2]) have presented a generic DESCENT algorithm that is useful in solving a large class of problems, including Bitonic Merge, FFT, Sorting, Matrix operations. This version of the algorithm for CCC networks is immediately applicable to HCSN networks. A difficulty, however, does arise in implementing the operations on data objects within PEs of a cycle, viz. LOOPOPER(.). An alternative implementation of LOOPOPER for HCSN networks can be obtained. This algorithm assumes that transmission is uni-directional, but that each PE is capable of storing log$n$ data objects. The time complexity of the DESCENT algorithm running on an HCSN network can be shown to be the same as that when it runs on a CCC network. The consequence of this is that many algorithms available for CCC networks can now be suitably recoded for implementation on HCSN networks.

**ABSTRACT** We analyze the random delay experienced by a message traversing a buffered, multistage packet-switching banyan network. We find the generating function for the distribution of waiting time at the first stage of the network for a very general class of traffic, assuming messages have discrete sizes. For example, traffic can be uniform or nonuniform, messages can have different sizes, and messages can arrive in batches. For light to moderate loads, we conjecture that delays experienced at the various stages of the network are nearly the same and are nearly independent. This allows us to approximate the total delay distribution. Better approximations for the distribution of waiting times at later stages of the network are attained by assuming that in the limit a sort of spatial steady state is achieved. Extensive simulations confirm the formulas and conjectures.

## 1. INTRODUCTION

Buffered interconnection networks are receiving increasing consideration for use in parallel computers. They are integral components of several machines currently under development, including the Cedar machine at the University of Illinois [7], the NYU Ultracomputer at New York University [9], and the RP3 machine [17] at IBM, where they are used to interconnect processors to shared memory. In order to study the multitude of options available in actually building a machine, it is extremely useful to have formulas that approximate the performance of an interconnection network. In fact, formulas derived in a previous paper by two of the authors [12] have been heavily used in designing both the NYU Ultracomputer [9] and RP3 [15]. While simulation results are often more accurate, they are time consuming and expensive. In this paper, we analyze the random delay experienced by a message traversing a buffered, multistage packet-switching banyan network, for a very general class of traffic. For example, traffic can be uniform or nonuniform, messages can have different sizes, and messages can arrive in batches.

Interconnection networks connect processing elements to memory modules through stages of switches (Figure 1). Early work in describing these networks was done by Goke and Lipovski [8], Lawrie [14], and Patel [16], among others. For more full explanations of interconnection networks see [6] or [18], for example. There have been a number of performance analyses of interconnection networks (e.g. [4,5,12,13]).

The basic building block of an interconnection network is a $k$-input, $s$-output ($k \times s$) buffered switch (Figure 2). Each input port can accept one packet per clock cycle, and route it to the appropriate output port. Each output port has a FIFO buffer. Conflicts between messages simultaneously routed to the same output port are resolved by queueing the messages. We idealize this structure by assuming that the output buffers have infinite length. While this is clearly infeasible in practice, it is well known that, for light to moderate loads, moderate sized buffers provide approximately the same performance as infinite buffers. We also assume that each output port buffer can accept any number of messages from the input ports in a clock cycle, and that arriving messages do not interfere with departing messages. Each output port can be viewed as a discrete queueing system.

We make the following probabilistic assumptions concerning traffic at the first stage of a network:

(1) The number of messages arriving at successive cycles to an output port are independent, identically distributed random variables. These random variables may have a different distribution at different ports, and are clearly dependent from port to port.

(2) The service requirements (the number of cycles required to forward a packet) for successive messages at an output port are independent, identically distributed random variables. This distribution may vary from port to port.

Constant service time is usually the appropriate assumption for interconnection networks realized with synchronous logic.

Assuming that the traffic is uniform (e.g. each request is equally likely to go to each output node) and that at each cycle a packet arrives at an input node with a fixed probability $p$, the expected delay has been computed [12]. This analysis is based on Little's identity, and it is not obvious that it can be extended to obtain more information about the delay distribution, such as the variance. Such information is quite important for two reasons: First, to obtain good performance on a parallel machine, it is not sufficient to have a low expected memory access time; high variance will impede performance, as it is often the case that the speed of the slowest processor dictates the system speed. Second, as we discuss in Section 5, the variance can be used to obtain an approximate formula for the waiting time distribution of a message through the entire network.

Exact formulas for both the average and variance of the waiting time at the first stage when all messages take a single cycle to service were obtained in a previous paper [13]. This was used to obtain approximate formulas for longer messages of constant size. Using stronger methods we obtain in this paper exact formulas for the average and variance of the waiting time at the first stage for long messages of constant size; in fact, we obtain the entire distribution of waiting times for any discrete service time distribution. In the previous paper [13], we also suggested a method for analyzing the waiting time at later stages of the network, by assuming that the output of a queue can be modeled by a Markov process; the approximations were in practice hard to obtain and not very accurate. This paper gives an alternative method for approximating the waiting time at later stages; it is easy to use and provides extremely good approximations, as evidenced by a comparison to simulation results.

In Section 2, we analyze the performance of the first stage of an interconnection network, by calculating the $z$-transform of the distribution of waiting times. This enables us to compute higher moments of that distribution. In particular we present explicit formulas for the expected value and variance. In Section 3, the formulas are used to find the expected value and variance of the waiting time under various

Part of the work was done while the first author was at the University of Illinois. The first author was supported in part by a grant from IBM.

standard assumptions. For light to moderate loads, we conjecture that waiting time experienced at the the later stages of the network are nearly the same as for the first stage. In Section 4, we obtain better approximations for the waiting time at the later stages. In Section 5, we discuss how to analyze the total delay through the network. Section 6 gives some concluding remarks.

## 2. ANALYSIS

Our model for the first stage of switching comes under the general rubric of a discrete time queueing system. We compute in this section the $z$-transform for the waiting time, and use it to derive the expectation and variance of the waiting time, for general discrete service and arrival distributions. The solution method we use was indicated by Kobayashi and Konheim [11]. We are not, however, aware of a complete solution to this problem in the literature. As will be seen in the remainder of this paper, for the queueing systems we are interested in, it is useful to carry out the calculations in their entirety.

We start with some definitions. Let $\lambda$ be the average number of arrivals at any cycle and $m$ be the average service time of a message. The *traffic intensity* is then $\rho = m\lambda$.

Let $f_j$ be the probability that $j$ messages arrive at any cycle, and

$$R(z) = \sum_{j=0}^{\infty} f_j z^j .$$

Then

$$R'(1) = \lambda .$$

Let $g_j$ be the probability that a message requires $j$ time units to serve and

$$U(z) = \sum_{j=0}^{\infty} g_j z^j .$$

Then

$$U'(1) = m .$$

THEOREM 1: Let $w$ be the steady state waiting time for a message. The $z$-transform of the waiting time distribution of an output queue at the first stage is

$$\begin{aligned} t(z) &= \mathrm{E}(z^w) \\ &= \frac{1-m\lambda}{\lambda}\,\frac{1-z}{R(U(z))-z}\,\frac{1-R(U(z))}{1-U(z)} . \end{aligned} \qquad (1)$$

PROOF: Let $s_n$ be the unfinished work at the end of the $n$th cycle, $a_n$ number of messages arriving at the $n$th cycle, and $c_n$ be the total service time for messages arriving at the $n$th cycle. Let $s$, $a$, and $c$ be the steady state variables corresponding to $s_n$, $a_n$, and $c_n$. Note that

$$\mathrm{E}(z^a) = \mathrm{E}(z^{a_n}) = R(z) ,$$

$$\mathrm{E}(z^c) = \sum_{j=0}^{\infty} \mathrm{E}(z^c | a=j) f_j = \sum_{j=0}^{\infty} (U(z))^j f_j = R(U(z)) ,$$

and

$$s_n = \max(0, s_{n-1}+c_n-1) .$$

Since $c_n$ is independent of $s_{n-1}$ we obtain the identity

$$\begin{aligned} \mathrm{E}(z^s) &= \mathrm{E}(z^{s+c-1} \mid s>0)\mathrm{P}(s>0) \\ &\quad + \mathrm{E}(z^{c-1} \mid s=0, c>0)\mathrm{P}(s=0, c>0) \\ &\quad + \mathrm{E}(z^0 \mid s=0, c=0)\mathrm{P}(s=0, c=0) \\ &= \mathrm{E}(z^c)\mathrm{E}(z^{s-1} \mid s>0)\mathrm{P}(s>0) \\ &\quad + \mathrm{E}(z^{c-1} \mid c>0)\mathrm{P}(s=0)\mathrm{P}(c=0) \\ &\quad + \mathrm{P}(s=0)\mathrm{P}(c=0) . \end{aligned}$$

Let

$$\Psi(z) = \sum_{j=0}^{\infty} h_j z^j = \mathrm{E}(z^s) .$$

The previous identity implies

$$\Psi(z) = R(U(z))\frac{(\Psi(z)-h_0)}{z} + h_0\frac{R(U(z))-R(U(0))}{z} + h_0 R(U(0)) ,$$

so that

$$\Psi(z) = \frac{h_0(1-z)R(U(0))}{R(U(z))-z} .$$

We compute, using L'Hospital's rule,

$$\Psi(1) = 1 = \frac{h_0 R(U(0))}{1-m\lambda} ,$$

so that

$$h_0 = \frac{1-m\lambda}{R(U(0))} ,$$

and

$$\Psi(z) = \frac{(1-z)(1-m\lambda)}{R(U(z))-z} .$$

Since the arrival process is memoryless, arriving batches see the steady state unfinished work distribution $s$. Thus the steady state waiting time for a message $w = s + w'$, where $w'$ is the steady state service time for messages arriving at the same cycle, but served first. We have

$$\mathrm{E}(z^w) = \mathrm{E}(z^s)\mathrm{E}(z^{w'}) = \Psi(z)\mathrm{E}(z^{w'}) .$$

Let $d$ be the steady state number of messages that arrive at the same cycle with any message, but are served before it; let $\phi(z) = \mathrm{E}(z^d)$. Then, using the same derivation as before, we get

$$\mathrm{E}(z^{w'}) = \phi(U(z)) .$$

We shall now compute $\phi(z)$. The probability that any message arrives in a batch of $j$ messages is equal to $j f_j / \lambda$. Thus

$$\begin{aligned} \mathrm{P}(d=j) &= \sum_{k=j+1}^{\infty} \mathrm{P}(d=j \mid \text{message arrives in a batch of } k \text{ messages}) \, k f_k / \lambda \\ &= \sum_{k=j+1}^{\infty} \frac{1}{k}(k f_k / \lambda) , \end{aligned}$$

so that

$$\begin{aligned} \phi(z) &= \frac{1}{\lambda}\sum_{j=0}^{\infty}\sum_{k=j+1}^{\infty} f_k z^j = \frac{1}{\lambda}\sum_{k=1}^{\infty} f_k \sum_{j=0}^{k-1} z^j \\ &= \frac{1}{\lambda(z-1)}\sum_{k=1}^{\infty} f_k (z^k-1) = \frac{R(z)-1}{\lambda(z-1)} . \end{aligned}$$

The $z$-transform of the waiting time distribution is

$$\begin{aligned} t(z) &= \mathrm{E}(z^w) = \Psi(z)\phi(U(z)) \\ &= \frac{1-m\lambda}{\lambda}\,\frac{1-z}{R(U(z))-z}\,\frac{1-R(U(z))}{1-U(z)} . \end{aligned} \qquad (1)$$

□

In principle this gives the complete distribution of the waiting time.

COROLLARY 2:

$$\mathrm{E}(w) = t'(1) = \frac{mR''(1) + \lambda^2 U''(1)}{2\lambda(1-m\lambda)} . \tag{2}$$

COROLLARY 3:

$$\begin{aligned}\mathrm{Var}(w) &= t''(1) + t'(1)-(t'(1))^2 \\ &= \frac{\begin{array}{c}(6m\lambda R''(1) + 4m^2\lambda R'''(1) + 6\lambda^3 U''(1) \\ + 4\lambda^3 U'''(1))\,(1-m\lambda) - 3m^2 R''(1)^2(1-2m\lambda) \\ + 3\lambda^4 U''(1)^2 + 6\lambda R''(1)U''(1)\end{array}}{12\lambda^2(1-m\lambda)^2} .\end{aligned} \tag{3}$$

(The derivation of $t''(1)$ used six applications of L'Hospital's rule, and took Macsyma all night on a minicomputer.)

## 3. EXAMPLES

We now apply the above formulas to derive the expected value and the variance of the waiting time for messages in several standard and important queueing systems. Note that the expected value formulas only give the waiting time of a message. To obtain the *delay* of a message in a queue, one must add to these formulas the service time. For the queueing systems in this section, message arrivals are independent of queue length. Thus, the variance of the delay of a message in a queue is simply the sum of the variance of the waiting time and the variance of the service time.

### 3.1. Service Time One

Suppose that all messages take exactly one unit of time to be serviced. Then $m = 1$ and $U(z) = z$. Thus,

$$U'(z) = 1 \quad \text{and} \quad U''(z) = U'''(z) = 0 .$$

Substituting into Eq. (1), we obtain

$$t(z) = \mathrm{E}(z^w) = \frac{1-\lambda}{\lambda}\,\frac{1-R(z)}{R(z)-z} .$$

Substituting into Eq. (2) we get

$$\mathrm{E}(w) = \frac{R''(1)}{2\lambda(1-\lambda)} \tag{4}$$

and substituting into Eq. (3) we get

$$\mathrm{Var}(w) = \frac{2(3R''(1) + 2R'''(1))\lambda(1-\lambda) - 3(1-2\lambda)(R''(1))^2}{12\lambda^2(1-\lambda)^2} \tag{5}$$

We analyze some special cases of this for $k$-input, $s$-output ($k \times s$) switches.

#### 3.1.1. Uniform Traffic, Single Arrivals

Suppose that each input port has a probability $p$ of receiving one message at each unit of time, and that each incoming message has an equal chance of going to any of the output ports. Then

$$f_j = \binom{k}{j}\left(\frac{p}{s}\right)^j \left(1 - \frac{p}{s}\right)^{k-j} .$$

This quickly yields

$$R(z) = \left(1 - \frac{p}{s} + \frac{pz}{s}\right)^k .$$

Calculating $R'(1)$, $R''(1)$, and $R'''(1)$ and substituting into Eqs. (4) and (5) yields

$$\mathrm{E}(w) = \frac{(1-\frac{1}{k})\lambda}{2\,(1-\lambda)} \tag{6}$$

and

$$\mathrm{Var}(w) = \frac{(1-\frac{1}{k})\,\lambda\,[6 - 5\lambda(1+\frac{1}{k}) + 2\lambda^2(1+\frac{1}{k})]}{12\,(1-\lambda)^2} . \tag{7}$$

#### 3.1.2. Bulk Arrivals

In many systems the size of a message exceeds the size of a transmission packet; a message is transmitted in several packets. These packets arrive at the first stage of the network in one bulk. This can be modeled as in the previous example, except arrivals at input ports are in batches. Assuming a constant batch size of $b$ messages,

$$R(z) = \left(1 - \frac{p}{s} + \frac{pz^b}{s}\right)^k .$$

Using Eqs. (4) and (5), this gives

$$\mathrm{E}(w) = \frac{(b-1) + (1-\frac{1}{k})\lambda}{2(1-\lambda)}$$

and

$$\mathrm{Var}(w) = \frac{b^2-1 + 2\lambda(b^2+2-\frac{3b}{k}) - 5\lambda^2(1-\frac{1}{k^2}) + 2\lambda^3(1-\frac{1}{k^2})}{12(1-\lambda)^2} .$$

These agree with our previous formulas for the case $b = 1$.

#### 3.1.3. Nonuniform Traffic

In many practical situations each input is likely to have a distinct favorite output port (e.g. the output port connecting a processor to its private memory — see [1]). We assume that $k = s$. (It is not hard to generalize this for $k \neq s$, but the equations become quite lengthy.) We do assume bulk arrivals. Each input port sends arriving messages to its favorite output port with probability $q$, and sends them with probability $(1-q)/k$ to each output port (including its favorite output). The distribution of messages at the output ports is the product of two terms: the first term accounts for normal messages and is essentially the same as given in 3.1.2, with $p$ replaced by $p(1-q)$; the second term accounts for favored messages. We get

$$\begin{aligned}R(z) = {} & (1 - p\frac{1-q}{k} + p\frac{1-q}{k}z^b)^{k-1} \\ & (1 - p(q+\frac{1-q}{k}) + p(q+\frac{1-q}{k})z^b) .\end{aligned}$$

Substituting into Eq. (4),

$$\mathrm{E}(w) = \frac{\lambda(1 - q^2)(1 - \frac{1}{k}) + b - 1}{2\,(1 - \lambda)} .$$

Note that, for $q = 1$ we get $\mathrm{E}(w) = 0$, and for $q = 0$ we obtain the same formula as in 3.1.1 (with $k = s$), as it should be. The general formula for the variance is quite lengthy.

### 3.2. Constant Service Times

We now consider the situation when messages can have one of several constant service times. We will only consider uniform traffic and single arrivals. Thus, as in Section 3.1.1,

$$R(z) = \left(1 - \frac{p}{s} + \frac{pz}{s}\right)^k .$$

### 3.2.1. Single Size

First, suppose that each message takes exactly $m$ units of time to transmit. This will occur, for instance, when each message is composed of an equal number $(m)$ of packets, and the constituent packets of a message are transmitted at consecutive cycles. Then

$$U(z) = z^m .$$

The traffic intensity is now

$$\rho = \frac{mpk}{s} .$$

Substituting into Eqs. (2) and (3), we obtain

$$E(w) = \frac{\rho(m - \frac{1}{k})}{2(1-\rho)} \tag{8}$$

and

$$\mathrm{Var}(w) = \frac{\rho \left( \begin{array}{c} (1-\frac{1}{k}) \, [6m - 5\rho(1+\frac{1}{k}) + 2\rho^2(1+\frac{1}{k})] \\ + (m-1) \, [2(2m-1) - \rho(m+1)] \end{array} \right)}{12\,(1-\rho)^2} . \tag{9}$$

These coincide, for $m = 1$, with the equations of 3.1.1.

### 3.2.2. Multiple Sizes

Now suppose there are $n$ service times $m_1,\ldots,m_n$, and service time $m_i$ occurs with probability $g_i$. This will occur when there are different kinds of requests. For example, read requests are likely to have different sizes than write requests.

We get

$$U(z) = \sum_1^n g_i z^{m_i} .$$

Thus

$$\rho = \frac{kp}{s} \sum_1^n m_i g_i$$

Substituting into Eq. (2), we obtain

$$E(w) = \frac{\lambda \sum_1^n m_i (m_i - \frac{1}{k}) g_i}{2\,(1-\rho)} = \frac{\rho \sum_1^n m_i (m_i - \frac{1}{k}) g_i}{2\,(1-\rho) \sum_1^n m_i g_i} .$$

The formula for the variance could also be obtained, but it is quite lengthy and not particularly enlightening.

## 4. LATER STAGES

We do not know how to analyze the later stages exactly as the inputs at successive cycles are not independent. We have, however, developed some very useful approximate formulas for the average and variance of the waiting time. These are based on two observations: First, as we progress through the network, the waiting time statistics quickly approach a limiting distribution. Second, nearly every waiting time distribution in queueing theory has an average on the order of $1/(1-\rho)$ as $\rho$ tends to one; that is, if $w_i(\rho)$ is the average waiting time at the $i$ th stage, and $w_\infty(\rho)$ is the limit as $i$ gets large, we expect $\lim\limits_{\rho \to 1} (1-\rho) w_\infty(\rho)$ to exist. We calculated $w_1(\rho)$ exactly in Section 3, and we expect $w_1(\rho)$ and $w_\infty(\rho)$ to have similar qualitative properties, i.e., they should depend on most parameters in roughly the same way. Hence, it seems reasonable to estimate

$$r(\rho) \overset{\text{def}}{=} \frac{w_\infty(\rho)}{w_1(\rho)} .$$

It is clear that $r(0) = 1$. We use simulations to estimate $r(1/2)$, and then simply linearly interpolate to obtain to obtain a value $a$ such that

$$r(\rho) \approx 1 + a\rho . \tag{10}$$

Then

$$w_\infty(\rho) \approx (1 + a\rho)\, w_1(\rho) .$$

We will also generalize the formulas to take into account the dependence of $w_i(\rho)$ on the stage, the switch size, and the message size distribution. This method of interpolation was previously applied to queueing systems by Burman and Smith [3] using light and heavy traffic theory. The light traffic limit is obvious in our case. We do not have a heavy traffic analysis for our process, so we rely on simulation instead.

Using the same ideas, we can obtain an approximation for the variance. Let $v_i$ be the variance of the waiting time at stage $i$, and $v_\infty$ be the variance in the limit. Since the formulas for variance have one higher power of $\rho$, we expect a good approximation of $v_\infty(\rho)/v_1(\rho)$ to contain (at least) one higher power of $\rho$, i.e. we obtain a quadratic interpolation for the variance. The variance after several stages can be approximated by

$$v_\infty \approx (1 + a\rho + b\rho^2) v_1 ,$$

where $a$ and $b$ are constants to be determined.

In the remainder of this section, we obtain our expression for the waiting time and variance in step-by-step generalizations. We first estimate them for uniform traffic when messages have size one, then size $m$, and then general size. Finally, we consider nonuniform traffic.

### 4.1. Service Time One

Consider service time one, 2×2 switches, single arrivals, and uniform traffic. For $p = .5$, $w_1 = .25$ (Eq. (6)), and, from the simulations in Table I, $w_\infty$ seems to be about .3. Substituting into Eq. (10) and solving for $a$ gives $a \approx 2/5$. Thus, we find $r(\rho) \approx 1 + 2p/5$, so the waiting time

$$w_\infty \approx (1 + \frac{2p}{5}) \frac{p}{4(1-p)} .$$

Table I compares the simulation results with our formulas. The waiting time values in the ANALYSIS row are from the exact formula for the first stage (Eqs. (6) and (7)), and the waiting time values in the ESTIMATE row are from the above approximation for the waiting time in the limit. Note that the approximation seems to be slightly low for $p$ small and slightly high for $p$ large. More complete simulation results (not included for brevity) show that $r(\rho)$ is actually slightly concave. An even better estimate could be obtained by using a quadratic approximation.

Using the same technique for 4×4 and 8×8 switches gives $a$ a bit less than .2 and $a$ a bit less than .1, respectively (see Eq. (6) and Table II). This suggests that the above formula can be (crudely) extended to $k \times k$ switches by linearly including $k$ as a parameter. This gives the waiting time

$$w_\infty \approx (1 + \frac{4p}{5k}) \frac{(1 - \frac{1}{k})\,p}{2\,(1-p)} . \tag{11}$$

Table II compares the simulation results with our formulas.

In Tables I and II it looks as if $w_i$ approaches $w_\infty$ geometrically. This suggests a formula of the form $r_i(\rho) = 1 + (1-\alpha^{i-1})(r(\rho)-1)$ for some $\alpha<1$, yielding

$$w_i \approx (1 + \frac{4p}{5k}(1 - \alpha^{i-1})) \frac{(1 - \frac{1}{k}) p}{2(1-p)} \tag{12}$$

as the expected waiting time at the $i$ th stage. Looking once again at the formula for $k = 2$ and $p = .5$ (Table I), gives $\alpha = 2/5$ as a good approximation. It turns out that this value of $\alpha$ works reasonably well for general $k$ and $p$. For brevity, we do not explicitly compare this formula to the simulations (although the interested reader can easily do the calculations). It is by no means surprising that, for a given $p$ and $k$, $w_i$ approaches $w_\infty$ geometrically; what is perhaps surprising is that a single value of $\alpha$ works well for all $p$ and $k$.

Applying the same techniques to variance, we find that a reasonable formula for the variance after several stages is

$$v_\infty \approx (1 + \frac{p}{2k} + \frac{2p^2}{k}) \frac{(1-\frac{1}{k})\, p\ [6 - 5p\,(1+\frac{1}{k}) + 2p^2(1+\frac{1}{k})]}{12(1-p)^2} . \tag{13}$$

(Since this is only an approximation and since the simulation results do not give exact answers, there is quite a bit of freedom in choosing coefficients $a$ and $b$ for the $p$ and $p^2$ terms. Other choices will surely work just as well or better.) We can also estimate the variance at stage $i$ to be

$$v_i \approx \left(1 + (\frac{p}{2k} + \frac{2p^2}{k})(1-\alpha^{i-1})\right) \frac{(1-\frac{1}{k})\, p\ [6 - 5p\,(1+\frac{1}{k}) + 2p^2(1+\frac{1}{k})]}{12(1-p)^2} , \tag{14}$$

where $\alpha = 2/5$.

### 4.2. Single Service Time

Consider the case when messages have a single constant size. Our model of the first stage is not a particularly good model for the later stages: At the first stage a source after sending a message can send a new message on the next or any later cycle. At later stages, since sources are outputs from queues, once a source sends a message, that source will not send a message for at least $m$ cycles. This will tend to reduce queueing delays at the later stages.

Later stages can be better modeled by assuming that messages take one cycle to be processed, but the cycle time is $m$ times as long. Following [12], we use the formula for service time one (Eq. (11)), and, for a fixed $p$, multiply the time to process a message by a factor $m$, and also multiply the average number of packets per cycle by $m$. In other words, for a fixed traffic intensity $\rho$, the cycle time is $m$ times as large. This gives the average waiting time

$$w_\infty \approx (1 + \frac{4mp}{5k}) \frac{(1 - \frac{1}{k})\, m^2 p}{2(1 - mp)} . \tag{15}$$

For $m \geq 2$, this formula is a reasonable approximation at all stages after the first, and, of course, we have an exact formula for the first stage. Table III compares the simulation results with our formulas.

Let us examine the behavior of the interior stages in light traffic. If we allow $m$ to increase and $p$ to decrease with $mp = \rho$ constant, then in time scaled by $m$, the first stage output queues become M/D/1 queues with arrival rate $\rho$ and service time 1. (Actually, the well-known waiting time statistics of M/D/1 queues can be obtained as limits of (8) and (9).) Now the interior stages are not precisely M/D/1 queues in this scaling, because the packets output from previous stages must be spaced by at least $m$ time units. Nevertheless, it is clear that in light traffic the interior stages will resemble M/D/1 queues, but the congestion will be lower than at the first stage, since packets will be very unlikely to collide with other packets from the same source. That is, the congestion will be as if the arrival rate were $(1-1/k)\rho$. Using the M/D/1 light traffic results

$$\mathrm{E(w)} = \frac{(1-\frac{1}{k})\rho}{2} + O(\rho^2)$$

and

$$\mathrm{Var}(w) = \frac{(1-\frac{1}{k})\rho}{3} + O(\rho^2) .$$

Our approximations should have these properties, too. Eq. (15) does satisfy this.

To obtain an approximation for the variance, we argue as before: start with formula for the variance at the first stage for unit size messages (Eq. (7)), multiply by $m^2$, change $p$ to $mp$, and then use the light traffic analysis and the simulations to interpolate. Our heuristic formula is (see Eq. (13))

$$v_\infty \approx \left(\frac{2}{3} + \frac{C_1\rho}{k} + \frac{C_2\rho^2}{k}\right) \frac{(1-\frac{1}{k})\, m^3 p\ [6 - 5mp\,(1+\frac{1}{k}) + 2(mp)^2(1+\frac{1}{k})]}{12(1 - mp)^2} ,$$

where 2/3 was obtained from light traffic analysis. Light traffic analysis is a limiting case for $m$ large; in practice we found that 7/10 works better than 2/3 for small and moderate message sizes. We match the constants $C_1$ and $C_2$ to simulation results, giving

$$v_\infty \approx \frac{7}{10}(1 + \frac{2mp}{3k} + \frac{4(mp)^2}{k}) \frac{(1-\frac{1}{k})\, m^3 p\ [6 - 5mp\,(1+\frac{1}{k}) + 2(mp)^2(1+\frac{1}{k})]}{12(1 - mp)^2} . \tag{16}$$

This approximation is still slightly low for $m$ small, as can be seen in Table III. Better approximations can be obtained for each individual value of $m$; in particular, Eq. (13) is a much better approximation for $m = 1$. As with waiting times, for $m \geq 2$, this formula can be used to approximate variances for all stages after the first.

### 4.3. Multiple Service Times

As in Section 3.4.2, suppose there are $n$ service times $m_1,\ldots,m_n$, and service time $m_i$ occurs with probability $g_i$. The average service time is $m = \sum_{i=1}^{n} g_i m_i$. To obtain an approximate formula for the average waiting time, replace the size of all messages by their average size $m$ and use the approximate waiting time formula from the previous section (Eq. (15)). This gives the average waiting time

$$w_\infty \approx (1 + \frac{4mp}{5k}) \frac{(1 - \frac{1}{k})\, m^2 p}{2(1 - mp)} .$$

The values obtained from this formula tend to be a bit low. The reason is that we are approximating multiple size messages by their average size. Since we are able to calculate everything at the first stage exactly, we know how much off such an assumption would be at the first stage: simply the ratio of the actual expected waiting time and the waiting assuming all messages have their average size. Assuming this ratio is fairly constant at the different stages, multiplying the above formula by this ratio gives a very good approximation:

$$w_{\infty} \approx (1 + \frac{4mp}{5k}) \frac{(1 - \frac{1}{k})mp \sum_{i=1}^{n} m_i (m_i - \frac{1}{k}) g_i}{2(1 - mp)(m - \frac{1}{k})} .$$

An approximate formula for the variance $v_{\infty}$ could be obtained similarly, but, as with the variance formula for the first stage, it is quite lengthy. We have, however, obtained numerical values from both variance formulas, i.e. for $v_1$ and $v_{\infty}$. Table IV compares the simulation results with our formulas.

## 5. TOTAL DELAY

Once we have formulas for the expected value and variance of the waiting time at a stage, these can be used to obtain approximations for the total waiting time. The expected value of the total waiting time is simply the sum of the average waiting time at the different stages. In particular, for messages of size one, summing the $w_i$ in Eq. (12) approximates the total waiting time for an $n$ stage network as

$$n \left( 1 + \frac{4p}{5k}(1 - \frac{1 - \alpha^n}{n(1-\alpha)}) \right) \frac{(1 - \frac{1}{k})\, p}{2(1 - p)} ,$$

where $\alpha = 2/5$. For $m \geq 2$ the average total waiting time can be approximated as the average waiting time from the first stage (Eq. (8)) plus $n-1$ times the waiting time at the later stages (Eq. (15)), which is

$$\frac{(m - \frac{1}{k})mp}{2(1 - mp)} + (n-1)(1 + \frac{4mp}{5k}) \frac{(1 - \frac{1}{k})\, m^2 p}{2(1 - mp)} .$$

If the waiting times from stage to stage were independent, as is the case with Poisson arrivals and exponential service times, the variance of the total waiting time would simply be the sum of the variances at the different stages. Simulations show that waiting times at neighboring stages have fairly low correlation, and the correlation seems to drop geometrically as stages become further apart. Thus summing the variances should be a good approximation.

To obtain a better approximation, note that the total variance is actually the sum of the covariances between stages. Let $v_{ij}$ be the covariance between stage $i$ and stage $j$. Covariances seem to drop geometrically as stages become further apart. In particular, the $v_{ij}$ can be approximated as follows: $v_{ii} = v_i$, $v_{i,i+1} \approx av_i$, $v_{i,i+2} \approx abv_i$, $v_{i,i+3} \approx ab^2 v_i$, $v_{i,i+4} \approx ab^3 v_i$, ..., where $a = (1 - \frac{2mp}{5})\frac{3mp}{5k}$ and $b = (1 - \frac{2mp}{5})/k$. Now summing all of the covariances approximates the total variance as

$$\sum_{i=1}^{n} \left( 1 + \frac{2a(1 - b^{n-i})}{1-b} \right) v_i .$$

For $m = 1$, we use the $v_i$ from Eq. (14). For $m > 1$, $v_1$ is the true variance for the first stage (Eq. (9)), and $v_i$, $i > 1$, can be approximated by the formula for $v_{\infty}$ (Eq. (16)). Tables VI and VII compare the simulation results with our formulas.

The distribution of waiting times seems to be about the same for all stages. If the distributions were independent, then by the central limit theorem, the total waiting times for a large number of stages could be approximated by a (truncated) normal distribution, whose sum is the sum of the expected values and variance is the sum of the variances. The central limit theorem actually holds under much weaker hypotheses than independence (see, for example, [2]), and we expect it essentially to apply here. Now, typically in queueing systems, the distribution of waiting times has an exponential or geometric tail. Thus, for few stages, we expect a gamma distribution with the proper expected value and variance to be even a better approximation. Figures 3 and 4 show an incredibly good match between the gamma and the observed distributions, especially at the tails. The gamma distributions were formed with the means and variances given by the estimates from Tables VI and VII. In practice, these moments and the tail of the waiting time distribution are the quantities of interest; we believe our formulas are accurate enough for all practical purposes.

So far we have obtained formulas for the total waiting time. In order to obtain the *total delay* in the network one has to add to the total waiting time the total service time. If service time is one, then the total service time is simply the number of stages. In general it is the sum of service times at the successive stages.

The waiting time at one stage may depend on service time at a previous stage. However, the correlation is weak, so that these random variables are stochastically nearly independent. Thus, the variance of the total delay is approximately the variance of the total waiting time plus the sum of the variances of the service times. If the service times are constant, then their variances are zero, so the variance of the total delay is exactly the variance of the total waiting time. In general, the distribution of the total delay can easily be approximated by looking at the distributions of individual service times and the distribution of the total waiting time.

## 6. CONCLUSION

We have analyzed the delay experienced by a message in a buffered, multistage, packet-switching banyan network. For the first stage, we were able to derive the complete distribution of the delay for a very general class of distributions, assuming messages have discrete sizes. The result is quite general: for example, one can use it to derive the Pollaczek-Khinchin formulas for M/G/1 queues. The result was used to determine exactly the average and variance of the delay for several commonly considered distributions. Using the delay formulas for the first stage, we developed extremely good approximations for the average and variance of the delay at later stages. Finally, this allowed us to obtain good approximations for the full distribution of the total delay of a message through the entire network.

In order to approximate the delay after the first stage, it was essential to have good formulas for the delay at the first stage. It was only by building on them that we were able to make educated guesses as to the delays at later stages.

One aspect of our results that is worth stressing is the dependency of waiting time on the message size $m$: For a *fixed* traffic intensity $\rho$, the average waiting time increases linearly in $m$ (see Eqs. (8),(15)), and the variance increases quadratically in $m$ (see Eqs. (9),(16)). Thus, while using larger messages may save the overhead of duplicating the same routing information over several packets, it may dramatically increase delays in all but very lightly loaded networks. This point has already been made in [9,12,13], but does not seem to be widely appreciated.

While our simulations seem to indicate clearly that average waiting time at successive stages converge, it would be nice to be able to prove this result formally, i.e. to show that average delay at successive stages can be bounded, independent of the network size.

# THE SNEPTREE – A VERSATILE INTERCONNECTION NETWORK[†]

Peyyun Peggy Li[‡] and Alain J. Martin

Computer Science
California Institute of Technology
Pasadena CA 91125

**Abstract** — A new interconnection network, the *Sneptree*, is investigated. The Sneptree consists of $2^n - 1$ identical nodes and each node has four links. The links are connected to form an augmented complete binary tree where the outgoing links of the leaves are connected to all the nodes in the network. We prove that a complete binary tree with arbitrary size can be mapped onto a Sneptree optimally. Hence, the Sneptree is well suited for distributed computations with tree-structured computation graph, such as divide-and-conquer and backtracking. One type of Sneptree, which contains two disjoint spanning cycles and is thus called the *Cyclic Sneptree*, is of particular interest since it can simulate a fully unbalanced tree optimally, such as a left/right skewed tree.

A recursive method is given to generate the H-structure layout of the Cyclic Sneptree. The number of crossings and the length of the longest wires in the H-structure layout are analyzed. A message routing algorithm between any two leaf nodes is presented. The routing algorithm, which is of O(n) complexity, gives a good approximation to the shortest path. The traffic congestion in the nodes at the upper levels is also significantly reduced compared to the binary tree case.

## 1. Introduction

Due to the development of VLSI technology, it is now possible to construct powerful computers by connecting thousands of small identical processors into a so-called "processor network." Each processor has independent control and local memory. Hence, each processor can run its own program independently and asynchronously. Synchronization and communication are done by message passing between neighboring processors. The computation is distributed over the network. Hence, high concurrency can be achieved.

Many different interconnection networks have been studied, such as the binary tree [1,11], the mesh, the systolic array [4], the boolean n-cube [10], etc.. Some machines are dedicated to some special applications; some are designed as a general purpose computing engine. One interesting problem which hasn't been investigated profoundly is the mapping of the computation graph onto the implementation network, and in particular the mapping of an over-sized problem onto a fixed size network to keep the load of each processor balanced. In [7], a double-twisted torus simulates an unbounded mesh perfectly. The torus introduced a homogeneous processor network which relieves the boundary problem from a regular mesh so that a bigger mesh can be mapped onto this network automatically and optimally.

In this paper, another homogeneous processor network is presented. The *Sneptree* [12] is a class of augmented binary trees with homogeneous nodes. Each node, including the root node and the leaf node, has four links. The links are connected such that a complete binary tree of arbitrary size can be mapped onto the Sneptree optimally.

The binary tree has the property that the distance between any two nodes is at most $2\log_2 n$, where n is the size of the tree. Such a network is called "logarithmic." The Sneptree is an expanded binary tree with more links in each node. Some connection patterns of the Sneptree are regular and symmetric and hence well suited for VLSI implementation. Furthermore, it can simulate an unbounded binary tree so that it is best for divide-and-conquer type applications. There are some other augmented binary tree networks been investigated, such as the X-tree[2], the Hypertree[3], and the De Bruijn Network[9]. Those networks are different in their connection patterns and applications. The comparison between the Sneptree and other networks will be given in the conclusion.

In section 2, the definitions of the Sneptree and the Cyclic Sneptree are given and different connection patterns are presented. The mapping of a complete binary tree onto the Sneptree is proven to be optimal in section 3. Like a binary tree, the Sneptree can be laid out into an H-structure plane nicely. Section 4 presents a recursive method to construct the H-structure Sneptree. In section 5, a routing algorithm that routes a message from a leaf node to another leaf node is presented. In the conclusion, the Sneptree is compared to other networks, and future research directions are discussed.

## 2. Definition of the Sneptree

**Definition:** An *n-level Sneptree* is a complete binary tree of $2^n - 1$ nodes, links directed from root to leaves, augmented with $2^n$ additional *Snep* links directed out of the leaves, such that each node has 4 incident links: 2 directed in and 2 directed out. Each node in the tree has an incoming Sneplink, except for the root, which has 2 incoming Sneplinks.

Notice that the Sneptree is defined to be a directed graph here for easier understanding. In the real implementation, the links should be bidirectional. Furthermore, we call the outgoing link which points to the left descendant of a node the "left link" and the one pointing to the right descendant the "right link."

There are many possible ways to connect those $2^n$ Sneplinks. One example of a planar connection is shown in Figure 1. This connection is not of particular interest because it ends up with a very unbalanced mapping for a highly unbalanced binary tree, such as a left skewed tree. Another type of Sneptree whose Sneplinks are connected to form two spanning cycles (i.e., Hamiltonian Cycles) renders an optimal mapping

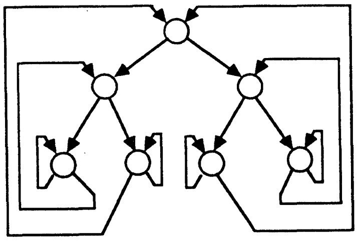

*Figure 1.* A Three–level Sneptree

for a left(right) skewed tree of any size (i.e., a linear array). This special type of Sneptree is called the *Cyclic Sneptree.*

**Definition:** A *Cyclic Sneptree* is a Sneptree containing two link-disjoint spanning cycles. The "left cycle" contains only left links and the "right cycle" contains only right links.

**Theorem 1.** *There are $[(2^{n-1}-1)!]^2$ connection patterns for the n-level Cyclic Sneptree.*

The proof is given in [6]. Notice that many of these $[(2^{n-1}-1)!]^2$ connection patterns are isomorphic because the left and the right links are indistinguishable in practice.

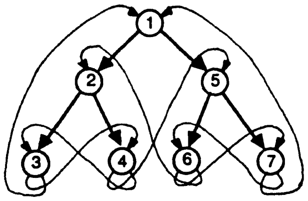

*Figure 2.* A Three-level Cyclic Sneptree

Figure 2 shows one connection pattern of the Cyclic Sneptree. The numbers attached to the nodes show the node ordering in the left spanning cycle. Symmetrically, the right spanning cycle of Figure 2 can be represented by node sequences (1,5,7,6,2,4,3,1). Such a connection pattern is regular and symmetric and it can be generated recursively from the smaller structures. This connection pattern is not planar; the two crossing Sneplinks between two adjacent subtrees make it possible to extend one subtree to the other subtree. This particular Cyclic Sneptree is chosen due to its regularity and extensibility, which are crucial properties for VLSI implementation. Another connection pattern with the same properties is compared in the conclusion. We'll show later that the connection we choose here is better than the other one.

## 3. Mapping of a Binary Tree onto a Sneptree

The mapping from a complete binary tree onto a Sneptree is independent of the connection patterns of the Sneptree. In other words, no matter how the Sneplinks are connected in a Sneptree, the mapping of a complete binary tree is always optimal. This is not true for an incomplete binary tree. The performance of the mapping of an unbalanced tree is affected by the connection pattern of the Sneptree.

Before describing the mapping performance, we shall define the ***computation graph*** and the ***implementation graph*** first. The computation graph represents the structure of the distributed computation and the implementation graph represents the network topology of the parallel machine. ***Cell*** and ***node*** are the names for a vertex of the computation graph and the implementation graph, respectively. An ***optimal mapping*** is defined as a mapping such that (1) the adjacent cells are mapped onto the adjacent nodes, and (2) the number of cells in a single node differs by at most one.

From now on, we assume that the computation graph is an m–level complete binary tree, the implementation graph is an n–level Sneptree and m ≥ n. Again, a cell denotes a node in the binary tree and a node denotes a node in the Sneptree. For this particular mapping problem, we use two figures to measure the mapping performance. The first figure is the total number of cells mapped onto one single node, so-called the *load factor*, which indicates the total work load of each node. The second figure is the number of cells of the same height in the binary tree mapped onto one single node, which is an useful measure when the computation wavefront goes downward and upward in the tree so that only the nodes at one particular level are active at a time. In the following, we are going to show that both measures are minimal for the mapping of a complete binary tree onto a Sneptree. Therefore, the mapping is optimal.

In an n–level complete binary tree, the root is at level 0 and the leaves at level (n–1). The height of a node is defined to be the distance of that node to the leaves. The height of a binary tree is the distance of the root to the leaves, which is (n–1) for a n–level complete binary tree. The above definitions also apply to a Sneptree.

The optimal mapping from a complete binary tree onto a Sneptree is to map the root of the binary tree onto the root of the Sneptree and the two children of a cell onto the two direct descendants of a node.

**Theorem 2.** *All the nodes in the Sneptree contain the same number of cells of one particular level, say $k$, except that each node at ($k$ mod $n$) level contains one more cell, when mapping an m-level complete binary tree onto an n-level Sneptree, $m \geq n$ and $0 \leq k < m$.*

*Proof:* If $k < n$, one cell will be mapped onto one node at the k-th level in the Sneptree. For $k \geq n$, the theorem can be proven by observing the construction of the Sneptree. A node at the j-th level of the Sneptree has two direct ancestors; one is its father at (j–1)-th level, and the other is a leaf, i.e. a node at the (n–1)-th level. Moreover, the number of cells of level k which are mapped onto this node is the sum of the cells of level (k–1) which are located in its direct ancestors. In other words,

$$T_k(j) = T_{k-1}(j-1) + T_{k-1}(n-1), \qquad j > 0 \qquad (1)$$

where $T_k(j)$ is the total number of cells at the k-th level of the binary tree which are mapped onto one node located at the j-th level of the Sneptree for $0 \leq k < m$ and $0 \leq j < n$.

The root node, i.e., the node at the 0-th level, has no upper level and its two direct ancestors are both from the bottom level, i.e. the (n–1)-th level. Combine with Eq.(1), $T_k(j)$ can be recursively defined by

$$T_k(j) = T_{k-1}((j-1) \bmod n) + T_{k-1}(n-1) \qquad (2)$$

where $n \leq k < m$ and $0 \leq j < n$. For $k < n$,

$$T_k(j) = \begin{cases} 0, & \text{if } 0 \leq k < n, 0 \leq j < n \wedge j \neq k; \\ 1, & \text{if } 0 \leq k < n, 0 \leq j < n \wedge j = k. \end{cases}$$

By induction, we assume that the theorem holds for $k$, $k \geq n$. Let $k = q \times n + r$, then $T_k(r) = T_k(j) + 1$, for all $j$ and $j \neq r$. We now prove that the theorem holds for $k+1$. From Eq.(2), when $r \neq n-1$,

$$\begin{aligned} T_{k+1}((k+1) \bmod n) = T_{k+1}(r+1) &= T_k(r) + T_k(n-1) \\ &= 2 \times T_k(n-1) + 1, \quad \text{and} \end{aligned}$$

$$\begin{aligned} T_{k+1}(j) &= T_k((j-1) \bmod n) + T_k(n-1) \\ &= 2 \times T_k(n-1), \quad j \neq (k+1) \bmod n. \end{aligned}$$

If $r = n-1$,

$$\begin{aligned} T_{k+1}((k+1) \bmod n) = T_{k+1}(0) &= T_k(n-1) + T_k(n-1) \\ &= 2 \times T_k(j) + 2, \quad \text{and} \end{aligned}$$

$$\begin{aligned} T_{k+1}(j) &= T_k((j-1) \bmod n) + T_k(n-1) \\ &= 2 \times T_k(j) + 1, \quad j \neq (k+1) \bmod n. \end{aligned}$$

Therefore, $T_{k+1}((k+1) \bmod n) = T_{k+1}(j)+1, j \neq (k+1) \bmod n$, holds for any k.

By induction, the theorem holds. ▮

**Theorem 3.** *All the nodes at the top ($m \bmod n$) levels of the Sneptree contain the same number of cells, Similarly, the rest of the nodes also contains the same number of cells and the amount is one less than that in the top level nodes, when mapping an m-level complete binary tree onto an n-level Sneptree, $m \geq n$.*

*Proof*: Let $T(j)$ be the total number of cells mapped onto a node at the $j$-th level of the Sneptree, i.e., $T(j) = \sum_{k=0}^{m-1} T_k(j)$. Let $m = q \times n + r$ and consider a node at one particular level $j$. Such a node contains one more cell at $(n+j)$-th, $(2n+j)$-th, ..., and $(q \times n + j)$-th levels respectively than the nodes not in level $j$, when $j \leq r$. In other words, there are $q$ such levels in the binary tree, in which one extra cell is assigned to the nodes at level $j$, for $j \leq r$. For $j > r$, there exists only $q - 1$ such levels. Therefore, we can conclude that all the nodes at the top $r = (m \bmod n)$ levels of the Sneptree contain the same number of cells, Similarly, the rest of the nodes also contains the same number of cells, and the amount of cells is one less than that in the top level nodes. ▮

**Corollary 4.** *For* $k = n, n+1, \ldots, m-1$

$$T_k(j) = \begin{cases} \left\lfloor \dfrac{2^k}{2^n - 1} \right\rfloor, & \textit{if } 0 \leq j \leq n-1 \textit{ and } \\ & \quad j \neq k \bmod n \\ \left\lfloor \dfrac{2^k}{2^n - 1} \right\rfloor + 1, & j = k \bmod n. \end{cases}$$

*and*

$$T(j) = \begin{cases} \left\lfloor \dfrac{2^m - 1}{2^n - 1} \right\rfloor + 1, & \textit{for } 0 \leq j < (m \bmod n) \\ \left\lfloor \dfrac{2^m - 1}{2^n - 1} \right\rfloor, & \textit{for } (m \bmod n) \leq j < n. \end{cases}$$

The above corollary can be derived immediately from Theorem 2 and Theorem 3. We now get to the conclusion which has been addressed at the beginning of this section.

**Theorem 5.** *The mapping of a complete binary tree onto a Sneptree is always optimal for any connection patterns of the Sneptree.*

From the above discussion, it is clear that an arbitrary size complete binary tree can be mapped onto a Sneptree optimally no matter how it is connected. On the contrary, the performance of mapping an unbalanced binary tree is dependent on the connection pattern of the Sneptree.

**Theorem 6.** *A left or right skewed tree of any size can be mapped onto the Cyclic Sneptree optimally.*

*Proof*: The theorem is true from the definition of the cyclic Sneptree. ▮

**Remark** A linear array of any length can be mapped onto the Cyclic Sneptree optimally if we map the linear array onto the left cycle or the right cycle of the Cyclic Sneptree.

## 4. Layout of a Cyclic Sneptree

In this section, we discuss how to layout a Cyclic Sneptree (shown in Figure 2) on a plane. From now on, we call the Cyclic Sneptree in Figure 2 "Sneptree" since all the discussions in Section 4 and 5 are based on this particular connection pattern. The H-structure layout for a binary tree [8] is modified to layout a Sneptree. The recursive rule to generate the layout is described. Also, the number of crossings and the length of the longest wires are analyzed. Finally, we will present a way to extend the size of the Sneptree by connecting two identical smaller Sneptrees.

### Recursive Generation of H-structure Layout

Like the binary tree, the Sneptree can be laid out into an H-structure plane. Because of the Sneplinks in the Sneptree, it is not that straightforward to build the H-structure Sneptree. The major concern is to minimize the number of crossings in the layout and keep the length of the Sneplinks as short as possible. With the two criteria in mind, a recursive construction algorithm is designed.

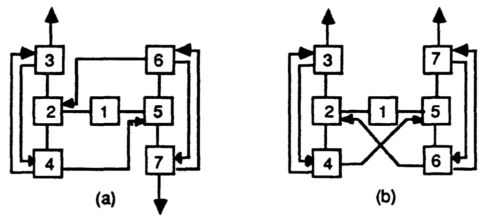

*Figure 3.* Two basic three–level H–Sneptrees

The n–level Cyclic Sneptree can be constructed recursively into an H–structure layout with two given basic three–level H–Sneptrees, $A_3$ and $B_3$ (Figure 3). In Figure 3, the node numbering is compatible with that of Figure 2. The dangling arrows out of node 3 and node 7 are the two links incident into the root in a regular 3-level Cyclic Sneptree. These two links are dangling in order to extend to bigger structures.

Let's define two basic operations on the layout G:

(a) mirror along x axis : $G^x$
(b) mirror along y axis : $G^y$

The recursive rules are as follows:

1. Construct two 3-level H-structure Sneptrees $A_3$ and $B_3$ as shown in Figure 3. $A_3$ is the one we intend to construct and $B_3$ is an auxiliary layout to be used in constructing bigger Sneptrees. Now we like to construct $A_n$ for all $n \geq 3$ and $B_n$ for $n \geq 3$ and n odd.
2. Given two k-level H-structure Sneptrees, $A_k$ and $B_k$, for $k \geq 3$ and odd, the (k+1)-level and (k+2)-level H-structure Sneptrees can be constructed as shown in Figure 4. A (k+1)-level Sneptree, $A_{k+1}$, can be constructed by two k-level subtrees, namely $A_k$ and $B_k$. And a (k+2)-level Sneptree, $A_{k+2}$, can be constructed by four k-level Sneptrees, $A_k$, $B_k$, $B_k^y$ and $A_k^x$. The auxiliary (k+2)-level Sneptree, $B_{k+2}$, can be constructed by $A_k^x$, $B_k$, $A_k^y$ and $B_k$.

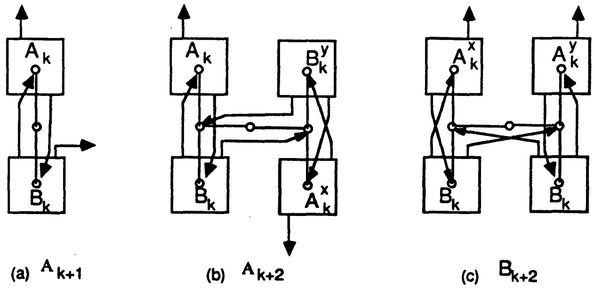

*Figure 4.* Construction of $A_{k+1}$, $A_{k+1}$ and $B_{k+2}$

For example, a 4–level Sneptree is constructed by connecting $A_3$ and $B_3$ to an extra node and by directing the Sneplinks as shown in Figure 5.a. Notice that $A_3$ is planar and $B_3$ has one crossing. $A_4$ has five crossings due to the introduction of new links, including the two links incident to the root, shown as dotted lines in Figure 5.a. The dotted arrows into the root node should be connected to the two dangling links coming out of the leaf nodes to make it a complete 4-level Sneptree. A 5–level Sneptree can be constructed as in Figure 5.b. There are in total eleven crossings in the layout; five in the left half of the graph, which is exactly $A_4$ except for the two links of the root coming out to the right; four in the right half as shown in the figure and two from the incoming links (dotted lines) of the root in the middle of Figure 5.b.

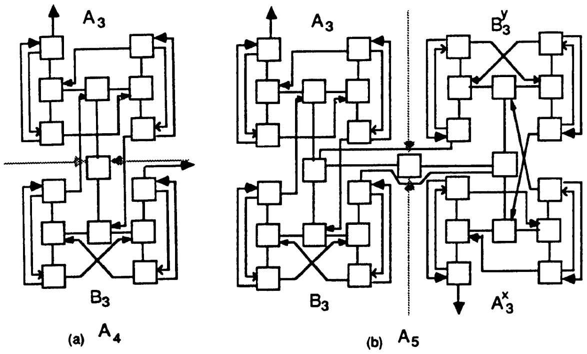

*Figure 5.* Construction of $A_4$, $A_5$ using $A_3$ and $B_3$

Since the Cyclic Sneptree is not planar and the Sneplinks are not of constant length, we would like to know the number of crossings and the maximum length of the Sneplinks.

Theorem 7 gives the number of crossings in $A_n$ and $B_n$. $B_n$ has one more crossing than $A_n$ and both figures are approximately 3/8 of the total number of nodes in the Sneptree. The two crossings introduced by the incoming links of the root node in $A_n$ are not counted. The proof of Theorem 7 is given in [6].

**Theorem 7.** *The number of crossings in $A_n$ is $3 \times (2^{n-3} - 1)$ and the number of crossings in $B_n$ is $3 \times (2^{n-3} - 1) + 1$.*

Assume that any single node in the layout is a square with area $a$, i.e., each side of the node is $\sqrt{a}$ in length and the wire width is negligible compared to $\sqrt{a}$. The area of the H-structure Sneptree is the function of node area $a$ and the height of the Sneptree $n$. The zero wire width assumption is reasonable because the number of wires passing through any two adjacent nodes in the layout is bounded by a fixed number.

Furthermore, we assume that the four links of each node may be pulled out of any side of the node. Two or more links may come out of the same side. The length of the wire connecting two nodes is the shortest distance from the center of one side of the source node to the center of the nearest side of the other node. The wire has to route around all the nodes in the way.

Theorem 8 shows that the length of the longest internal wire in an H-layout Sneptree is about 1/4 of the width of the layout. It is only $(3/2)\sqrt{a}$ longer than the longest wire of the H-layout binary tree of the same size. The proof of Theorem 8 is given in [6].

**Theorem 8.** *The longest internal wires of an n-level H-structure Sneptree are the two wires connecting the root and two leaf nodes at the left and the right corners. The length is*

$$l_n = \begin{cases} \sqrt{a}(3 \times 2^{n/2-3} + 1/2), & n > 3 \text{ and even} \\ \sqrt{a}(2^{(n-3)/2} + 1/2), & n > 3 \text{ and odd} \\ 2\sqrt{a}, & n \leq 3 \end{cases}$$

### Extension of the Sneptree

From the above discussion, it is clear that we can layout a Sneptree of any size onto a single chip as long as the chip capacity is not exceeded. Here we present a method to extend the Sneptree by connecting two identical H-structure Sneptrees, which is modified from the recursive construction technique of binary tree from a single chip proposed by [5].

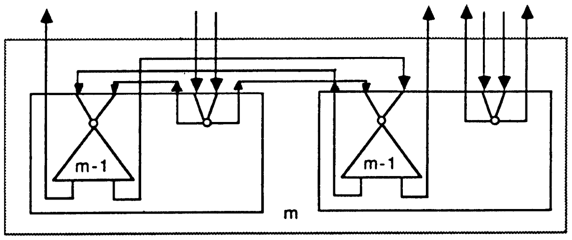

*Figure 6.* Extension of the two (m-1)-level Sneptrees to an m-level Sneptree

Let one chip consist an (m–1)-level H-structure Sneptree with four dangling links and a single processor with its four links. Two of the four dangling links in the Sneptree are out of the leftmost and the rightmost leaf nodes, respectively. The other two are the incoming links to the root node. There are eight connectors in a single chip as shown in the solid box in Figure 6.

Figure 6 illustrates how to connect two such chips into an m-level Sneptree. The resulting layout contains one m-level Sneptree with four dangling links and a single processor, which is now able to extend to bigger structures recursively.

## 5. Routing Algorithm for Leaf Nodes

In this section, a leaf node routing algorithm for the Sneptree is presented. It is motivated by the opportunities to map a linear array onto the leaf nodes of the Sneptree and to utilize the Sneplinks to shorten the communication distance between two arbitrary leaf nodes.

The design of the routing algorithm is constrained by the following criteria: *communication distance* (to find a route as short as possible), *congestion constraint* (to use the extra links to avoid traffic jam at the upper level nodes), and *time constraint* (to keep the routing time as low as possible).

The time to route a message from a node x to another node y is the sum of the message transmission time and the processing time at the source node and each intermediate node. Let $t_p$ and $t_c$ be the time of one processing step and the time of one message transmission between adjacent nodes, respectively. Suppose $< x = x_0, x_1, \ldots, x_{k-1}, x_k = y >$ is the route which the message is sent through and $f(i)$ is the number of processing steps necessary to compute the following route at the intermediate node $x_i$. The total routing time is

$$\sum_{i=0}^{k-1} f(i)t_p + k \times t_c \qquad (3)$$

In an n-level binary tree, $k$ is bounded by $2(n-1)$ and $f(i)$ is constant for all $i$ so that the routing time is O(n). Notice that the bitwise operations, such as detecting if one node is in the subtree of another node, is assumed to take constant time. In a Sneptree, it is obviously that the shortest distance of any two nodes is not longer than that in the binary tree due to the Sneplinks of the Sneptree. Hence, the second term, k, of Eq.(3) for the Sneptree is smaller than that for the binary tree. To keep the total routing time for the Sneptree in the same order of magnitude as for the binary tree, we have to keep $f(i)$ constant in the intermediate nodes. As a consequence, the algorithm can't always find a shortest route. It finds a route which is shorter and less congested than the one in a pure binary tree in O(n) time.

The leaf node routing algorithm is presented in the following subsection and the program is given in [6].

### The Routing Algorithm

Before describing the algorithm in detail, we shall first define the *breadth-first normal ordering* of the nodes.

**Definition.** The *breadth-first normal ordering* is an addressing method for a binary tree. The nodes in an n-level binary tree are numbered from 1 to $2^n - 1$. The root node has address 1, and the left descendant and the right descendant of a given node $x$ have addresses $2x$ and $2x + 1$, respectively.

Suppose that each address is represented by an n-bit binary number; the addresses of the left and the right descendants of a nonleaf node are derived by shifting its address one bit to the left and adding 0 or 1 to it.

With such an addressing scheme, the binary address of the lowest common ancestor of any two leaf nodes can be easily decided, which is an n-bit binary number with leading zeros followed by the common prefix of the binary addresses of the two leaf nodes. Furthermore, the binary addresses of the left and the right corner leaf nodes of a subtree with height h have h trailing 0's and h trailing 1's, respectively.

In our routing algorithm, the source node computes and selects the shortest route between the source node and the destination node. Then, a four-variable message carries all the routing information necessary for a receiving node to determine the next node on the route. The intermediate nodes need not recompute the shortest routes.

Suppose a message is sent from a leaf node x to a leaf node y in a Sneptree of height n. Without loss of generality, we assume x<y; i.e., node x is to the left of y. Let A be the lowest common ancestor of x and y, B and E be two direct descendants of A, and triangles BCD and EFG be the two subtrees containing x and y (see Figure 7). In the sequel, UV denotes the shortest path between two nodes U and V, and |UV| represents the length of this path. Four possible routes between x and y are (xB,BAE,Ey), (xD,DE,Ey), (xB,BF,Fy) and (xD,DEABF,Fy). The lengths of these four routes are |xB|+|Ey|+2, |xD|+|Ey|+1, |xB|+|Fy|+1, and |xD|+|Fy|+4, respectively. In order to find the shortest route among the four candidates, we need to compute |xB| ,|Ey|, |xD|, and |Fy|. Notice that |xB| and |Ey| are bounded by the height of the triangle BCD (or EFG), and |xD| and |Fy| are bounded by twice of the height of the minimal subtree containing x and D (or y and F). The routing algorithm takes advantage of the Sneplinks within the triangles to find the shortest paths xB,xD,yE, and yF.

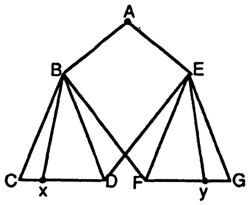

*Figure 7.* Four Possible Routes Between x and y

The length of xB (or yE) can be computed recursively. The shortest distance between B and a leaf node is 2 regardless of the height of B. The leaf nodes that have distance 2 from B are the two inner corner leaf nodes of the two subtrees of node B, and the shortest paths take one of the treelinks to a descendant of B and then take the Sneplink to the leaf (see Figure 8.a). Let a and b be the two direct descendants of B and let c and d be the two corner leaf nodes that have distance 2 from B. Then the leaf nodes that are at distance 3 from B are the nodes at distance 2 from nodes a or b, as well as the nodes at distance 1 from nodes c or d. There are six such nodes: two (a1 and a2 in Figure 8.b) are at distance 2 from a, two (b1 and b2) at distance 2 from b, and c1 and d1 are at distance 1 from c and d, respectively. Applying this technique recursively, we can find the shortest path between any leaf node and node B. The shortest path xB for an arbitrary leaf node x is a path starting from node B, following the treelinks down to a certain level of the tree, then taking the Sneplink to a leaf node and following the shortest route from this leaf node to node x (see Figure 9.a).

To find xB, the algorithm finds a sequence of leaf nodes whose binary addresses differ from x only in trailing bits, and their trailing bits are all 1's or all 0's. Those leaf nodes can be routed to node B through a Sneplink so that the distance to B is shorter that the height of B. The length of a route from x via one of such leaf node, say $x_j$, to B is the sum of the shortest distance of x to $x_j$ and the distance of $x_j$ to B.

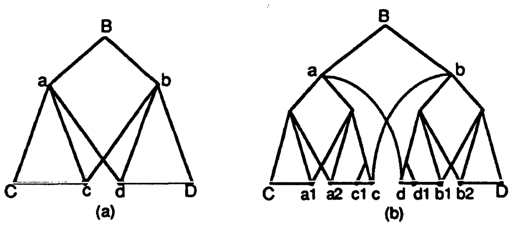

*Figure 8.* The Leaf Nodes with Distance 2 or 3 from Node B

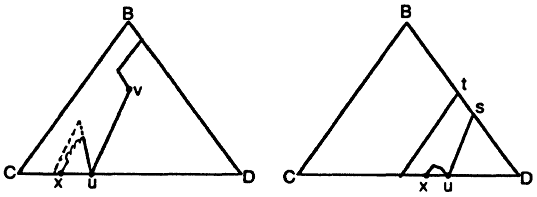

*Figure 9.* The Shortest Paths xB and xD

After all such routes have been computed, the shortest one is the candidate to the shortest route of xB. If the shortest distance is longer than the height of B, then the direct route from x to B (going upwards through treelinks) is the shortest route. For instance, let the binary address of x be 00111010, where we ignore the leading bits that are the common prefix of the binary address of x and y because they are irrelevant in computing xB. The height of B is 7 so that the shortest distance of x and B won't exceed 7. The first leaf node which can take advantage of one of the Sneplinks is $x_1$=00111011 ($x_1$ is derived by changing the LSB of x to 1), which is of distance 1 from x and 6 from B by taking the Sneplink. Hence, the distance is 7 by routing through $x_1$. The second leaf node is $x_2$=00111111, which happens to be node c in Figure 8.a and has distance 2 from B. The distance of x and $x_2$ can be computed recursively and it turns out to be 4. Therefore, the distance of xB by routing through $x_2$ is 6, which is shorter than 7. Since there are no other leaf nodes which can take advantage of the Sneplinks, we can conclude that the shortest route of xB is from x to $x_2$, taking the Sneplink to the right descendant of B, and then up to B.The length of the shortest route is 6.

The distance of xD can be derived during the computation of xB. Let the lowest common ancestor of x and D be t, the right descendant of t be s, and the leaf node at the other end of the Sneplink out of s be u. Then, the route (Bs,su,ux) is one of the candidates for the shortest path Bx. Hence, the distance of ux is computed while computing xB and the shortest path between x and D is (Ds,su,ux) whose distance can be derived immediately (see Figure 9.b).

In the computation described above, we need to find the shortest route from x to another leaf which is a corner node of a subtree containing x. Again, this distance can be computed recursively. For instance, to route xu in Figure 9.a, we try to find a sequence of leaf nodes starting with x and ending with u. Each pair of adjacent nodes in the sequence has Hamming distance 1. We now route the message through the nodes in the sequence. The distance from x to any intermediate node can be computed recursively by the previous value. Let u be a right corner leaf node of a subtree and let the node sequence be $(x = x_0, x_1, \ldots, x_k = u)$, where $x_i$ is derived from $x_{i-1}$ by changing the least significant 0 of $x_{i-1}$ to 1, and k is the Hamming distance of x and u. Notice that the address of u has m trailing 1's, where m is the height of the minimal subtree containing x and u. The recurrence relation is

$$|x_0 x_i| = \min(|x_0 x_{i-1}| + j,\ \ 2 \times j) \tag{4}$$

where $j$ is the position of the bit that differs in $x_{i-1}$ and $x_i$. All the bits to the right of the $j$-th bit of $x_{i-1}$ and $x_i$ are 1's (Figure 10). The shortest route from $x_{i-1}$ to $x_i$ takes the left Sneplink of $x_{i-1}$ to an ancestor node of $x_i$ and then takes the right tree links down to $x_i$. The distance is j, i.e., the height of the lowest common ancestor of $x_{i-1}$ and $x_i$. Furthermore, the shortest route between $x_0$ and $x_i$ could be either the route $(x_0 x_{i-1},\ x_{i-1} x_i)$ or the route containing only treelinks and passing through the lowest common ancestor of $x_0$ and $x_i$ (the distance of this route is $2 \times j$). In the previous example, the shortest route from x=00111010 to $x_2$=00111111 is taking the Sneplink to leaf node $x_1$=00111011, then Sneplink again to the ancestor of $x_2$ and taking the right treelinks down to $x_2$. The distance is 1(x to $x_1$)+3($x_1 x_2$)=4.

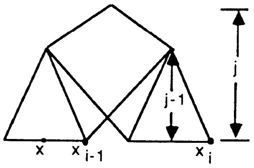

*Figure 10.* The Shortest Path Between $x_{i-1}$ and $x_i$

Similarly, if u is a left corner leaf node (with trailing 0's), |xu| can be derived by computing the distance of x and a series of intermediate nodes whose addresses are derived by changing the least significant nonzero bits of x to 0 until it reaches u.

Now, we can select the shortest path among the four candidates, (xB,BAE,Ey), (xD, DE,Ey), (xB,BF,Fy) and (xD,DEABF,Fy). So far, all the computation and decision being made are accomplished at the source node x. To achieve O(n) time performance, we don't want to repeat the computation in any other intermediate nodes along the route. Hence, the routing information should be sent to the intermediate nodes to guide them to select the proper next node along the route. It appears that a four-variable message is enough to carry the route information and avoid extra computation.

When the shortest route goes through xB, two figures are needed to guide the route. Suppose the message is routed from x to another leaf node u, then take the Sneplink to a nonleaf node v and send up to node B, (Figure 8.b), we first need to know the route information of xu. If the route xu follows the treelinks up and down to some intermediate leaf node, (i.e., when $2j$ is the smaller one in Eq.(4).) we record the highest point of this route, otherwise it is zero. The second figure we need to know is the distance of B and v. Let's call these two figures $m1$ and $h1$. When xB contains treelinks only, $m1$ is zero and $h1$ is the height of node B. Similarly, $m2$ and $h2$ are the corresponding information needed to describe the route yE. Furthermore, we need a direction flag to guide the message to either the left descendant, the right descendant or the father node.

When route xD is in the shortest path, the only information we need to know is the highest point that the route reaches through the treelinks. (i.e., when $2j$ is the smaller one in Eq.(4).) Let's call it $l1$ and when the route contains no upward treelinks, $l1$ becomes zero. Similarly, $l2$ is the corresponding information needed to describe route yF.

Let a four-variable message be $(level1, dir, level2, dest)$. In general, the routing information for the route in triangle BCD is carried in the first two variables of the message. The third variable carries the information for the route in triangle EFG. The last variable is always the destination. More specifically, $level1$ carries the value of $l1$ or $m1$ depending on which route is selected. Variable $dir$ is usually a three-value variable used to select the next node in the route when a leaf node or the highest nonleaf node is reached. When xB is selected, $h1$ is also carried by $dir$. Variable $level2$ carries either the value of $h2$ or $l2$ depending on whether yE or yF is selected in triangle EFG. The value of $m2$ has to be reproduced by a specific node in route Ey when Ey is selected, since there is no room to carry the value in a message. That specific node is the lowest nonleaf node traveling down from E through treelinks, from where the route takes the Sneplink to a leaf node and then takes the shortest route to y. Such a node corresponds to node v in route xB (see Figure 9.b). The second variable is also used to select one of the four possible routes. When $dir$ is used to carry the direction information of the route in the triangle BCD, the route information for node A,B and E is carried by the fourth variable instead. For instance, the value of the fourth variable is negative when yF is selected. The routing information for triangle EFG will be resumed at node A,B or E by moving the information carried by the third and the fourth variables back to the first two variables.

### Performance

The computation time in the source node $x$ is O($n$). When Ey is selected, one of the intermediate nodes along route Ey needs to reproduce the value of $m2$ in $k$ steps, where $k$ is the height of this specific node. When xB is selected, a few nonleaf nodes along the route need to compute the height of the lowest common ancestor of themselves and the destination node. Such bitwise operation is again assumed to take constant time. In conclusion, only the source node and at most one intermediate node need to do some computation in O(n) time. From Eq.(3), we can conclude that the routing algorithm takes O(n) time to route the message from the source to the destination.

The result of the routing algorithm gives a good approximation to the shortest path of xy. Furthermore, the routing algorithm always find the shortest path within the triangle ACG. This routing algorithm uses only the links local to the minimal subtree containing the source and the destination nodes. The Sneplinks external to this subtree are never considered. As a consequence, the two Sneplinks of the root node are never used for routing. Because of this restriction, the routing algorithm does not always compute the shortest path. (For example, the route from the left corner leaf to the right corner leaf has a distance 2, whereas our algorithm chooses a route of length twice the height of the tree.) However, this restriction has many advantages. The algorithm is simple and yet computes nearly optimal routes, and the traffic of the upper level nodes is reduced.

In a binary tree, the nodes at the upper levels are the most congested nodes because half of the leaf nodes have to route through the root node to communicate with the other half of the leaf nodes. In case any leaf node is communicating with all the other leaf nodes, the root node has to transmit about half of the messages and the nodes one level down the root have to transmit 5/8 of the messages. Then, the traffic at each node decreases level by level from 13/32, to 29/128,.... In a Sneptree, four routes may be chosen to route a message between two arbitrary leaf nodes and only two of them pass through the lowest common ancestor of the two leaf nodes. Assuming the four alternatives are equally possible, the traffic at the common ancestor is reduced to a half of the binary tree case and the traffic at the nodes one level down the common ancestor is reduced to three quarters since three of the four routes pass through that node (see Figure 7). In case any leaf node is communicating with all the other leaf nodes, the traffic at the top level nodes become 1/4, 7/16, 19/64, 43/256,... of the total amount of messages. The figures show that the traffic at the top level nodes is reduced to about a half of the binary tree case. The actual figures depend on the height of the Sneptree. The traffic at the nodes of the same height is no longer the same and the exact figures need more analysis.

The simulation result shows that the average routing distance of any two leaf nodes is getting closer to the optimal average distance when the Sneptree is bigger. The simulation also shows that for some specific communication patterns, the routing result is almost optimal, such as shift by $2^k$ operations, i.e. routing one leaf to another leaf at $2^k$ distance apart. Figure 11 shows the optimal results and our routing algorithm results of the average distance of any two leaf nodes and the average distance of a perfect shuffle operation. Figure 12 shows the average distance of shift by $2^k$ operations, the curves for routing results and optimal results overlap in Figure 12.

## 6. Conclusion

The Sneptree is a versatile interconnection network for distributed computation. The boundary problem of a binary tree is eliminated in the Sneptree so that the mapping of an over-sized computation tree is done automatically. Moreover, a complete binary tree of arbitrary size can be mapped onto a Sneptree optimally. And a left/right skewed tree can be mapped onto a Cyclic Sneptree optimally.

The Sneptree is also suitable for VLSI implementation. It is possible to build a Sneptree of any size in a single chip with area proportional to the total number of processors. The H-structure layout of the Sneptree is regular and can be recursively constructed. The number of crossings due to the extra links is proportional to the number of nodes of the Sneptree. The longest wire length is about the same as that in an H-structure binary tree. Furthermore, the Sneptree can be expanded easily by connecting two or more chips together.

The leaf node routing algorithm allows us to take advantage of the extra links in the Sneptree. Hence, a shorter and less congested route between any two leaf nodes can be found in O(n) time. The routing algorithm gives a good approximation to the optimal solution. In some special communication pattern, such as shifting by $2^k$, the average routing result is almost optimal. Besides, the traffic at the upper-level nodes is reduced to about a half of the traffic in a pure binary tree.

### Comparison with Other Networks

Like the Sneptrees, the X-tree [2] is an augmented binary tree with identical nodes. Three ports per node, four ports per node and five ports per node are considered. The degree of each node is not fixed but the maximal degree is limited by the number of ports per node. Besides the binary tree connection, the extra ports can be connected arbitrarily. The main purpose of the X-tree is to provide fault-tolerance and uniform message traffic.

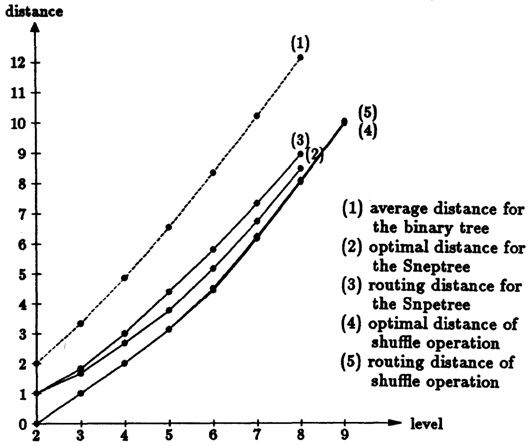

*Figure 11.* The average routing distances

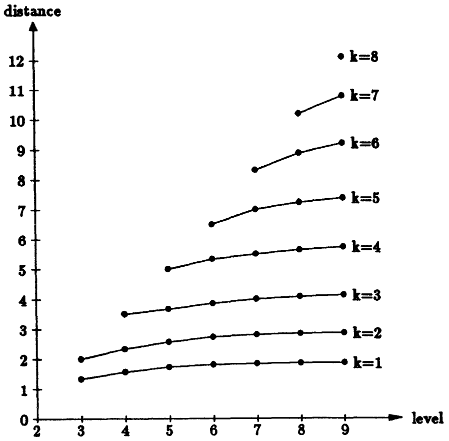

*Figure 12.* The ave. routing dist. of shifting by $2^k$ ops.

The Hypertree [3] is a binary tree with extra horizontal links (i.e., the links connecting the nodes located at the same level). The horizontal links provide a set of n-cube connections. Four ports per node and five port per node are considered. Similarly, the main concern of the Hypertree is to provide fault-tolerance and shorten the distance between two arbitrary leaf nodes.

De Bruijn Networks [9] are a class of fixed degree logarithmic networks with arbitrary number of nodes and degree. A De Bruijn Network with $(2^n - 1)$ nodes and degree 4 happens to be a Sneptree. Such networks are good for a communication network since the optimal routing path can be decided with local information and fault-tolerance is easily provided.

Comparing with the other similar networks, the Sneptree is the only network which can simulate an over-sized binary tree. The X-tree and the Hypertree contain extra links between sibling nodes so that it can simulate ring connection or n-cube connection. They cannot handle the mapping of an over-sized problem well. The de Bruijn network with degree 4 is one type of Sneptree. The connection pattern is neither cyclic, symmetric nor regular. There is no way to layout the network or extend the network.

### Different Connection Patterns

From Theorem 1, we know there are many different connection patterns for the Cyclic Sneptree. It will be interesting to compare the performance of different connection patterns of the Cyclic Sneptree in terms of the communication distance and the mapping performance of an unbalanced tree.

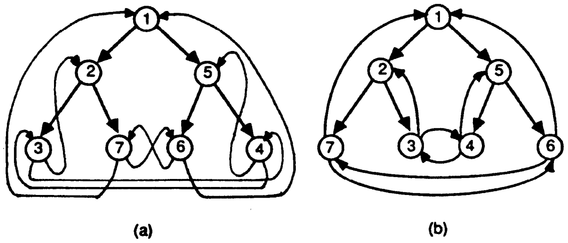

*Figure 13.* A Planer Cyclic Sneptree

Figure 13.a shows another Cyclic Sneptree. the numbers attached to the nodes show the node ordering in the left spanning cycle. Symmetrically, the right spanning cycles can be represented by node sequence (1,5,4,3,2,7,6,1). Such connection pattern also has regular structure and hence can be generated recursively. It is interesting to observe that this connection is planar if we switch the position of the leaf node pairs (3,7) and (6,4) as shown in Figure 13.b. Comparing the Cyclic Sneptree shown in Figure 2 with this one, the latter one (Figure 13.b) contains four duplicate links, i.e., (2,3), (4,5), (3,4) and (6,7) while the former one (Figure 2) has only two duplicate links, i.e., (3,4) and (6,7). The duplicate links prevent the Sneptree from connecting more nodes together. Hence, the second connection pattern doesn't perform as well as the first one in terms of communication.

There are many other connection patterns for the Cyclic Sneptree, some of them may perform better than the one we chose in terms of the communication distance between arbitrary two nodes and the mapping performance of an unbalanced tree. But only the two connection patterns discussed above can be constructed recursively from the smaller Sneptrees without breaking the internal Sneplinks in the smaller structures. This property is important for VLSI implementation.

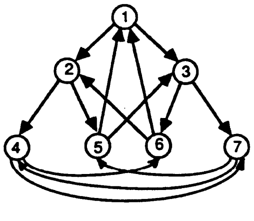

*Figure 14.* A three–level Exchange Sneptree

The *Exchange Sneptree* is a different type of Sneptree. In a Exchange Sneptree, the outgoing Sneplinks of the leaves in the left half of the Sneptree are directed to the incoming Sneplinks of the nodes in the right half plus one incoming link of the root, and similarly for the other half of the Sneplinks.

One example of the Exchange Sneptree is shown in Figure 14. This connection is symmetric but neither extensible nor cyclic. This connection has a very nice property: no matter which node the root is mapped onto, it results in a nearly optimal mapping for a complete binary tree. As a consequence, we found that mapping performance of a unbalanced binary tree onto such a Exchange Sneptree is better than the same mapping onto a Cyclic Sneptree. The properties of the Exchange Sneptree need further investigation.

# The Onset of Hot Spot Contention

Manoj Kumar and Gregory F. Pfister

IBM T.J. Watson Research Center
Yorktown Heights, NY, 10598

**Abstract:** Non-uniform traffic distributions in a multistage network characterized by "hot spots" — destinations getting more than their share of traffic—can cause dramatic reductions in the maximum throughput of the network. In this paper we develop an analytical model predicting how long a "hot spot" must be persist in shuffle/exchange networks before its its full effect is felt. The model predicts that hot spots will disrupt network traffic severely in a very short time: 10 to 50 instruction execution times in a shared-memory machine. This result, verified by simulation, leads to the conclusion that if stringent measures are not taken to ensure uniformity, the performance of large multistage networks will be substantially worse than has been previously predicted.

## 1.0 Introduction

Multistage interconnection networks with distributed routing have often been proposed as a means of connecting large parallel or distributed computing systems. However, for such networks it has been shown that statistically non-uniform traffic patterns—patterns containing a **hot spot** [6] that gets more than its share of the traffic—can cause severe performance degradation for all network traffic, not just traffic to the hot spot. For example, as little as 0.125% imbalance in a 1000-way network can limit network throughput to less than 50% of its maximum value. This is independent of network topology, redundant paths, or mode of use of the network (e.g.: message passing, shared memory, circuit vs. packet switching, etc.). This effect was discovered in the IBM RP3 project [5,1,4], and first reported in [6]. It was also reported there that the technique of "combining" messages in the interconnection network could solve the problem for some cases of interest.

However, the analysis and simulation reported in [6] does not address a crucial issue: Over what time interval must a non-uniform pattern be sustained in order to reach tree saturation? This is important, because it is a critical measure of how uniform the traffic must be to avoid hot spot problems. Statistical uniformity is much more easily achieved when averaged over hours (for example) than when averaged over microseconds.

We address that issue here by developing a model, verified by simulation, of how long a hot spot must persist before its effects are fully felt. This provides a lower bound on the interval over which uniformity must be measured.

Unfortunately, the result is that the required interval is quite short indeed. For example, with a 1024-way network of 4-way switches containing 4-element queues, a 0.125% hot spot non-uniformity will have its full effect within (approximately) 10 to 50 times the minimum time to traverse the switch. (See Figure 4.)

We can only derive a crude lower bound for the time for a network to recover from a hot spot; that appears to be a more complex process. However, both that lower bound and our simulations demonstrate that the recovery time is much longer than the onset time.

Before deriving these results and comparing them with simulation, a brief overview of the hot spot effect will be given. A discussion of possible remedies, and of our conclusions, ends the paper.

## 2.0 Hot Spot Contention and Tree Saturation

Here we summarize the results presented in [6], with a slight addition.

Consider a two-sided packet-switched multistage network, with $p$ ports on each side, connected to message sources on one side and message sinks on the other, such as the Omega network [3] illustrated in Figure 1.

Suppose the traffic pattern is initially uniform, with messages emitted from each source at a rate $r$ $(0 \leq r \leq 1)$. Then, at some time after a steady state has been achieved, the traffic pattern is altered to direct a fraction $h$, $0 \leq h \leq 1$, of all references are aimed at a specific sink: the **hot sink.** I.e., each source emits $r(1-h)$ messages uniformly distributed, and $rh$ messages to the hot sink. $h$ is the hot spot rate. As a result, the hot sink receives two components of traffic: $r(1-h)$ from the uniform background, and $rhp$ from the hot spot.

If $h$ is large enough, the rate into the hot sink will be unity due to the $rhp$ term. If this happens, the queues in

0190-3918/86/0000/0028 $01.00 © 1986 IEEE

the network switch closest to that sink will fill. This causes the preceding switches' queues to fill; then the next preceding; etc. Finally, a tree of switches rooted at the sink and extending to every source is saturated. This is called **tree saturation**, and is illustrated by the marked switch queues in Figure 1.

Once tree saturation is in effect, every message from any source to any sink must cross the saturated tree and so is delayed. In effect, all the network traffic is gated by the speed at which the single hot sink can dispose of its messages. In the steady state, this occurs when the total traffic rate into the hot sink ($r(1 - h) + rhp$) equals unity. In [6] it was shown that this has a dramatic effect as the system is scaled up in size, as noted in the examples cited in the present paper's introduction. In the steady state, hot spot effects are independent of network topology, finite queue size, etc. (However, the timing analysis presented here does depend on these factors.)

Beyond what was presented in [6], we note here that tree saturation is a finite queue effect. But in order to eliminate it, the queues in the final stage of the network must be large enough to accommodate the maximum hot spot traffic of the entire system. In other words, their size must be equal to $M$ × the number of network ports, where $M$ is the maximum number of messages that can be simultaneously outstanding from each source. Thus if queue sizes are taken into account, the total network size has another factor equal to the number of network ports. This raises the network size to $O(M \times N^2 \log N)$, rather than the usually-cited $O(N \log N)$. The factor of $N^2$ negates any size advantage over a full crosspoint switch.

## 3.0 Modelled Behavior

The network behavior modelled here assumes that the network is initially in a steady state with uniformly distributed traffic flowing through it at a rate $r$. At time 0, all the sources simultaneously change their traffic patterns to include a hot spot. $r$ does not change, but a fraction $h$ of $r$ sufficient to cause tree saturation is now directed at a hot sink. The throughput of the network now declines until at a time $T$ it reaches a steady-state minimum caused by tree saturation. We wish to estimate T as a function of r, h, network size, etc.

Packet switching is assumed, with one packet per message. In the analysis, one time unit is required for a packet to move from one switch to the next. For reasons explained later, the results shown in the figures are scaled to be in units equal to the minimum time to traverse the switch.

## 4.0 Model of Onset

It is convenient to imagine the messages sent to the hot sink after time 0 as being colored red, and all other messages colored white. The total rate at which each source emits red messages is

$$R = rh + \frac{r(1 - h)}{p}$$

$R$ is not simply $rh$ because $1/p$ of the messages from the uniform background are sent to the hot sink, where $p$ is the number of network ports.

Rather than dealing directly with the complex dynamics of message flow through the network, we will count the red messages in the network. On the one hand, the number $N$ of red messages is a function of time and of their total arrival and departure rates from the network as a whole. On the other hand, when tree saturation is reached there is a steady-state number $N$ of red messages in the network that is a function of the input traffic and the amount of buffering available. So equating $N$ in both formulations can tell us how long it takes to reach saturation.

### 4.1 Arrival and Departure

To estimate the arrival and departure rates, we make a set of assumptions that, overall, amount to the general assumption that the onset of tree saturation happens fast and suddenly — too fast and suddenly for the internal dynamics of the network to have much effect on arrival and departure rates until the point of saturation is reached.

We assume that the total arrival rate of red messages is constant (i.e., is $Rp$) until tree saturation is reached; and then it drops instantly to the tree saturation value. Under this assumption, the number of red messages generated by time $T$ is simply $RpT$. Our simulations do not verify a constant arrival rate: the input rate does decline with time. Nevertheless the final results are adequate.

For the departure rate, we assume the following:

At $T$, the first red messages enter the first switch stage. They make their way through the tree of switches that will be saturated, gradually becoming more and more concentrated, until they reach the hot sink. Then:

1. Until the hot sink is reached, there is no effect on the rate at which messages are transported. The first red messages reach the hot sink at a time $D(r)$ that equals the average delay through the network at a total input rate of $r$.
2. At D(r), the concentration of red messages is immediately sufficient to saturate the hot output port; i.e., after D(r) that port emits messages at a rate of unity.
3. After D(r), all the messages emitted by the hot output port are red.

While somewhat unrealistic, these assumptions are conservative. They overestimate the departure rate, and thus indicate that the saturated tree fills with red messages sooner than it actually will.

With those assumptions, the number of messages that have left the network at time $T$ is simply $T - D(r)$. Then, since the number of red messages arriving by time $T$ is $RpT$, $N = RpT + T - D(r)$. Solving this for $T$ yields

$K$ is the size of each individual switch, i.e., number of input and output ports, so $K^i$ is the number of switches at each stage that lie within the saturated tree. $q$ is the size of each queue; (K + q) is the total storage available for messages aimed at the hot spot in each switch stage. (The additional K is due an additional buffer on each input port used in the simulation; this is discussed later).

For each switch at stage i in the saturated tree, $mix_i$ is the fraction of red messages in its queue during steady-state tree saturation:

$$mix_i = \frac{AR_i}{AR_i + AW_i}$$

$AR_i$ and $AW_i$ are respectively the arrival rates of red and white messages at stage i:

$$AR_i = R \times \frac{p}{K^i}$$

because $p/K^i$ is the number of sources in the subtree leading to each switch in stage i.

$$AW_i = r(1 - h) \times \frac{K^i - 1}{K^i}$$

Recall that $r(1 - h)$ is the total rate of uniform background traffic, part of which is directed at the hot sink. Since there are $K^i$ possible destinations for the cool traffic

$$T = \frac{N - D(r)}{Rp - 1}$$

The denominator becomes zero as the combinations of R and p reaches a point inadequate to sustain an output rate of unity. I.e., as that point is approached the time to saturation approaches infinity, which is expected.

To estimate $D(r)$ we use the well-known formula for the average queue length in a switch stage [2]:

$$B(r) = \frac{r}{2(1 - r)}\left(1 - \frac{1}{K}\right)$$

Where r is the steady state rate and K is the number of ports of each switch in the network. Then $D(r) = S(1 + B(r))$. Because it assumes infinite queues, $B(r)$ will again produce conservative results (faster transportation than reality) for high total rates $r$.

## 4.2 Steady-State Population

In the steady state of tree saturation, $N$ is the sum of the number of red messages $n_i$ at each network stage (we count stages from 0, starting at the stage closest to the sinks):

$$N = \sum_{i=0}^{S-1} K^i \times (K + q) \times mix_i$$

at stage i, and one of them is the hot sink, the fraction above follows.

If we substitute back into the expression for $mix_i$, substitute the original expression for $R$, and simplify, we obtain

$$mix_i = \frac{Hp + 1}{Hp + K^i}$$

where $H = h/(1 - h)$, the ratio of hot to cool packet generation.

Finally substituting back into T, with slight simplification, we get

$$T = \frac{\left((K + q)\sum_{i=0}^{S-1} K^i mix_i\right) - S(1 + B(r))}{Rp - 1}$$

## 5.0 Simulation

To verify the above model, we ran simulations of the situation described above for a number of cases. These results are plotted with the analytical predictions in Figure 2 through Figure 4.

The switches simulated had two non-standard characteristics that match those of [6], and serve to make the simulated network act more like the ideal network modelled:

1. Each output queue can simultaneously accept $K$ messages in one time unit. While fairly realistic for $K = 2$, this is undoubtedly unrealistic for larger switches.
2. Each input port to a switch has an additional one-message lookaside buffer that is not counted in the queue size. This allows the queues to be more fully utilized, since without it there must be $K$ empty positions in every queue of a switch for any of the switch's predecessors to be enabled to send messages. This is the source of the additional $K$ buffers per switch that was included in the prior analysis.

A complication arose in deciding what to measure as the time at which the switch reaches saturation. Our formula effectively assumes that all the queues in the saturated tree fill up simultaneously, and this is clearly not the case. What we did was find, from the simulations, the average red message occupancy of the queues in steady-state tree saturation. Then the time to saturate was taken to be the time at which 80% of that steady-state value was reached. 80% was chosen because at approximately that value there is a single message slot unused in each queue.

All plotted points are the means of 200 simulation runs each.

## 6.0 Results

A surprisingly short amount of time is required to reach tree saturation.

Figure 2 shows the time to tree saturation as a function of the initial uniform background rate $r$ for values of $h$ ranging from 0.125% to 16% in factors of two. It assumes a 64-way Omega network where each 2-way switch has queues of size 4. The time unit is not $T$ as derived above, but rather $T/S$, the minimum time required for a message to traverse the switch in one direction; in our formulation, that equals the the depth of the network. This unit was chosen for two reasons: First, it allows meaningful comparison across different network and switch sizes; it turns out that, when expressed in this unit, the time to saturate is relatively constant across network and switch sizes (10-50, for 4 element queues). Second, in a shared memory system, it is typically comparable to the time required to execute a single instruction in a processor. (It is not identical to the time required to perform a complete memory reference; that time includes two trips across the network—request and reply—as well as memory access time and other delays.)

The dotted lines at the top of the figure mark the minimum background rate below which each plotted hot spot rate will not cause tree saturation; this is equivalent to the maximum rate sustainable with the associated hot spot rate. Thus the graphs can be interpreted as follows: Pick a given initial background rate (point on the lower axis). Proceed vertically to the curve corresponding to the hot spot rate of interest. The time that curve indicates (shown on the vertical axis) is the amount of time required for that hot spot rate to drive the network throughput from the initial rate to the asymptote associated with the hot spot rate (dotted line).

Figure 3 shows the same information, but in this case for a 256-port network with 4-way switches. Figure 4 shows the predicted results for a large (1024 port) network; this was not simulated. As can be seen, the onset time is very short.

As can be seen, our predicted results match the simulated results reasonably well except for two situations: very high $r$ in the 256-port network; and very low $r$ in the 64-port network. At high $r$ in the 256-port network we are pushing the actual maximum capacity of the network and would expect all the approximations we are using to break down. At low $r$ in the 64-port network, there is a breakdown in our assumptions about total arrival and departure rates: Onset is a more diffuse process with more time for complex internal feedback effects. However, in this case our estimates are on the optimistic side.

## 7.0 Recovery Time

Figure 5 shows the throughput of a 64-way network as a hot spot of 16% is applied and then removed within a total background rate of 0.4. As can be seen, the recovery time is substantially longer than the onset time. A rationale for this follows.

Intuitively, many sources "cooperate" to saturate the tree; but only one sink (the hot one) operates to eliminate saturation. The time to recover "normal" traffic flow should be related to the time to remove all red messages from the switch after the sources stop generating them. If the hot output port runs at the maximum rate (unity), this time is simply equal to the steady-state count of red messages $N$ during tree saturation, derived previously. This is longer than the time to saturation, since the onset time $T$ is $(N - D(r))/(Rp - 1)$. One might imagine that after a time $2mix_{S-1}N/K$, for K-way switches, all the switches closest to the sources would be clear; so after that time, $1 - 1/K$ of the traffic would resume its normal rate. Then after an additional time equal to $2mix_{S-2}N/K$, $1 - 1/K^2$ of the traffic will resume its normal rate; etc. The slow rise of throughput shown in Figure 5 tends to indicate that something like this is occurring. However, we have not yet compared this to simulation results, and consider it unlikely to be correct, for the following reason: Until all the red packets are gone, they should tend to delay uniformly distributed messages that happen to be directed to the hot sink; and by filling queues, this will affect other messages. This may cause continued congestion even after all the red messages have left the network.

## 8.0 Discussion

The time required to reach tree saturation is distressingly short. What points of leverage can be used to improve the situation?

Increasing the switch size ($K$) actually makes the situation worse: Even when, as we have done, the units are the depth of the network—giving larger switches a large advantage—smaller switches saturate more slowly.

Increasing the queue size also helps. But the queue size is a linear factor in the total saturation time, so very large queues are necessary to make a substantial difference. E.g., to get saturation time up to the range of 100 switch traversals, queues on the order of 40 elements are needed. This is unreasonable with present technology.

The addition of redundant paths will also help, but only because the total queue storage available rises with the number of paths. So this decrease is also linear.

One thing that certainly can help is over-design, in the sense of using the network only at at traffic rates less than the rates where the expected hot spot activity will cause tree saturation. This adds significantly to the expense of the network. Furthermore, at present there is little experience available to define exactly what degree of non-uniformity to expect in general.

As discussed in [6], "combining" of identical messages within the switch nodes themselves can eliminate the problem completely. However, combining only works when the the hot spot is caused by references to identical entities at the sinks (e.g., identical memory locations).

When the hot spot occurs because many sources are accessing many different entities that happen to occupy the same sink, combining cannot help. What may help in that case are techniques to ensure that non-identical references are scattered uniformly among the destinations, such as the combination of interleaving and randomization used by RP3 [5]. How well this will work in practice is not yet known; if it does, simultaneously using both this technique and "combining" (also present in RP3) may solve the problem, at least for shared memory systems. It is not obvious at this time how to solve the problem for systems based on other computational models.

Global control over routing can avoid the problem completely, of course, as discussed in [6].

To summarize:

1. Very little perturbation, over a very short time, can drastically reduce network throughput.
2. Recovery after the perturbation takes much longer than than the onset of the problem.

This leads to the conclusion that multistage networks with distributed routing are unstable under non-uniform traffic loads, in the sense that they tend to "fall into" tree saturation easily. For large networks in particular, e.g., networks of size 512 or greater, if stringent measures are not taken to maintain a uniform traffic pattern, swift onset and slow recovery makes it very probable that at least partial tree saturation will always be present; and thus large multistage networks may not perform anywhere near as well as has previously been predicted.

## Abstract

Concurrent requests to a shared variable by many processors on a shared memory machine can create contention that will be serious enough to stall large machines. This idea has been formalized in the "hot spot" traffic model [PfNo85], where a fixed fraction of memory requests is for a single shared variable. "Combining," in which several requests for the same variable can be combined into a single request, has been suggested as an effective method of alleviating this contention. The NYU Ultracomputer [GGKM83] and the IBM RP3 [PBGH85] machine use "pairwise" combining, in which only two requests for the same variable can be combined at a switch. We study the effectiveness of combining. In particular, it turns out that pairwise combining cannot handle hot spots if the machine size is large enough. We suggest ways to overcome this weakness.

## 1. Introduction

The popularity of shared memory parallel computers, where processors and memory modules are interconnected through a multistage network, can be seen in several current projects, including the University of Illinois Cedar machine [GKLS83] [KDLS86], the NYU Ultracomputer [GGKM83] [EGKM85], and the IBM RP3 machine [PBGH85]. Sharing the memory in a parallel computer suggests that there is a possibility of many processors requesting the same variable at the same time (*concurrent requests*). This can create congestion in a machine, and the congestion becomes more serious as the number of processors in the machine (*machine size*) increases. To reduce congestion, when several requests directed at the same shared variable meet at a switch, they can be combined into a single request, which is forwarded toward the shared memory. When the response from the memory returns, the switch satisfies all of the requests, one at a time. The idea of reducing the congestion in this way, known as "combining," has been suggested as an effective way of allowing concurrent requests to a common location; combining can be found in the Columbia CHoPP [SuBK77], the NYU Ultracomputer, and most recently the IBM RP3 machine. (See [KrRS86] for a general discussion of what types of memory requests can be combined.)

Pfister and Norton [PfNo85] suggested that the effectiveness of combining could be studied with the "hot spot" traffic model: a fixed fraction of the total memory traffic is concurrent requests to a single shared variable. Hot spots capture the effect of all of the processors continually accessing a common variable. Pfister and Norton argue that hot spots will seriously degrade the performance of any machine that lacks combining, and that this effect is quite general. They also discuss how well the hot spot model captures reality.

In this paper, we study the effectiveness of several different combining schemes. In particular, we will see that the pairwise combining scheme used in the NYU Ultracomputer and in the IBM RP3 machine is not powerful enough to handle hot spots. We suggest ways to modify their designs in order to overcome this weakness.

## 2. The Model

There have been many studies on the performance of multistage interconnection networks for processor-memory connection (see [Sieg85] and the references therein). One common traffic model for these studies is: A stream of memory requests from each processor is an independent, identically distributed random process; each processor's requests are uniformly distributed to all of the memory modules. This *uniform* traffic model does not capture the effect of traffic with requests to a single shared variable. To represent such traffic patterns, we use the *hot spot* model [PfNo85]: each request has a (finite) probability $q$ of being headed to the same shared variable. The hot spot model is *nonuniform* in the sense that the requests are not uniformly distributed onto the memory modules. There are two types of request streams: the *noncombinables*, which are uniformly distributed to the memory modules as in the (usual) uniform model, and the *combinables*, which are headed to the same shared variable (and hence the same memory module).

We consider a buffered square banyan network [GoLi73] as the multistage network for interconnecting the processors and the memory modules. Square banyan networks include Omega networks [Lawr75] and Delta networks [Pate81]. (For details and general characteristics of multistage networks, see, for example, [Feng81], [KrSn82], [Sieg85].)

A network is composed of $n$ stages of $2 \times 2$ (crossbar) switches with FIFO queues (i.e. buffers) at each output port. We assume that the network is packet-switched and synchronous, so that packets can be sent only at times $t_c$, $2t_c, \cdots$, where $t_c$ is the *network cycle time.* Without loss of generality, we assume $t_c = 1$. We make the following further

This work was supported in part by the National Science Foundation under Grant No. US NSF DCR84-10110, and the U.S. Department of Energy under Grant No. US DOE DE-FG02-85ER25001. Part of this work was done while the second author was at the University of Illinois.

0190-3918/86/0000/0035 $01.00 © 1986 IEEE

assumptions:

- Each request is a single packet.
- Each queue can accept at each cycle up to two distinct requests, one from each input port. If at some cycle a queue has only one free location and two requests are directed to it, the queue randomly accepts one of the two (the other request remains on the queue of the previous stage).
- The enqueuing process of a request and the dequeuing process are overlapped (i.e. while the request in front of the queue, if there is one, is being removed, other requests can be inserted onto the queue).
- The service time of a request in a queue is the same as the cycle time. So, the delay of a request at a switch is the number of requests ahead of it in the queue.
- Each processor has an infinite queue for requests. If a request is blocked from entering the first stage it is placed on the queue, and the processor continues issuing requests.

A square banyan network has a complete tree leading from the processors to each memory module (Figure 1). The tree that combinable requests traverse will be called the *fan-in tree*. Our main concern is with the average queuing delay in the fan-in tree.

*Combining* works as follows: When several combinable requests meet at a switch they are combined into a single request, which is forwarded toward the shared memory. A record of this is kept at the *wait buffer*. When the response from the memory returns, the switch satisfies all of the requests, one at a time (and the record is removed from the wait buffer). To concentrate our attention on queuing delays, we assume in Sections 2-6 that wait buffers have infinite size. Also, we will consider the delay of a request only from the processors to the memory modules, temporarily ignoring the delay on the return trip. Section 7 considers finite wait buffers, and their effect on the delay of a request in both directions of the network.

We will distinguish queue size and queue length. *Queue size* is the number of requests a queue can store at one time. We use *infinite queue* to mean that the queue size is infinite, and *finite queue* to mean that the queue size is finite. *Queue length* is the number of requests stored on a queue at some particular time. We will use equivalent definitions for wait buffer size and wait buffer length.

We consider several different combining schemes. In each case, we will consider what happens both with finite queues and with infinite queues. Infinite queues provide a nice yardstick to compare the more practical finite queue schemes. For finite queues, unless otherwise specified, we will always consider queue size four. This is large enough so that for the traffic loads considered, the performance under uniform traffic is almost as good as with infinite queues.

A network is *stable* if in steady state average delays in the network are uniformly bounded. This is an important property of a network. Under the *uniform* traffic model, buffered multistage interconnection networks are generally believed to be stable for "light" traffic (see [KrSn83],[KrSW86]).

We assume that at each cycle each processor issues a request with probability $r$, i.e. $r$ is the rate of requests. Each request has probability $q$ of being a combinable request. Let $r_c$ be the rate of combinables (i.e. hot spot requests), and $r_n$ be the rate of noncombinables. Then

$$r_c = qr \qquad \text{and} \qquad r_n = (1-q)r \ .$$

Let $r^i$ be the rate of requests at the stage $i$ of the fan-in tree ($r^0 = r$). Let $r_c^i$ and $r_n^i$ be the rate of combinable requests and noncombinable requests, respectively, at the stage $i$ of the fan-in tree ($r_c^0 = r_c$ and $r_n^0 = r_n$).

## 3. No Combining

In this section we will consider the performance of systems without combining. It is obvious that the combinables will create congestion in the network. The question is, how much will this degrade performance?

### 3.1. Infinite Queues

Assume the queues have infinite size and there is no combining. Recall that the rate of requests at the first stage is $r_n = r(1-q)$ and $r_c = rq$. Since there is no combining, the rate of combinable requests keeps doubling at each stage approaching the root of the fan-in tree. In particular, the rate of requests at stage $i$ will be

$$r^i \ = \ r_n + 2^i r_c \ .$$

For any finite value of $r_c$, after several stages, the requests will be arriving at each queue at a greater rate than the queue can forward them. Networks large enough to see this effect will be unstable. For example, consider the case of $r = 0.25$ and $q = 0.01$. Even with $q$ so small, by the ninth stage the arrival rate of the combinables alone will be $r_c = 1.28$, so the queuing delay will be unbounded.

In practice one expects short intensive periods of "hot spot" contention. If there are not too many stages of the fan-in tree in which the rate of requests is greater than one, the system may still provide acceptable performance. Only the combinable requests will suffer extraordinary delays, along with the relatively few noncombinable requests traversing the fan-in tree near its root.

### 3.2. Finite Queues

With finite queues the situation is worse. Pfister and Norton [PfNo85] noticed a very interesting phenomenon they call *tree saturation*. When the queue at the root of fan-in tree becomes full, the two queues feeding it can no longer send requests to it. They too will become full and stop the four queues feeding them from sending requests. Eventually the entire fan-in tree will consist of full queues. All of the queues at the same level of the fan-in tree can together satisfy combinables only at the same rate as the root satisfies them. In other words, at the $i$th level from the root, each queue can satisfy combinables only at a rate $1/2^i$ as fast as the root does. So, although each queue at this level has on average only $1/2^i$ as many combinables as the root, with respect to combinables the queues are not progressing any faster. Thus, progress of the whole system is governed by the service rate at the "hot spot"; noncombinables will suffer delay proportional to the queue size on each stage of the fan-in tree traversed.

Kumar and Pfister [KuPf86] have observed that a relatively short period of hot spot contention will produce tree saturation. Furthermore, after the processors stop issuing hot spot requests, the network takes a long time to return to normal.

## 4. Pairwise Combining

Ideally, one would like to combine all of the combinables that reside concurrently on a queue. This, however, makes the combining process complicated, and also creates congestion at a wait buffer when the response returns from memory. To simplify the combining process and to avoid contention at the wait buffer, the NYU Ultracomputer and IBM's RP3 machine support combining only a pair of requests at a switch. This section studies the effectiveness of such *pairwise* (or *two-way*) combining.

### 4.1. Infinite Queues

We did simulations to check the effectiveness of pairwise combining with infinite queues. Our concern is whether congestion at the hot spot still occurs. (Recall that $r_c^i$ is the traffic load of combinables from each input port of a switch at stage $i$ of the fan-in tree.) In our experiments, $r_c^i$ increased rapidly until $r_n + r_c^i$ reached 1.0 (see Figure 2). This shows that with pairwise combining and infinite queues large networks are unstable.

The reason for congestion even with combining is that a combinable request does not always encounter another combinable request to combine with. Whenever a combinable request does not combine, it will be added to the traffic of the combinables coming out of the queue. Thus, the rate of combinables will necessarily increase towards the root of the fan-in tree. It is conceivable that this rate approaches some limit less than $1\text{-}r_n$, in which case the network would be stable. However, our experiments show this simply does not happen: the rate of combinables increases without bound.

### 4.2. Finite Queues

It may seem *a priori* that finite queues will always provide worse performance than infinite queues, since infinite queues have more storage capacity. However, this is not necessarily so: Suppose at stage $i$ of the fan-in tree, a queue becomes full. Then, the two queues at stage $i$-1 of the fan-in tree feeding this queue will become blocked (at least for requests destined to the full queue). This will increase the chances of these two queues becoming full, thereby blocking the queues at stage $i$-2 that feed them, and so on. Thus, if the rate of requests is large enough to create congestion at the root of the fan-in tree, the whole fan-in tree will tend to become congested. The overall affect on a message traversing the fan-in tree will be that its total delay will be fairly large at every stage, which contrasts with infinite queues where the delay is large only near the root. This means that combinables will spend more time near the leaves of the fan-in tree, and therefore have more chance of combining near the leaves. This will reduce the traffic rate of combinables which in turn will improve the overall performance of the network. (Recall that with pairwise combining, if a combinable traverses a stage without combining, it increases the rate of combinables for all later stages.)

We performed simulations on networks of nine stages with finite queues and pairwise combining. The queue size was assumed to be four. For the traffic of $r = 0.6$ and $q = 0.1$, we observed tree saturation: the average waiting times at each stage of the fan-in tree was approximately equal to the queue size. Waiting times of requests at each processor's queue seem to increase without bound as the number of network cycles simulated increased. Although we did not observe tree saturation for lower traffic loads, we expect that it would occur in larger machines. (See Figure 3.)

Since the probability of combining increases as a combinable request stays in a queue longer, larger sized queues should help combining, which in turn can help avoid tree saturation. One might think that the tree saturation reported here conflicts with the results of Pfister and Norton [PfNo85], where pairwise combining was effective in handling hot spots with queue sizes of only four. Although there were some minor differences in our two models, which could account for the different results, the main difference was that they were simulating a network with only six stages. We believe that adding a few more stages to their network would produce tree saturation and make their network unstable. Minor changes in switch design cannot overcome the inherent weakness of pairwise combining, at least not without making the delays at each stage of the fan-in tree unacceptably long.

## 5. Unbounded Combining

*Unbounded combining* allows any number of combinables to be combined into a single request at a queue. Although the combining of the Columbia CHoPP is very similar to unbounded combining, our study is not directly applicable CHoPP because of its "repetition filter memory", which allows the combining of incoming requests with requests already in the wait buffer.

We have done extensive simulations of networks with infinite queues and unbounded combining. The networks seem to be stable and provide reasonable delay irrespective of the machine size and the traffic load. The traffic of the combinables adds only slightly to the average queuing delay of the noncombinables alone. It seems that unbounded combining eliminates the contention on the fan-in tree because there can be at most only a single combinable request waiting in a queue at any given time.

Simulations show that with unbounded combining, finite queues provide only slightly larger delay than do infinite queues. When compared to infinite queues, delays are just about the same at the first few stages and slightly larger at all the later stages.

## 6. Bounded Combining

We have so far considered two extreme combining schemes: unbounded combining and pairwise combining. Unbounded combining provides good performance, but seems to be expensive (even to approximate); pairwise combining suffers from tree saturation, but is *relatively* easy to implement. We suggest a compromise scheme, *bounded* combining, where more than two, but at most a predetermined constant number of, combinables can be combined into a single request at a queue; in *k-way* combining the bound is $k$. Bounded combining is easier to implement than unbounded combining; the hope is that it will provide approximately the same performance. The question is, how large does $k$ have to be?

In the experiments with unbounded combining, we observed that a combinable request coming out of the switches at the later stages represents on average only slightly more than two combinables. This suggests that *three-way combining,* i.e. at most three combinables can be combined into a single request at a queue, will be effective. Simulations show that three-way combining performs almost as well as unbounded combining for both finite and infinite queues (see Figure 4). This indicates that pairwise combining may be slightly too restrictive with respect to the number of combinables it supports.

## 7. Wait Buffers and Return Queues

Up until now we have considered the delay of a request only from the processors to the memory modules. For the return trip, there must be two *return queues* exiting each switch passing responses from the memory modules towards the processors. The performance of a network will be sensitive to the size of these return queues. We have assumed that the size of wait buffers is infinite. This is unrealistic in practice. The wait buffer size is an important factor for good performance, because combining cannot take place if the wait buffer is full.

A combining of $k$ requests is represented as $k$-1 pairwise combinings, i.e. it uses $k$-1 wait buffer locations. When the response returns from memory, all $k$-1 locations are immediately freed and the $k$ response messages are placed on the return queue.

This section considers the effect of wait buffer size and return queue size on queuing delay. Our main concern is to determine the proper size of wait buffers and return queues for three-way combining to obtain performance close to that of unbounded combining with infinite return queues and infinite wait buffers.

### 7.1. Infinite Queues, Returns Queues, and Wait Buffers

To get an idea of the appropriate size of wait buffers, we measured the average length of the buffers assuming infinite queues, return queues, and wait buffers. Although the unbounded and three-way combining schemes avoid congestion by inserting more combinables into the buffer at a time than pairwise combining, our simulations show that the average length of the buffers with pairwise combining is actually unbounded while it is quite moderate with three-way combining (see Figure 5). The reason for this is that the average length of the buffers is proportional to queuing delays.

Suppose combining takes place in a switch at stage $i$ of an $n$-stage network. Then, a record of the combining will remain in the wait buffer until a response from the memory arrives at the switch some time later. So, the average length of the wait buffer is determined by the average number of combinings and the average number of cycles until the memory responds. Let $c_i$ be the average number of combinings per cycle at the switch and $t_i$ be the average response time from memory (to the switch) for a combinable request. Then, the wait buffer is a queuing system with arrival rate $c_i$ and service rate $1/t_i$. The arrival rate $c_i$ is determined by the traffic load and the position ($i$) of the switch in the network. The service rate is determined by the queuing delays at stage $i$ and later stages. Given fixed traffic load and fixed network size, the average length of the wait buffer will be unbounded if there is severe enough congestion at later stages for $c_i \geq 1/t_i$.

Since the service rate $1/t_i$ is smaller for switches closer to processors, one may worry about the average length of the wait buffers at earlier stages. However, this is counterbalanced to some extent by the fact that there is less contention in the earlier stages so that fewer combinings take place. Notice that the wait buffer lengths become unbounded as the network size increases, for any fixed arrival rate $c_i$ at the wait buffer, irrespective of the combining scheme. The wait buffer size needs to grow with the network size.

### 7.2. Finite Queues, Return Queues, and Wait Buffers

To see the effect of small wait buffer sizes, we did simulations with queues of size four, infinite return queues, and wait buffers of size six. As can be seen in Figure 6, three-way combining with "small" wait buffers performs as badly as pairwise combining does. The reason is that the buffers at the later stages are almost always nearly full, and three-way combining effectively changes to pairwise combining.

To see the effect of small return queue sizes, we did simulations with queues of size four and infinite wait buffers. It turns out that, for three-way combining, return queues of size four are not large enough to provide good performance. This may seem surprising, since (forward) queues of size four are sufficient, and the responses are just returning along the same path that the original request traversed. The reason is that on the return path combinables are returning in bursts, since a combinable response can split into two or three responses. Thus, each return queue in a switch is effectively a queuing system with the same traffic intensity as the (forward) queue in the same switch, but with fewer, larger-sized packets. The former system will provide worse performance and require larger queue sizes (see [KrSW86]). With three-way combining, return queues of size of ten obtained approximately the same performance as infinite return queues.

In our experiments for moderate traffic loads, return queues of size ten and wait buffers of size fifteen seem to be large enough to obtain performance close to that of unbounded combining with infinite sized queues and wait buffers (see Figure 7). Neither return queues of size eight and wait buffers of size fifteen nor return queues of size ten and wait buffers of size ten produced good performance.

## 8. Conclusion

Shared memory machines have the potential of congestion due to concurrent requests to a shared variable. Since hot spot contention becomes more serious as the machine size grows, congestion can severely degrade the performance of "large" machines. To avoid potentially serious congestion, pairwise combining was suggested in the NYU Ultracomputer and IBM RP3 machine as an effective way of eliminating congestion.

We studied the hot spot traffic model, where a fixed fraction of the total memory traffic is for a single shared variable. As observed by Pfister and Norton [PfNo85], large networks with finite queues and no combining suffer from tree saturation. With finite queues, even pairwise combining has the potential of tree saturation creating unbounded delay no matter how "light" the traffic load is, for large enough machines. If hot spots are a real-life phenomenon, pairwise combining as suggested for the NYU Ultracomputer and the IBM RP3 machine is too restrictive. Three-way combining resolves the congestion. It remains to be seen whether three-way combining can be realized efficiently in hardware.

A combining network must be carefully balanced. There are many parameters: the network size, the boundedness of the combining, the queue size, the wait buffer size, the queue size on the return path, etc. It is not obvious how any particular choice of these parameters will behave. For example, we have seen that changing finite queues to infinite queues, which one might expect would improve performance, can actually degrade performance.

One must be very careful in interpreting our results. We do not believe that processors are likely to concurrently access the same shared (synchronization) variable for extended periods of time. If hot spots are only transient, i.e. if there are short, intensive periods of hot spot contention, pairwise combining may very well combine enough to provide acceptable performance. One might consider the (steady state) hot spot model suggested by Pfister and Norton to be a conservative worst case scenario.

We have restricted our attention to square banyan networks composed of 2×2 switches, and to messages of length one. We believe our results generalize to other network topologies, other switch sizes, and other message size distributions. Any interconnection network will have to have a tree, maybe implicitly, leading from every processor to any given memory module. This will create the possibility of tree saturation when there are hot spots, but also the opportunity for combining. With $k \times k$ switches, it seems that $k$-way combining is not enough; some fraction slightly higher than that will be necessary. Longer messages seem to increase the amount of combining, but not enough to avoid tree saturation with only pairwise combining.

## Abstract

This paper examines the issue of shared memory emulation for performance prediction of applications running on multiprocessors. It emulates memory contentions of different target multiprocessors on a given multiprocessor. This approach provides not only the average performance measures, but also the instantaneous values of memory contentions which are essential to find bottlenecks of user's application programs.

An algorithm producing an exact emulation result is presented and its implementation trade-off is discussed. To solve these problems, a heuristic approximation approach is introduced. Experimental results on a uniprocessor system show the approach gives a reasonable accuracy. In order to alleviate the emulation overhead, parallel implementation of the algorithms is investigated.

## 1. Introduction

With the advent of commercial parallel processors we enter a new era of proliferation of parallel computation models for problem solving. One of the known characteristics of such endeavors deals with the nonlinear performance behavior of parallel programs with respect to the speed-up ratio as a function of the number of processors. As it is practically and economically not attractive to build a new parallel processor each time we may want to evaluate a parallel application on a new architecture with a different number of processors, emulation techniques are employed. Such techniques are likely to generate a ratio of 50,000 to 100,000 per one multiprocessor instruction step. Hence, the emulation process itself has to be executed in parallel on a multiprocessor.

As we look closer at the nature of this emulation, one can see that multiprocessor systems share some of their resources such as memories, buses and I/O devices to facilitate parallel access. Sometimes, an access to a shared resource has to be serialized because the shared resource may be occupied by another access. This situation is called *contention* and is related to all of the shared resources. The more processors a multiprocessor system has, the more accesses it requires in unit time, so the probability of contentions is increased accordingly. In general, due to the contention phenomenon mentioned above, the performance of an application will not be improved linearly with the number of the processors.

A practical approach to this issue is an emulation facility running on a host multiprocessor and emulating bus and memory contention of another multiprocessor. When contrasted with the performance modeling methods, the emulation method provides, aside from better accuracy, instantaneous performance profiles. The performance modeling provides, in general, statistical average performance profiles which are insufficient to accurately indicate detailed user application performance bottlenecks.

In this paper we are exploring the problem of emulating shared memory multiprocessors on shared memory multiprocessors, as well as indicating and evaluating algorithms for achieving this proposed goal.

## 2. Basic Structures

### 2.1. Memory Access Model

First, we define the memory access mechanism of the *target* multiprocessor. The multiprocessors we want to emulate are shared memory multiprocessors. In this system, global memories and processors are connected by a shared bus. These memories are divided into several banks, called *memory modules*. Access requests are transmitted from each processor to the destination memory module through the shared bus. Then, read/write operation is taking place with results returned from/to the memory module.

Because there are more than one processor and each bus/memory can accept only one request at each cycle, an access request may have to wait if bus or destination memory is servicing another request.

### 2.2. The Emulation Problem

Suppose we have a *host* multiprocessor system with *P* processors. An user of this system may want to know how much performance improvement of the user's program will be gained if there are more processors in this multiprocessor system. The purpose of the emulation facility is to provide such a *virtual* multiprocessor system within the *host* multiprocessor system. More specifically the goal and the problem can be defined as follows;

**The goal:**

> Performance prediction for applications running on a *target* multiprocessor when the number of processors are larger than that of the *host* multiprocessor. We are interested in the instantaneous

[a] Visiting Scientist from Hitachi Ltd., Tokyo, Japan.

values for the performance vector.

**The problem:**

1. Emulation of bus and memory contention for a shared-memory shared-bus multiprocessor.

2. Do step 1 using a multiprocessor with a fixed number of processors.

If we consider $N$ processes ($N > P$), each of which is to be assigned to each of $N$ processors of the *target* multiprocessor system, they can not be executed at once on the $P$ processor multiprocessor system. Therefore we adopt a *divide-composite* approach to this problem. The emulation algorithm proposed here consists of the following three steps;

1. **Divide** $N$ processes $PROC_1 \cdots PROC_N$, which are to be assigned to $N$ processors of emulated multiprocessor, into $K$ groups $Q_1 \cdots Q_K$, each group has $P$ processes. That is:

   $PROC_1 \cdots PROC_P \rightarrow Q_1$
   $PROC_{P+1} \cdots PROC_{2P} \rightarrow Q_2$

   $PROC_{(K-1)P+1} \cdots PROC_N \rightarrow Q_K$

2. **Execute** $P$ processes in each group on the $P$ processors for a certain fixed time span $T$. During execution construct the *memory access profile* consisting of time stamp, process id and memory module id. (See Fig. A) The data collection mechanism will be disussed in Section 3.

3. **Composite** memory access profile for multiprocessor of $N$ processors from $K$ individual profiles of $Q_1 \cdots Q_K$. (Also see Fig. A) This is done by eliminating bus/memory contentions among groups. Details of this part will be explained in Section 4.

Step 2 and 3 are iterated until all processes are terminated.

### 2.3. Related Works

Several performance prediction methods based on statistical models have been discussed elsewhere. [1]- [3] In these methods, distribution of memory requests is assumed to be a statistical distribution and fixed all over the period. Statistical models are quite useful for general case analysis of multiprocessor systems and when performance averages are sufficient, however application programmers may want to know the performance of their own programs rather than of the generalized program, as well as the instantaneous values of the performance measures in order to deal with performance bottlenecks.

The purpose of our research is to provide application programmers a way of performance prediction for their programs. Memory access distribution of such programs will vary time to time and process to process, and these irregularities will cause adaptability problems for statistical models. Alternately, we present an emulation mechanism for memory contention. The novelty of this work is related to the availability of instantaneous values for contentions for a specific user application, as well as the use of a multiprocessor for emulating a multiprocessor.

## 3. Data Collection Mechanism

Since the *memory access profiles* have to be constructed in parallel with the execution of a user's application program, the data collection procedure should be performed without affecting the application program. Toward this end, a hardware sensor which is transparent from the user's program is preferable to its software counterpart. If memory access data is collected by a software sensor, the overhead time for the sensor may disturb the execution of the application program and the emulation result will be different from the exact solution.

## 4. The Composition Algorithm

In this section we will present two versions of algorithms, the first is simple and produces an exact emulation, however it requires an infinite memory space. The second one is a modified version of the first algorithm which can be implemented within a bounded memory space. However, it provides an approximation of the problem.

### 4.1. The First Algorithm

Compared with the bus and the memory access, the bus cycle is the shortest of the two. Accordingly, we will consider the bus cycle as the unit of time; we call it *time slot*. Intuitively, the algorithm goes on as follows (see also Fig. B as an example):

At first, read $K$ profiles into memory. These profiles are constructed during execution phase and stored somewhere.

At time slot *1*:

- Accesses of time *1* (in Fig. B, "a","e" and "i") in those profiles are considered as candidates.
- Select one ("a") from the candidates and have unselected accesses ("e" and "i") wait for the next slot.

In general at time slot $t$:

- Accesses which are not selected in the previous stages and accesses which have time stamp $t$ are considered as candidates (for example, at time *3* "i","f","b" and "j" are candidates).

- For each candidate, check whether it is ready to be requested by the process. This check is done by seeing the time slot when the latest access of the process was accepted.

- Also check whether the destination memory module is ready to accept it by comparing memory cycle and the access interval.

- Select one from the candidates which passes the above feasibility check and have others wait for the next time slot.

- Each candidate has priority for selection. Priority is based on the group to which it belongs and the original access time stamp. Priority on groups is dynamically changed to emulate round robin strategy of multiprocessor system.

After the time slot $T$ (end of cycle):

- We have a composite profile of length $T$ and a set of accesses which are not yet selected, called *overflows*. To proceed to the next time slot ($T+1$), memory access profiles for the next cycle are needed because some accesses in the next cycle can be performed in the next time slot. So, *overflows* are combined with the memory access profiles of the next cycle and considered as the input for the next cycle. In Fig. B, access "l" and "m" are overflow accesses of the first cycle ($t = 1 \cdots T$) and should be considered as candidate accesses at the top of the next cycle ($t = T+1$).

Continue the above procedure for the next cycle ($t = T+1 \cdots 2T$) and so on.

### 4.2. The Second Algorithm

Although the algorithm described in the previous section is straightforward and produces exact emulation result, we should do some modifications when its computer implementation is considered.

At the end of every cycle($t = T, 2T \cdots$), we have a set of *overflows*. The amount of overflows can be estimated by the difference between the number of access requests (*Req*) and the capacity of the shared bus (*Cap*) when $Req > Cap$. The overflows should be added to the requests for the next cycle. When *Req* and *Cap* are constant over cycles and $Req > Cap$, we have the following relation:

$$|Overflow_j| = |Overflow_{j-1}| + Req - Cap$$

where $|Overflow_j|$ denotes the amount of overflows after $j$-th cycle. Thus,

$$|Overflow_j| = j(Req - Cap).$$

Since the above relation shows the amount of overflows grows monotonically and infinitely, the overflows will eventually become too large to keep them in memory.

To overcome this problem, we modified the algorithm so that it suspends reading the next profiles until the amount of overflows becomes smaller than the limit instead of reading them at the end of each cycle.

The modified version of the algorithm may overlook access requests because some of the access requests are not read into memory. This will cause overestimation. However, the degree of overestimation is considered to be fairly small for the following reason. At first, overflow accesses have higher priorities than accesses in the next profiles because of the *first-in first-out* nature of the selection strategy. And, the greater overflows become, the less likely it is that the next access can not be selected from overflows. This means that if we have moderate amounts of overflows, composition procedures can produce good approximation results without reading the next profiles.

## 5. Experimental Results

In order to evaluate both versions of the algorithm, we have experimented with the proposed algorithms. Since the multiprocessor system on which the emulator will run is currently under construction [4], we implemented the algorithms on a VAX 11/780 and simulated the behavior of the emulation using various simulated access profiles at different request rates generated from random distribution. The access rates of profiles are arranged to vary from time to time.

Experiment results for the case of $P = 100$ and $N = 200$ (i.e., emulating 200 processors on a multiprocessor system with 100 processors) are shown in Fig. C. In this figure, the results of the first (exact) version and modified (approximated) algorithm are indicated by circle and box, respectively. In the approximated version of the algorithm, the limit of overflows is set to $2T$ ($T$:time span).

Fig. C shows the relation between required bus access frequency, which is the total of frequencies of all groups, and resulted (composed) bus access frequency. In the ideal case, the relation between them follows the dashed line in Fig. C. However, in general, the actual relation is the dotted line below the ideal line. The maximum difference of composed access frequency between the first and modified algorithm is about 1.5%. This shows that the modified (approximated) algorithm gives a good approximation of the first (exact) algorithm.

## 6. Outline of Parallel Implementation

In this section, we discuss the implementation of the emulation algorithm in a multiprocessor. In Fig. D, the algorithm is described in a pseudo programming language. It has a triple nested loop for time slots, groups and candidate accesses in each group. Within the inner double loop each candidate access is examined as to whether processor and memory are ready for access. If more than one access are feasible at a time slot $t$, one access is selected based on the priority mentioned earlier.

Notice that feasibility check procedures for candidate accesses are mutually independent, allowing these procedures to be invoked simultaneously. The number of accesses to be checked (= the number of procedures invoked) becomes large and increases in proportion to the number of emulated processors. However, if candidates are allocated to the processors in the descending order of their priorities, unnecessary check procedures can be suppressed. Simultaneous feasibility check and priority-based processor allocation will make the check procedure work within a small number of iterations and also will make the algorithm work nearly in proportion to the length of time regardless of the number of emulated processors.

The experimental program on a uniprocessor (VAX 11/780) takes about 20*sec.* to compose two memory access profiles of 1 *ms*; that is, emulation time / execution time ratio is 20 *sec.* / 2x1 *ms* = 10,000. But, from the above discussion, we can expect high performance gain when the algorithm is finally implemented on a multiprocessor. Basically, search processes can run concurrently if they belong to the same time slot, and, even if they belong to a different time slot, they can run in parallel under the control of shared variables. If, for example, we implement the algorithm on a multiprocessor with 100 processors and gain 50 times performance gain, then the emulation overhead will be alleviated to 10,000 /50 = 200.

## 7. Conclusion

In this paper, we have presented two versions of a shared memory emulation algorithm for multiprocessor systems. The first algorithm can emulate exactly but requires an infinite amount of memory. Then, we modified this algorithm to eliminate this implementation problem. The modified version requires a finite amount of memory and experiment results show that the modified algorithm can be a good approximation for the the first algorithm. Also, the algorithm proposed here is suitable for parallel processing.

# BEHAVIOR OF THE BUTTERFLY$^{TM}$ PARALLEL PROCESSOR IN THE PRESENCE OF MEMORY HOT SPOTS

Robert H. Thomas

BBN Laboratories Incorporated
Cambridge, MA 02238

**Abstract** – – This paper describes a set of experiments designed to measure the behavior of the Butterfly Parallel Processor in the presence of memory "hot spots". The experiments were motivated by a paper by Pfister and Norton [3] that reported results from simulation studies on multistage switching networks for shared memory parallel processors. Their results indicated that, for machines with a large number of processors, very slight non–uniformities in memory reference patterns can lead to severely degraded performance for the entire machine, including processors that avoid referencing the hot memories. The results were explained in terms of a phenomenon called "tree saturation" where traffic to the hot memories backs up into the switch and interferes with other switch traffic. The experiments reported here show that those results do not generalize to the Butterfly Parallel Processor. The access time for a memory that contains a hot spot is degraded, but the presence of the hot spot has little effect on the performance of programs that avoid the hot memory. Furthermore, tree saturation does not occur in the Butterfly Switch.

## INTRODUCTION

This paper describes a set of experiments that measure the behavior of the Butterfly Parallel Processor [2] in the presence of memory "hot spots". The experiments were motivated by a paper on memory hot spots by Pfister and Norton [3] that presented results of simulation studies of the switching network for RP3, a research parallel processor being developed at IBM Yorktown Heights.

The simulation results showed that non–uniformities in memory reference patterns, which make certain memories "hot", can have a devastating effect on the performance of an entire machine, including processors that avoid referencing the hot memories. Pfister and Norton explained their results in terms of a phenomenon called "tree saturation", where traffic to the hot memories backs up into the switch and interferes with other traffic, including that to non–hot memories. Their results indicated that for machines with a large number of processors (>=100) even slight non–uniformities in reference patterns can lead to tree saturation and severely degraded performance for the entire machine.

Pfister and Norton claim generality for their results, stating that they apply to all multistage blocking networks. Furthermore, their paper claims that attempts to avoid the problem, such as providing multiple paths through the network, do not really help. Finally, the results are used to motivate the use of a second, combining switch in the RP3 architecture.

The switching networks studied by Pfister and Norton were multistage shuffle exchange switches similar in topology to the switch used in the Butterfly Parallel Processor. However, there is one key difference in switch operation: the switches studied were "blocking", whereas the Butterfly Switch is not. In a blocking switch, when contention for an output port of a switching element occurs, the path from the source to that switching element is held until the desired output port can be obtained. When contention for an output port occurs in a non–blocking switch, the message encountering the contention is rejected (to be retransmitted later) and switch resources associated with it (i.e., the path to the point of contention) are released. When the message is retransmitted, it again competes with other messages for switch resources.

Thus, like the switches studied by Pfister and Norton, the Butterfly Switch is multistage. However, unlike them, it is non–blocking. Because the Butterfly Switch is non–blocking, the behavior of a program on a Butterfly system can be expected to be less severely affected by non–uniformities in memory reference patterns (caused either by the program itself or by other programs on the machine).

Nonetheless, obvious questions to ask are: how does the Butterfly Parallel Processor perform in the presence of memory hot spots? Does it exhibit tree saturation? Does the architecture break down in large configuration for programs whose memory reference patterns exhibit moderate or even very slight non–uniformities?

The experiments described below show that the results presented by Norton and Pfister do not generalize to the Butterfly Parallel Processor. The access time for a memory that contains a hot spot is degraded, but the effect of switch contention is very small, even when severe non–uniformities in memory reference patterns are present. The experiments indicate that tree saturation does not occur in the Butterfly Switch.

## THE BUTTERFLY PARALLEL PROCESSOR

This section presents enough information about the Butterfly Parallel Processor to understand the experiments described in this paper. More information about the Butterfly machine can be found in [2].

The Butterfly Parallel Processor is composed of processors with memory and a multistage switch that interconnects the processors. A Butterfly system can be configured with from 1 to 256 processors. One processor and memory are located on a single board called a Processor Node. All Butterfly Processor Nodes are identical. Collectively, the memory of the Processor Nodes forms the shared memory of the machine. All memory is local to some Processor Node; however each processor can access any of the memory in the machine, using the Butterfly Switch to make remote references. From the point of view of an application program, the only difference between references to memory on its local Processor Node and memory on other Processor Nodes is that remote

0190-3918/86/0000/0046 $01.00 © 1986 IEEE

references take a little longer to complete. (The typical memory referencing instruction takes about 6 microseconds when the data referenced is remote and about 2 microseconds when it is local.) The speeds of the processors, memories, and switch are balanced to permit the system to work efficiently in a wide range of configurations.

Each Butterfly Processor Node contains a Motorola MC68000 microprocessor (or a MC68020 with a MC68881 floating point co-processor), at least 1 MByte of main memory, a co-processor called the Processor Node Controller, memory management hardware, an I/O bus, and an interface to the Butterfly Switch. I/O connections can be made to each Processor Node, making I/O configuration very flexible.

The Butterfly machine supports a very efficient operation for transferring blocks of data from one Processor Node to another. The block transfer operation is implemented by Processor Node Controller microcode. Once initiated, a block transfer occurs at the full 32 MBit/second bandwidth of a path through the Butterfly Switch.

## THE EXPERIMENTS

Two experiments were conducted to measure the performance of the Butterfly Parallel Processor in the presence of hot spots. The objective of the first experiment was to time execution of a typical program, first in an environment without any hot spots, and then in one where N processors were used to generate a hot spot. A matrix multiplication benchmark program [1] was chosen. The objective of the second experiment was to determine the effect hot spots have on typical memory references by systematically measuring the behavior of the machine under non-uniform memory reference patterns. This was done by timing remote read, write, and block transfer operations for various memories, first in an environment without any hot spots, and then in an environment where N processors were used to generate a hot spot.

Hot spots were generated in two different ways:

1. Via read and write references. N processors were used to make a given memory hot by reading and writing the same location in that memory. This was accomplished by having each processor execute the tight loop:

   ```
   for (i = 0; i < count; i++)
       * hotmemp = * hotmemp;
   ```

   where *hotmemp* is a pointer (*short* *) to a location in the hot memory.

2. Via block transfer. N processors were used to make a given memory hot by using the block transfer operation to copy data from that memory to their local memories. This was accomplished by having each processor execute the tight loop:

   ```
   for (i = 0; i < count; i++)
       Do_bt (hotmemp, localp, numbytes);
   ```

   where *Do_bt* initiates a block transfer that moves *numbytes* bytes from the location beginning at *hotmemp* in the hot memory to the location beginning at *localp* in the processor's local memory.

The difference between these two methods is in the duration of the switch messages they generate. Simple read and write references use the switch in 2 microsecond bursts. Each iteration of the loop generates 3 messages, 2 for the read and 1 for the write. Block transfers are broken into 256 byte packets, each of which uses the switch in 64 microsecond bursts. Each iteration of the block transfer loop generates 2 messages for each packet, a short request message and a 64 microsecond response message.

Although all Processor Nodes in a Butterfly system are functionally equivalent, there is a distinguished King Node that is special in two ways: it is the node to which the console terminal is connected; and it controls the machine while the operating system is being booted. Because a terminal handler and window manager run on the King Node, it appears about 8%–10% slower than the other nodes to application programs. To ensure that the measurements were not affected by the processing requirements of the terminal handler and window manager, the King Node was avoided in both experiments.

The experiments were run on a 128 processor Butterfly system. When the experiments were run, 16 processors had been temporarily removed to configure several smaller systems, leaving 112 processors in the system. Since the King Node was not used, 111 processors were available for the experiments. The switch for this system has 4 columns (stages) of 4-input 4-output switching elements, and is configured to contain 2 paths between each pair of Processor Nodes.

## EXPERIMENT #1: MATRIX MULTIPLICATION

The matrix multiplication program was timed in a number of environments:

1. Without any hot spots.

2. With a hot spot generated by read and write references, using only cool memories for the matrices. That is, both the hot memory and the memories of processors used to generate the hot spot were avoided.

3. With a hot spot generated by read and write references, using both the hot memory and the cool memories for the matrices.

4. With a hot spot generated by block transfers, using only cool memories for the matrices. As in (2) above, both the hot memory and the memories of processors used to generate the hot spot were avoided.

5. With a hot spot generated by block transfers, using both the hot memory and the cool memories for the matrices.

### Data

For runs involving a hot spot, 100 processors were used to generate the hot spot. This left 11 processors with cool memories.

Matrix Size = 192x192

| | Time (seconds) | | | | |
|---|---|---|---|---|---|
| | Number processors. | | | | |
| | 1 | 2 | 4 | 8 | 11 |
| No hot memory | 65.73 | 32.73 | 16.37 | 8.22 | — |
| Hot memory - 100 processors doing simple read/write references | | | | | |
| Avoid hot memory (11 cool memories) | 66.02 | 32.97 | 16.67 | 8.47 | 6.27 |
| Use hot memory (11 cool memories + 1 hot memory) | 67.55 | 33.72 | 17.10 | 8.67 | 6.39 |
| Hot memory - 100 processors doing 768 byte block transfers | | | | | |
| Avoid hot memory (11 cool memories) | 66.07 | 33.13 | 16.62 | 8.50 | 6.25 |
| Use hot memory (11 cool memories + 1 hot memory) | 92.01 | 46.51 | 23.42 | 12.05 | 8.90 |

**Table 1: Data from matrix multiplication benchmark program.**

All runs used square matrices of size 192x192. This size was chosen because:

1. The run time for the matrix multiplication is long enough to give statistically interesting results, and short enough to run a series of experiments.
2. The matrix multiplication benchmark is written in a way that makes analysis of the results simpler when the matrix dimensions are multiples of 6 (see below).

The data obtained by timing the matrix multiplication benchmark on successively larger processor configurations for each set of experimental conditions is shown in Table 1.

## Discussion

When the matrix multiplication program avoids the hot memory, the presence of the hot spot has negligible impact on the program's performance: there is less than 1% increase in execution time. When the program uses the hot memory, the impact depends upon the way the hot spot is generated. There is a small increase in run time when the hot spot is generated by read and write references (2.76% in the single processor case) and a substantial increase when the hot spot is generated by block transfers (40% in the single processor case). Since block transfer operations keep the memory busy longer than single read and write references, this result is not surprising.

Switches for larger Butterfly machines are typically configured with alternate paths to make the machine resilient to failures in switching elements (which almost never occur) and to reduce contention within the switch. For example, as mentioned in the previous section, the switch for the 128 processor machine used in these experiments has one alternate path (for a total of two paths) between each pair of nodes. The data presented above was collected with the alternate switch paths enabled. Measurements were also made to determine the sensitivity of the timing data to alternate paths by repeating the experiment with the alternate paths disabled.

Use of alternate paths within the switch makes a small difference. When the hot spot is generated by read and write references and the hot memory is used, the program runs about 1% slower when the alternate paths are disabled. When the hot spot is generated by block transfers and the hot memory is used, the program runs about 2 1/2% slower when the alternate paths are disabled.

The following is an analysis of the program's behavior when running on a single processor in the presence of a hot spot generated by block transfers. It shows that the increase in execution time is due almost entirely to the increase in time required to access data in the hot memory.

The matrix multiplication program uses the block transfer operation to make local copies of matrix rows and columns before accessing the individual elements to multiply and add.

To multiply matrices of size 192x192, 36864 dot products must be computed. The program is written to compute dot products in groups of 36. This involves 12 block transfer operations to obtain 6 rows and 6 columns. Thus, 12 block transfers yield 36 results, each result requiring 1/3 block transfer. Therefore, the program performs 12288 block transfer operations.

Twelve memories were used to hold the matrices, one of which was hot. Therefore, 1/12 of the block transfers can be expected to be delayed due to the hot spot. The block transfer delay from a hot memory was measured separately by timing a 768 byte block transfer from a cool memory, and then timing it again when the memory was made hot by 100 processors doing block transfers from it:

Reference times (microseconds)

| | read | write | bt-from | | bt-to | |
|---|---|---|---|---|---|---|
| | | | 256 bytes | 768 bytes | 256 bytes | 768 bytes |
| No hot memory | | | | | | |
| remote | 15.41 | 7.87 | 111.38 | 317.17 | 112.00 | 339.26 |
| Hot memory - 100 processors doing simple read/write references | | | | | | |
| cool memory | 16.70 | 8.75 | 112.35 | 316.20 | 113.94 | 340.19 |
| hot memory | 701.93 | 306.80 | 473.99 | 1393.59 | 276.61 | 470.09 |
| Hot memory - 100 processors doing 768 byte block transfers | | | | | | |
| cool memory | 15.95 | 9.02 | 112.88 | 315.97 | 113.26 | 335.85 |
| hot memory | 17410.04 | 153.30 | 8178.84 | 25820.95 | 254.55 | 827.14 |

Table 2: Data from remote reference experiment.

| | Time to block transfer 768 bytes (microseconds) |
|---|---|
| No hot memory | 322.18 |
| Hot memory<br>100 processors doing<br>768 byte block transfers. | 25885.81 |

Therefore, the additional time for the matrix multiplication program to perform block transfers from the hot memory should be about:

```
(1/12) * 12888 * (25885.81-322.18) = 26.18 seconds
```

The measured increase in the execution time for the matrix multiplication program for a single processor was

```
92.01 - 65.73 = 26.28 seconds
```

Thus, the performance degradation resulting from the hot memory is due almost entirely to contention at that memory. The effect of switch contention on program performance is negligible, even with severely non-uniform memory reference patterns.

Note that communication (accessing remote memory) accounts for about 6%[1] of the execution time of the matrix multiplication program. Our experience with the Butterfly Parallel Processor is that communication typically accounts for 4%-10% of the execution time for an application. Because a relatively small part of total program execution time is due to communication, remote memory reference times must be severely degraded before memory hot spots can have a signficant effect on overall program performance. The purpose of the second experiment was to measure the effect memory hot spots have on remote memory references as opposed to overall program performance.

## EXPERIMENT #2: REMOTE REFERENCES

The second experiment timed references made from a given processor node to memory on every other processor node. Four types of references were timed:

1. Single word (4 byte) read references;

   ```
   t = * p;
   ```

   where *t* is a variable in local memory and *p* is a pointer (*int* *) to the word to be read.

2. Single word (4 byte) write references;

   ```
   * p = t;
   ```

   where *t* is a variable in local memory and *p* is a pointer (*int* *) to the word to be written.

3. Block transfer of data from the remote memory;

   ```
   Do_bt (remotep, localp, numbytes)
   ```

   where *remotep* is a pointer to a block of data on a remote node to be copied, *localp* is a pointer to an area in local memory, and *numbytes* is the number of bytes to be copied to local memory.

4. Block transfer of data to the remote memory;

   ```
   Do_bt (localp, remotep, numbytes)
   ```

   where *localp* is a pointer to a block of data in local memory to be copied, *remotep* is a pointer to an area on a remote node, and *numbytes* is the number of bytes to be copied from local to remote memory.

The measurements for a given reference type were made by timing a tight loop that included the memory reference:

```
Start_timer;
for (i = 0; i < loopcount: i++)
    Make_reference;
Stop_timer;
```

In addition, the empty loop was timed to measure loop overhead:

[1] = 100% * (12288 blk xfers * 322.18 microsec/blk xfer) / (66.02 sec).

```
Start_timer;
for (i = 0; i < loopcount: i++) ;
Stop_timer;
```

### Data

Runs that involved hot spots used 100 processors to generate the hot spot. Therefore, in those runs there was 1 (remote) hot memory, 10 (remote) cool memories, 1 (local) cool memory, and 99 (remote) memories for processors generating the hot spot.

The timing data in Table 2 shows average times for one iteration of the memory referencing loop for the various memory reference types under the conditions indicated. For the first set of data, which was collected without any hot spots, the "remote" reference times were computed by averaging the loop times measured for each of the 110 remote memories and dividing by *loopcount*. Data from the hot memory measurements was treated similarly. For example, the "hot memory" reference times were computed by dividing the measured times through the reference loop by *loopcount*; and the "cool memory" reference times were computed by averaging the loop times for the 10 cool memories and dividing by *loopcount*. *Loopcount* for this data was 10000. The loop overheads for each of the conditions were measured as described above, and factored out of the data. That is, the times presented exclude the measured loop overheads.

### Discussion

When there is a hot memory, references to cool memory are slowed down slightly. This is probably due to contention within the switch; switch messages used to reference cool memory collide with the switch messages used to make the memory hot.

When there is a hot memory, simple references to cool memory are slowed down about the same amount as block transfer references to cool memory. For example, remote reads from a cool memory when the hot spot is generated by read and write references are slowed by 1.29 microseconds (16.70 versus 15.41), and 256 byte block transfers from a cool remote memory are slowed by .97 microseconds (112.35 versus 111.38)[2]. This is not surprising since the slow down is due to the increased time for initiating successful message transmission through the switch, and the increase is independent of message size.

References to the hot memory are substantially slower. For most types of references a memory made hot by block transfers is slower than one made hot by read and write references. The major exception is that simple writes are slower when the memory is made hot by read and write references than when it is made hot by block transfers (306.80 versus 153.30). This is due to the buffering strategy in the Processor Node switch interface which, in effect, gives preference to simple writes: when the memory is hot due to read and write references, the write being timed must compete with the writes making the memory hot; whereas when the memory is hot due to block transfers, there are no other writes to compete with.

## CONCLUSIONS

The principal conclusion to be drawn from these experiments is that the results reported by Pfister and Norton do not generalize to the Butterfly Parallel Processor. While memory contention has an important effect on program performance in a Butterfly system, switch contention does not.

The matrix multiplication experiment showed that non-uniformities in memory reference patterns have very little effect on the behavior of a program that avoids the hot memory. When the hot memory is avoided, its presence has virtually no effect on a program's performance, even if the non-uniformities are large.

If a program uses a hot memory, the performance degradation due to the hot memory depends on the extent to which the hot memory is used by the program. That is, the program is appreciably slowed only when it references the hot memory. Although the memory reference experiment showed slight slow down in references to the cool memories, the matrix multiplication experiment showed that the slight slow down has negligible impact on overall program performance.

There is no evidence that the tree saturation phenomenon described by Pfister and Norton occurs in the Butterfly Switch. Severe non-uniformities can lead to a small increase in contention within the switch, but the saturation effect simply does not occur.

## ABSTRACT

When a large number of processors try to access a common variable, referred to as *hot-spot* accesses in [6], not only can the resulting memory contention seriously degrade performance, but it may also cause *tree saturation* in the interconnection network which blocks both hot-spot and regular requests alike. It is shown in [6] that even if only a small percentage of all requests are to a hot-spot location, these requests can cause very serious performance problems, and networks that do the necessary combining of requests are suggested to keep the interconnection network and memory contention from becoming a bottleneck.

Instead we propose a *software combining tree* concept and show that it is effective in decreasing memory contention and preventing tree saturation because it distributes hot-spot accesses over a software tree whose nodes can be dispersed among many memory modules. Thus it is an inexpensive alternative to expensive combining networks.

## 1. INTRODUCTION

A large, shared-memory multiprocessor system like Cedar [1], the Ultracomputer of NYU [2], or the RP3 of IBM [3], may contain hundreds or even thousands of processors and memory modules. Multistage interconnection networks such as the Omega network [4] or its variations [5] are usually employed to provide communication between these processors and memory modules.

In these systems, any variable shared by these processors will create memory contention at some memory modules. Those shared variables could be locks for process synchronization [15], loop index variables for parallel loops [12], etc. Even though accesses to these shared variables (called *hot-spot* accesses in [3,6]) may account for a very small percentage of the total data accesses to the shared memory (typically less than 10% are observed in most applications), this memory contention can create a phenomenon called *tree saturation* [6], and can cause severe congestion in the interconnection network. It is shown [6,14] that tree saturation due to hot-spot contention can seriously degrade the effective bandwidth of the shared memory system.

Various schemes like combining networks used in the IBM RP3 [3] and NYU Ultracomputer [2], or the repetition filter memory in the Columbia CHoPP [7] has been proposed to eliminate such memory contention. The basic idea of these schemes is to incorporate some hardware in the interconnection networks to trap and combine data accesses when they are fanning in to the particular memory module that contains the shared variable. Because data accesses can be combined in the interconnection network, it is hoped that memory contention at that memory module can be eliminated.

However, the hardware required for such schemes is extremely expensive. It is estimated [6] that the extra hardware increases the switch size and/or cost by a factor between 6 and 32, and this is only for combining networks consisting of 2×2 switches. With $k \times k$ switches ($k > 2$), the hardware cost will be even greater. The extra hardware also tends to add extra network delay which will penalize most of the regular data accesses that do not need these facilities, unless the combining network is built separately as in RP3 [6].

Furthermore, the effectiveness of the combining network depends very much on the extent to which such combining can be done. If such combining is restricted as described in [8], i.e., if the number of requests that can be combined is restricted to $k$ in a $k \times k$ switch, then the effectiveness of the combining network can be limited. Unless this combining is unrestricted, tree saturation can still occur even in a combining network [8].

In this paper, we are studying this problem from a different perspective. We assume a shared memory multiprocessor system like Cedar [1] with a standard, buffered Omega network providing interconnection [9], and without expensive combining hardware. In addition we use a hardware facility in the shared memory modules to handle necessary indivisible synchronization operations for the shared variables [10]. Regular memory

This work was supported in part by the **National Science Foundation** under Grants No. US NSF DCR84-06916 and US NSF DCR84-10110 and by the **US Department of Energy** under Grant No. US DOE DE FG02-85ER25001.

accesses bypass this hardware without delay and, hence, will not be penalized. Each memory module will handle memory accesses, including those memory accesses to shared variables, one at a time.

To eliminate memory contention due to the hot-spot variable, a software tree is used to do the combining. This idea is similar to the concept of a combining network, but it is implemented in software instead of hardware. We will show that this scheme can achieve quite satisfactory results as compared to more expensive hardware combining.

## 2. HOT-SPOTS AND TREE SATURATION

The phenomenon of how hot-spot accesses can cause tree saturation is briefly described here. For a more detailed analysis and discussion, please refer to [6].

Assume $N$ is the number of processors in the system, and there are also $N$ memory modules in the shared memory system. Each processor issues $r$ requests to the shared memory per network cycle ($0 \leq r \leq 1$). Among those requests, $h$ percent of the requests are hot-spot requests. Thus, in each network cycle, there are $Nrh$ hot-spot requests and $r(1\text{-}h)$ normal requests directed to the "hot" memory module for a total of $Nrh + r(1\text{-}h)$. If each memory module can accept 1 request per network cycle (i.e., the maximum rate), the maximum network throughput per processor is

$$H=1/(1+h(N\text{-}1)) \qquad (1)$$

and the total effective memory bandwidth for the shared memory system is

$$B=N/(1+h(N\text{-}1)). \qquad (2)$$

Fig. 1 shows B as a function of $N$ for various $h$. This clearly shows that in a system with 1000 processors, hot-spot traffic of only 1% can limit the total memory bandwidth B to less than 10%.

Notice that this discussion assumes that hot-spot requests can continue to be issued from a processor even if that processor still has an unsatisfied hot-spot request pending in the network. In many applications this is not true, because hot-spot requests are usually related to some kind of synchronization operation: A processor usually has to wait for the outcome of the synchronization operation before it can issue another request to the synchronization variable. So, the issuing rate from a processor is inherently limited. We will address these issues in more detail in later sections.

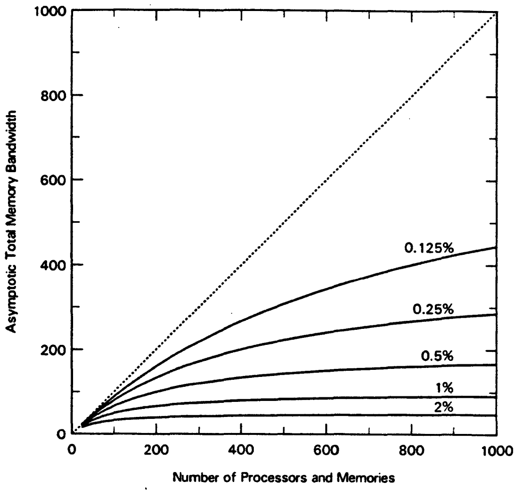

Fig. 1. Asymptotically maximum total network bandwidth as a function of the number of processors for various fractions of the network traffic aimed at a single hot spot.

(results from [6])

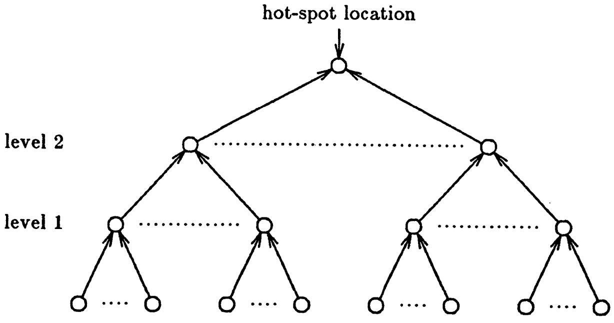

Fig. 2. A tree with fan-in = 10 to the hot-spot location.

## 3. SOFTWARE COMBINING TREES

To illustrate the principle of a software combining tree, let us assume that we have a variable whose value is N and that we want each processor to decrement this variable so that when all processors are finished, the value will be zero. This is a common way of making sure all processors are finished with a given task before proceeding with a new task, for example, and is one cause of hot-spot accesses. Now suppose that instead of one single variable, we build a tree of variables, assigning each to a different memory module, as shown in Fig. 2. If N = 1000 and assuming a fan-in of 10, we have 111 variables each with value 10. We partition the processors into 100 groups of ten, with each group sharing one of the variables at the bottom of the tree. When the last processor in each group decrements its variable to zero, it then decrements the value in the parent node. Thus, we have increased the total number of accesses from 1000 to 1110, but instead of having one hot spot with 1000 accesses, we have 111 hot spots with only 10 accesses each. It should be clear that this will result in a significant improvement in throughput rate and bandwidth, and the simulations we describe later verify that even if we account for the increase in total accesses, the improvement is still quite significant. It should also be clear that a three-level tree with fan-in equal to 10 is not necessarily optimal, but that the optimal point depends on access times and on other factors.

Another basic operation that can be implemented with a software combining tree is *busy-wait.* Here it is assumed that processors are waiting for a shared variable to change in some way. Presumably some other processor will cause this change. We build a combining tree as before, this time assigning one processor to each node in the tree. Each processor monitors the state of its node by continually reading the node. When the processor monitoring the root node detects the change in its node, it in turn changes the state of its children's nodes, and so on until all processors have detected the change and are able to proceed with the next task.

This idea, in a sense, is not very different from a hardware combining tree built from 10X10 switches, except that the combining buffer that would be inside each switch now resides in a shared memory module in a software combining tree. One distinct advantage for a software combining tree is that we can tune our performance by changing the fan-in of each node without incurring any hardware cost.

### 3.1. Modeling of Software Combining Tree

We will classify hot-spot accessing in two ways. First, accesses will be *limited* or *unlimited* depending on whether a given processor can have only one or more than one hot spot request outstanding. We let $\eta$ denote the number of outstanding hot-spot requests. Second, the number of accesses will be *fixed* or *variable* depending on whether the total number of accesses is fixed, or whether the total number varies depending on the number of conflicts or some other factor. For example, assume we are adding a vector of numbers to form a sum. Then each processor can have more than one outstanding request to add an element to the shared sum, but since we assume the addition is done indivisibly by logic in the memory, the total number of requests generated by all the processors is fixed. This case is *unlimited-fixed.* A case like that described earlier where processors are decrementing a counter to see who is the last processor is *limited-fixed.* A third example is illustrated by *busy waiting* where the processors may all be waiting for one processor to complete some task. Each processor continually reads the value of a shared variable until the value changes, for example from zero to one. Thus the number of requests to the hot spot depends on how soon the variable gets reset, and this case is *limited-variable.* Notice that a barrier synchronization [11] can be implemented by a counter decrement (*limited-fixed*), followed by a busy wait (*limited-variable*) triggered by the final processor which decrements the counter.

When we implement combining trees for hot-spot accesses, it is important to minimize the possible memory contention, and so it is preferable that all shared variables in a software combining tree (i.e., the nodes of the tree) reside in separate memory modules. The largest combining tree we can construct for a hot spot is a tree with minimum fan-in, i.e., a fan-in of 2. The total number of nodes in a combining tree with N leaves is N/2 + N/4 + $\cdots$ + 2 + 1 = N-1. Hence, it is always possible to spread those nodes across N separate memory modules. Our simulations in this study assume all of the nodes in a software tree to be in separate memory modules.

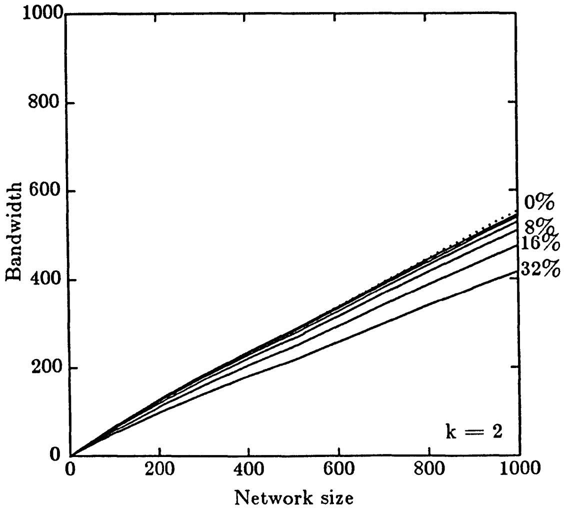

Fig. 3. Lower bound of network bandwidth under various hot-spot rates ($\eta$ = unlimit).

We also assume the following system configuration:

(1) There are two identical, back-to-back, uni-directional Omega networks: one is for traffic from processors to the shared memory; the other is for traffic from memory returning to the processors. Both networks are packet-switching, pipelined networks.

(2) Each network consists of 2X2 switching elements with an output buffer of finite size at each output port of a switching element. The fan-in capability of each output port is 2, i.e., it can accept two simultaneous requests from its two input ports. One request is forwarded to the next stage and the other is stored in the output buffer. If the output buffer is full, no more requests are accepted by the output port. In our simulations, we assume the size of the output buffer to be 4.

(3) When a software combining tree is used, accesses to a shared variable are distributed over the nodes of a tree instead of a single shared variable, and additional memory accesses are needed to access these nodes in the tree. This occurs both in a counting operation where the last processor to decrement a node must also decrement the parent node, and in the busy-waiting case where each processor except at the leaves must propagate the state change to the node's children. These extra accesses are accounted for in our simulations.

(4) All requests are of the same length. In our simulations, we assume each request consists of only one packet.

(5) The access time of a memory module is 1 network cycle, i.e., the time for a request to go through a switching element when no conflict exists.

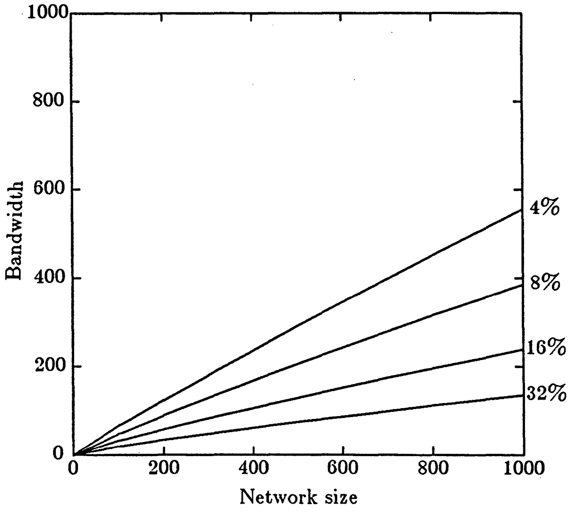

Fig. 4. Upper bound of network bandwidth under various hot-spot rates ($\eta = 1$).

### 3.2. Possible Overhead in a Software Combining Tree

As mentioned earlier, constructing a software combining tree creates many shared variables. Therefore, more hot-spot traffic is created even though that traffic generates less memory contention.

As before, let us assume that the hot-spot rate from a processor is $r \times h$, and the software combining tree has a fan-in of $k$ for each node. For *fixed*-type access patterns, the fractional increase in hot-spot traffic will be

$$\sum_{l=1}^{\log_k N-1} rh/k^l = rh(\frac{1-(k/N)}{k-1}).$$

When $k = 2$, the increased hot-spot traffic is $rh(1-2/N)$, which approximates the original hot-spot traffic for large $N$. This means that the hot-spot traffic can not be more than doubled after all of the extra hot-spot traffic is included. As we will see later in our simulations, the decreased memory contention will more than offset the increased hot-spot traffic if $h$ is less than 30%.

For *variable* access patterns, the additional accesses caused by the combining tree are difficult to quantify because the number of accesses is not fixed to begin with. In practice, since busy-waiting is often the cause of *variable* access patterns (with $\eta = 1$), and the number of accesses for a busy-wait operation depends on how quickly the state change is propagated to the children in the tree, the total number of accesses could even be less than that required by a single shared variable because the state change can be propagated more quickly by the combining tree than by N accesses to a single shared variable.

## 4. BOUNDS ON BANDWIDTH

### 4.1. Unlimited Hot-Spot Requests per Processor

In a packet-switching Omega network, with finite buffers in each switching element and with hot-spot rate $h = 0$, we still cannot achieve 100% memory bandwidth because of conflicts in the network [9]. These conflicts are also possible if a crossbar switch is used. If we assume R to be the maximum request rate reaching a memory module when no hot-spot exists, then in a steady state, R is also the maximum request rate allowed for a processor. Therefore, we can consider R to be an absolute upper bound on the bandwidth per processor.

The value of R depends on the network buffer size, the length of a request, and the network switch size, etc.

[13]. However, as $h$ increases, the request rate to the hot memory module, i.e., $r(1\text{-}h)+rhk$, will increase from R to 1. Tree saturation will occur when the request rate to the hot memory module approaches 1, and the maximum processor request rate $r$ will decrease. Hence, we have

$$R \leq r(1\text{-}h)+rhk \leq 1.$$

By rearranging the above equation, we have the following:

$$R/(1+h(k\text{-}1)) \leq r \leq 1/(1+h(k\text{-}1))$$

$1/1+h(k\text{-}1))$ is equal to 1 when $h$ is 0. Since the absolute upper bound is $R$ ($R \leq 1$) as discussed before, we can have a tighter upper bound by using $R$, i.e.,

$$R/(1+h(k\text{-}1)) \leq r \leq R. \qquad (3)$$

Notice that Eq. (3) also shows a lower bound for the maximum processor request rate $r$ when a software combining tree is used with a fan-in of $k$, and $\eta$ is unlimited, i.e., even when $\eta$ is unlimited, the maximum bandwidth cannot be worse than $NR/(1+h(k\text{-}1))$.

We obtained $R$ from simulations, and in Fig. 3 we plot lower bounds for various system sizes with $h$ varying from 0% to 32%. Notice that those curves are in a very narrow range, i.e., the lower bound in Eq. (3) seems to be tight at least for systems up to size 1024. The top dotted line in Fig. 3 shows R, the maximum bandwidth we can get when there are no hot-spot requests.

The degradation factor in Eq. (3) is $1+h(k\text{-}1)$. This degradation factor is independent of the system size and reaches a minimum when $k = 2$. Given unlimited hot-spot requests, i.e., $\eta \geq 1$, the optimal software combining tree for maximum memory bandwidth has a minimum fan-in of 2.

### 4.2. Single Hot-Spot Request per Processor

If the hot-spot request rate is limited ($\eta = 1$), then there cannot be more than N hot-spot requests in the system at any time. For systems with instruction look-ahead or with data prefetching capability, regular requests still may be issued while a hot-spot request is pending. However, this case is not different from that of unlimited hot spot requests with a very small $h$: when $h$ is very small, it is unlikely that there will be more than one hot-spot request pending at any time.

Hence, when $\eta = 1$, we will only consider the case where no additional requests, hot or regular, are issued by the processor when there is a pending hot-spot request. Thus, the bandwidth depends on the delay of the hot-spot requests. The request rate from the processor is further restricted by any increased delay. If a software combining tree is used to eliminate the memory contention caused by the hot-spot requests, the limiting factor for the memory bandwidth will only be $\eta$; the inherent nature of the hot spot that prohibits further processor requests.

During a long period of time $T$, there will be $rT$ requests generated from a processor, among which $rhT$ requests are hot-spot requests. The processor will be barred from issuing any request for a total period of $rhTC$, where $C$ is the average round-trip delay for a hot-spot request. The processor can issue a request only for a total period of $T-rhTC$. Within that period, $r(1\text{-}h)T$ regular requests are issued. Hence, the real issuing rate for regular requests is $r(1\text{-}h)T/(T-rhTC)$. This rate can not be greater than 1, i.e.,

$$r(1\text{-}h)T/(T-rhTC) \leq 1.$$

This equation can be rearranged to obtain an upper bound for $r$:

$$r \leq 1/(1\text{-}h+hC) \qquad (4)$$

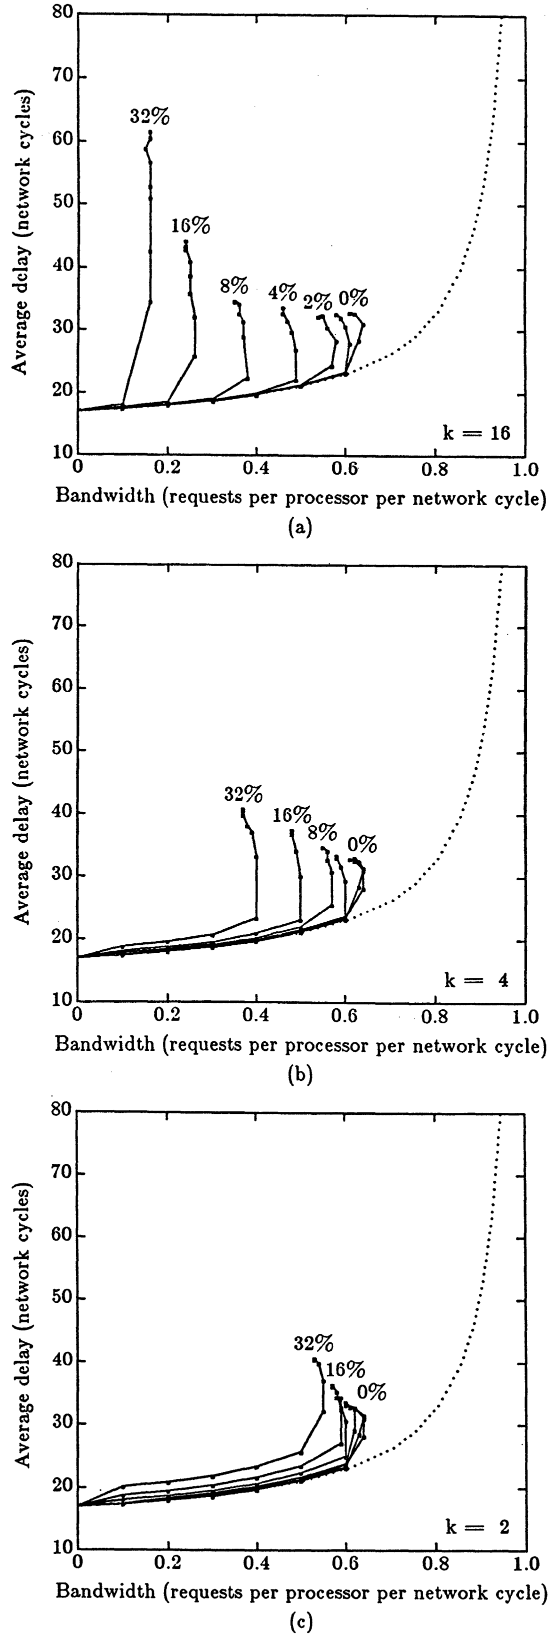
As expected, the maximum rate of $r$ is greatly dependent on the hot-spot delay $C$. This bound gets tighter as the hot-spot rate $h$ gets larger. When $h = 1$, the equality in Eq. (4) will hold. Fig. 4 shows this upper bound for various hot-spot rates $h$ with minimum hot-spot delay of $C = 2\log_2 N$. For N = 1000 and $h = 8\%$, the upper bound will be around 40% of the total bandwidth. Notice that *the upper bound in Eq. (4) is valid even for a hardware combining network* because it is a bound imposed by the inherent nature of the hot-spot request (i.e., $\eta = 1$).

## 5. SIMULATION RESULTS

To study the effectiveness of a software combining tree, we performed several simulations for N = 256, with $h$ varying from 0% to 32%. Fig. 5 shows the delay and maximum bandwidth when neither a software combining tree nor a hardware combining network is used. Following each curve from left to right, each point represents a larger value of r. As shown in [6], while r increases, bandwidth increases while delay stays relatively constant up to a point of saturation. After the saturation point, bandwidth ceases to increase while delay gets worse. This clearly shows low bandwidth and increased average network delay results. The maximum bandwidth of 0.63N is achieved when $h = 0$.

Fig. 6 represents *fixed*-type access patterns with unlimited $\eta$, and shows the use of a software combining tree to reduce hot-spot contention. The fan-in's for the software combining trees are varied from $k = 16$ to 2. The improvement is quite significant compared to the result in Fig. 5(a). According to Eq. (3), the minimum degradation factor for the bandwidth can be obtained when the software combining tree has the minimum fan-in. In Fig. 6 we can see that when $k = 2$, the degradation is indeed the smallest.

As presented in section 3.2, the hot-spot traffic can be nearly doubled by the extra hot-spot traffic created by the software combining tree with the minimum fan-in $k = 2$. In Fig. 6 $h$ is indicated as the original hot-spot request rate; the results shown there already include all

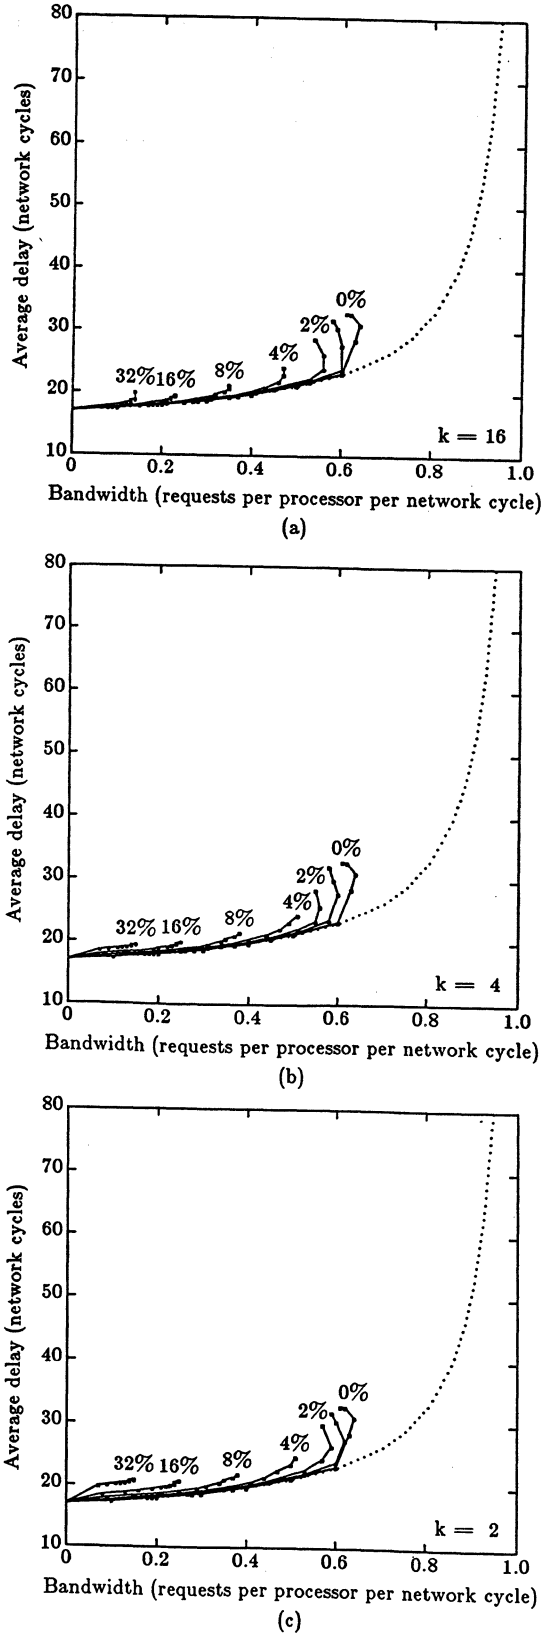


(a)

(b)

(c)

Fig. 6. Average delay versus bandwidth for unlimited-fixed access patterns. (N = 256, $h$ varies from 0 to 32%)



(a)

(b)

(c)

Fig. 7. Average delay versus bandwidth for limited-fixed access patterns. (N = 256, $h$ varies from 0 to 32%)

extra hot-spot traffic. This shows that with an original hot-spot request rate of 16%, the degradation remains small. The elimination of the hot-spot contention, indeed, more than offsets the results of increased traffic.

Fig. 8 represents *limited-variable* access patterns, wherein no additional requests are issued by a processor while it has a hot-spot request pending, but the total number of requests allowed over time is not fixed. The upper bound on the bandwidth given in Eq. (4) will depend on $C$, the average delay of the hot-spot requests. The value of delay $C$ includes the overhead from traversing the software tree, busy waiting in the intermediate nodes, and the possible memory contention. From these figures, we can see that the optimal fan-in $k$ for the software tree is no longer $k = 2$, but rather at around $k = 4$. The increased fan-in $k$ allows for a lesser number of levels of nodes in the tree, thus reducing the time required for requests to traverse the tree.

Furthermore, when $h$ increases, the upper bound in Eq. (4) becomes tighter. There is less traffic in the network due to the restriction that no more requests will be issued when a hot-spot request is pending. In this case, the turnaround time for a request can actually be improved as Fig. 9 shows.

We also simulate some cases for fixed-type access patterns with $\eta = 1$ (Fig. 7). If we take into account the fact that busy waiting is not required in this kind of access pattern, we can see that the results are quite similar to those from our simulations of variable-type access patterns discussed above. In fact, the average hot-spot request delay, i.e., $C$ in Eq. (4), is smaller in this case. Also, as shown in Eq. (4), we can expect an improved maximum rate $r$.

The lower dotted lines in Fig. 5 through Fig. 9 are the average delay of a request through the network assuming the buffer size in each switching element is infinite. These values are calculated based on the analytical model in [16].

## 6. DISCUSSION

Our simulations show that the software combining tree effectively eliminates tree saturation caused by hot-spot contention. However, the main purpose of the software combining tree differs slightly from the original purpose of the hardware combining networks [2,6].

Hardware combining networks were originally proposed to speed up hot-spot requests by combining those requests in the interconnection network and in this way eliminate memory contention at the hot memory module. Because such memory contention creates the serious side effect of tree saturation that can adversely affect even regular requests [6], such requests must also be processed through the hardware combining network. Although it alleviates the problem of tree saturation, hardware combining can cause extra delay in processing regular requests.

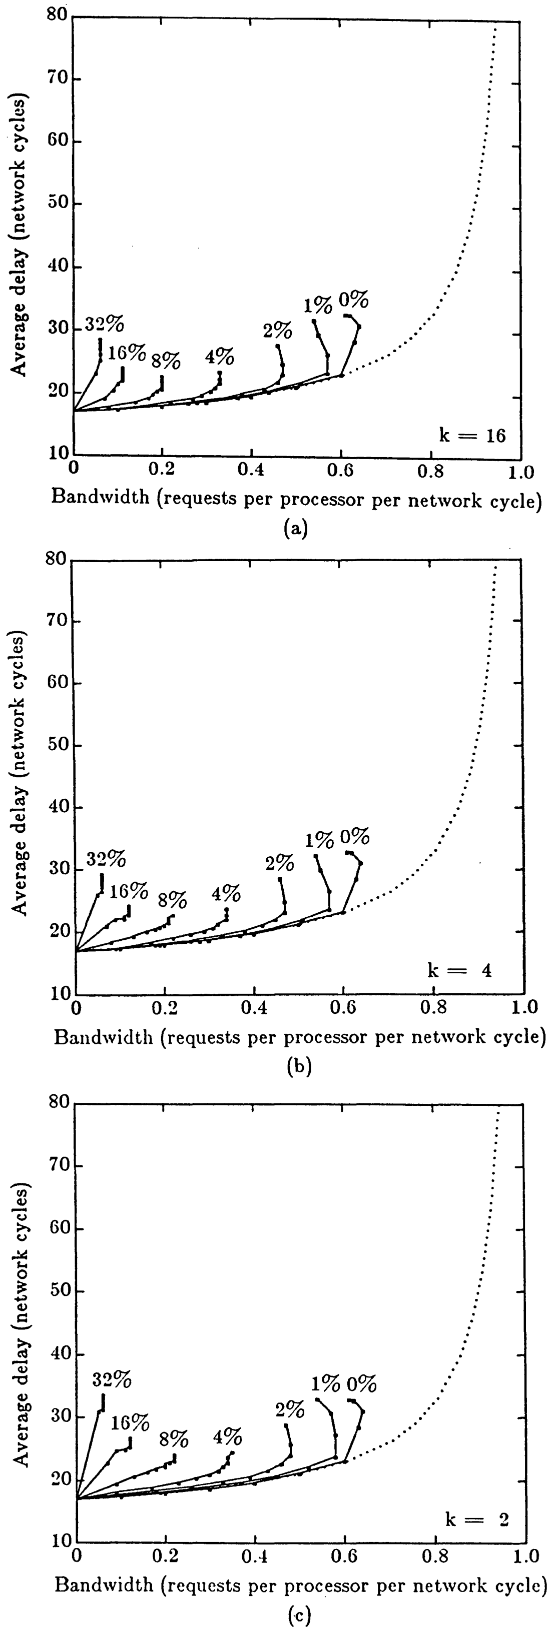


Fig. 8. Average delay versus bandwidth for limited-variable access patterns. (N = 256, $h$ varies from 0 to 32%)

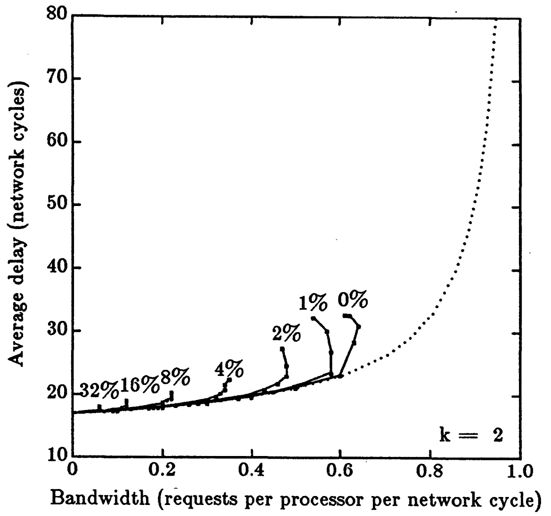

Fig. 9(a). Average delay of regular requests versus bandwidth for limited-variable access patterns. (N = 256, *h* varies from 0 to 32%)

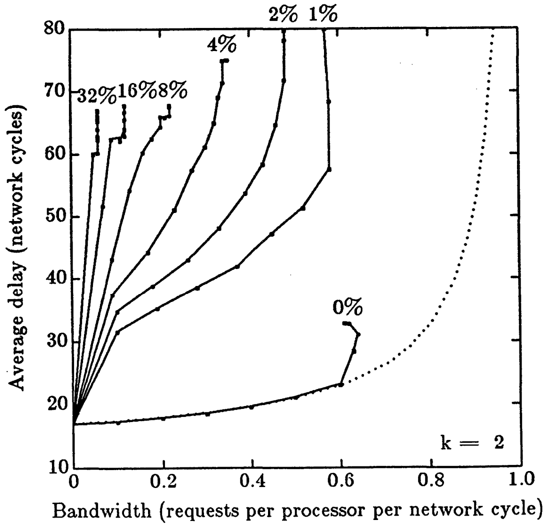

Fig. 9(b). Average delay of hot-spot requests versus bandwidth for limited-variable access patterns. (N = 256, *h* varies from 0 to 32%)

Software combining trees seem to effectively relieve regular requests from the side effect of tree saturation, without the expense of hardware combining networks. The beneficial side effect from this scheme is that the service time of hot-spot requests decreases. Theoretically, this improvement cannot be as good as a hardware combining network with unrestricted combining capability: in a software combining tree, a hot-spot request must traverse the interconnection network $\log_k N$ times, whereas in a hardware combining network the request must traverse the network only once. However, in a real implementation, unrestricted combining in a switch is impossible due to the complexity of the switches in a hardware combining network. This will inevitably hamper the effectiveness of a combining network [8], and also introduces increased delay due to the extra hardware. It is difficult to determine at what system size requirements necessary to prove the hardware combining network to be the optimal method of speeding up hot-spot requests. The effect of the somewhat slower hot-spot requests will have on total system performance, if the rate is very small, also remains to be seen.

## Abstract

The method of simultaneous iteration with shift is extended to extraction of m-eigenpairs of a general eigenvalue problem of large order n, n>>m, in a parallel processing environment. The algorithm combines the power method and the Jacobi technique and reduces to performing four basic operations: decomposing a banded matrix of order n into upper and lower triangular factors; forming a product of matrices that may be banded, rectangular or square; extracting all eigenpairs of m-order problems by a generalized Jacobi technique; and forward/backward substitution.

Parallel implementation of the algorithm is discussed in detail. The analysis accounts for computation and communication costs, and utilizes a parallel processing architecture of the ensemble type. Expressions for the computational efficiency and speedup are defined as a function of the problem and hardware parameters. Selected representative problems exhibit efficiencies ranging from 60% to 98%.

## 1. Introduction

Parallel processing is particularly attractive for large computationally intensive problems where hours of sequential computing might be reduced to minutes of parallel computing. Unlike vector computers such as the Cray or Cyber 205, parallel computers of the ensemble type, such as the Cosmic Cube[1] and the CHIP[2], require the use of computational strategies that permit decomposing the solution of a problem into concurrently executable computational tasks (or processes). Each task is executed on one processor which is a member of a network of communicating processors that operate in parallel. Communication between tasks is inevitable, since all tasks contribute to the solution of a single problem. However, such communications must be minimized in order to achieve the full potential of these machines. This offers the challenge of restructuring existing algorithms and discovering others so that they are best suited for the parallel processing environment.

To this end, the present work addresses a strategy for the parallel extraction of the eigenpairs of the general eigenvalue problem:

$$\underset{\sim}{A}\,\underset{\sim}{x} = \lambda\,\underset{\sim}{B}\,\underset{\sim}{x} \tag{1}$$

where $\underset{\sim}{A}$ and $\underset{\sim}{B}$ are Hermitian banded matrices of large order n and half bandwidth b<<n. As is the case in many technologically important problems, the interest here is in computing only the set of eigenpairs $(\lambda_\ell, x_\ell)$, $\ell$=1,...,m residing within a prescribed range $\lambda_L \leq \lambda_\ell \leq \lambda_U$, where m<<n. For this class of problems, a mixture of power methods and the Jacobi technique appears to be most suitable, and is therefore explored herein.

## 2. Power Methods

When $\underset{\sim}{B}$ is positive definite, the general eigenvalue problem in (1) may be reduced to the standard form:

$$\underset{\sim}{\mathcal{A}}\;\underset{\sim}{x} = \lambda\,\underset{\sim}{x} \quad ; \quad \underset{\sim}{\mathcal{A}} = \underset{\sim}{B}^{-1}\,\underset{\sim}{A} \tag{2}$$

Furthermore, if $\underset{\sim}{Q}(\underset{\sim}{\mathcal{A}})$ and $\underset{\sim}{R}(\underset{\sim}{\mathcal{A}})$ denote any polynomials of $\underset{\sim}{\mathcal{A}}$, it can be shown[3] that $(\underset{\sim}{Q}(\underset{\sim}{\mathcal{A}})\;\underset{\sim}{R}(\underset{\sim}{\mathcal{A}})^{-1})^r$, r = integer, has the same eigenvectors as $\underset{\sim}{\mathcal{A}}$, with eigenvalues $(Q(\lambda_i)R(\lambda_i)^{-1})^r$, provided that det $\underset{\sim}{R}(\underset{\sim}{\mathcal{A}}) \neq 0$. By starting with any vector $\underset{\sim}{v}$, iterations of the type

$$\begin{aligned} &\underset{\sim}{Q}(\underset{\sim}{\mathcal{A}})\;\underset{\sim}{R}(\underset{\sim}{\mathcal{A}})^{-1}\;\underset{\sim}{u}_{k-1} = \underset{\sim}{v}_k \\ &\underset{\sim}{u}_k = \underset{\sim}{v}_k / \max\,(\underset{\sim}{v}_k) \qquad k = 1,2,\ldots \end{aligned} \tag{3}$$

lead to

$$\lim_{k \Rightarrow \infty} \underset{\sim}{u}_k = \underset{\sim}{x}_p \tag{4}$$

where $\underset{\sim}{x}_p$ is the p<u>th</u> eigenvector of (1) such that

$$\|Q(\lambda_i)/R(\lambda_i)\| \max_{i=1,2,\ldots} = \|Q(\lambda_p/R(\lambda_p)\| \tag{5}$$

The algorithm implied by (3) is a power method which enables one to extract the eigenpairs of (1) selectively. For example, by taking

$$\underset{\sim}{Q}(\underset{\sim}{\mathcal{A}}) = \underset{\sim}{I} \quad ; \quad \underset{\sim}{R}(\underset{\sim}{\mathcal{A}}) = (\underset{\sim}{\mathcal{A}} - \lambda_o \underset{\sim}{I}) \tag{6}$$

where $\lambda_o$ is a prescribed shift, (3) and (5) reduce to the method of inverse iteration with shift:

[+] The paper presents research results carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA).

$$(A - \lambda_o B)\, v_k = B\, u_{k-1}$$

$$u_k = v_k/\max(v_k) \qquad k = 1,2,\ldots \tag{7}$$

and $$\|1/(\lambda_i - \lambda_o)\|\max_{i=1,2,\ldots} = \|1/(\lambda_p - \lambda_o)\| \tag{8}$$

The iterations will converge to the eigenvectors with eigenvalues closest to the shift $\lambda_o$.

It is known that when $A$ and $B$ are Hermitian (i.e., $A=A^H$, $B=B^H$), all eigenvalues $\lambda_i=\bar{\lambda}_i$, $i = 1,2,\ldots,n$ are real; and if $A$ and $B$ are also positive definite then $\lambda_i > 0$ for $i = 1,2,\ldots,n$. When $A$ and $B$ are Hermitian, if the labels of the eigenvalues are such that $\lambda_1 < \lambda_2 < \ldots < \lambda_n$, then by Sylvester's law of inertia of quadratic forms[3], it may be shown that the index p of the converged eigenpair is such that:

$$p = \eta' \quad , \quad \text{if} \quad \lambda_p < \lambda_o \tag{9}$$

$$p = \eta' + 1 \; , \quad \text{if} \quad \lambda_p > \lambda_o$$

where $\eta'$is the number of negative diagonals $d_i$ in the factorization:

$$(A - \lambda_o B) = U'^H \operatorname{diag}(d_i)\, U' \tag{10}$$

Equivalently, $\eta'$is the number of pure imaginary diagonals of the upper triangular matrix $U$ in the Cholesky factorization of:

$$(A - \lambda_o B) = U^H U \tag{11}$$

The algorithm given by (6), (7) and (8) can also be carried out with m iteration vectors, $V_k$, simultaneously. In this case, instead of the normalization in (7) one may orthonormalize the set of m vectors, $V_k$, with respect to $A$ and $B$. This can be done either by Gram-Schmidt, Givens or Householder orthogonalization; or by replacing $V_k$ with an orthogonal set of m-basis vectors $U_k$ which span the same subspace, $S_k$, as $V_k$. In the latter scheme, the orthogonality property is derived from satisfaction of the relation between the projected operators $A$ and $B$ onto the $S_k$ subspace. This is accomplished by the following recursive relationship:

$$(A - \lambda_o B)\, V_k = B\, U_{k-1} \tag{12}$$

and the transformation

$$U_k = V_k\, Q_k \qquad k = 0,1,2,\ldots,K_{\max} \tag{13}$$

Initially, for $k = 0$, $V_k$ is any set of m linearly independent vectors. For succeeding steps, $Q_k$ is determined so as to satisfy the eigenvalue problem of order m<<n:

$$A_k\, Q_k = B_k\, Q_k \operatorname{diag}(\Omega_k) \tag{14}$$

in which,

$$A_k = V_k^H (A - \lambda_o B)\, V_k \quad ; \qquad B_k = V_k^H\, B\, V_k$$

Normalization of $Q_k$ with respect to $B_k$, i.e., ($Q_k B_k Q_k = I$) is enforced such that

$$U_k^H\, B\, U_k = I \tag{15}$$

With Equations (12) to (15), the resulting eigenpairs are assured to converge to:

$$\lim_{k \Rightarrow \infty} U_k = [x_{1\ell}, x_{2\ell}, \ldots, x_{m\ell}]_{K_{\max}} \tag{16}$$

$$\lim_{k \Rightarrow \infty} \operatorname{diag}(\Omega_k) = \operatorname{diag}(\lambda_{1\ell} - \lambda_o, \lambda_{2\ell} - \lambda_o, \ldots, \lambda_{m\ell} - \lambda_o)_{K_{\max}} \tag{17}$$

where the indices $1\ell, 2\ell, \ldots, m\ell$ are those of $\lambda_i$ of (1) which reside nearest the shift $\lambda_o$.

## 3. Generalized Jacobi Technique

The generalized Jacobi technique[4] is most suitable for obtaining all eigenpairs of the reduced general eigenvalue problem in (14). In the generalized Jacobi, both $A_k$ and $B_k$ are diagonalized simultaneously by a sequence of orthogonal transformations of the form:

$$A_{k,r+1} = P_r^T \cdots P_2^T P_1^T A_k P_1 P_2 \cdots P_r$$

$$B_{k,r+1} = P_r^T \cdots P_2^T P_1^T B_k P_1 P_2 \cdots P_r \tag{18}$$

where $P_r$ is a rotation matrix:

$$P_r = \begin{array}{c} \left[\begin{array}{cccccccc} 1 & & \cdot & & & & \cdot & \\ & 1 & \cdot & & & & \cdot & \\ \cdot & \cdot & 1 & \cdot & \cdot & \cdot & \alpha_{ij} & \cdot \\ & & \cdot & 1 & & & \cdot & \\ & & \cdot & & 1 & & \cdot & \\ & & \cdot & & & 1 & \cdot & \\ \cdot & \cdot & \beta_{ij} & \cdot & \cdot & \cdot & 1 & \cdot \\ & & \cdot & & & & \cdot & 1 \end{array}\right] \begin{array}{c} \\ \\ i \\ \\ \\ \\ j \\ \\ \end{array} \\ \begin{array}{cccccccc} \quad & \quad & i & \quad & \quad & \quad & j & \quad \end{array} \end{array} \tag{19}$$

Each transformation in (18) involves one pre- and post- multiplication, and will simultaneously reduce to zero the symmetric off-diagonal terms (ij) and (ji) of $A_{k,r+1}$ and $B_{k,r+1}$ if:

$$\alpha_{ij} = \omega_1/\theta \quad ; \quad \beta_{ij} = -\omega_2/\theta$$

$$\text{where} \quad \theta = \frac{\omega_3}{2} + (\operatorname{sign}\omega_3)\left[\left(\frac{\omega_3}{2}\right)^2 + \omega_1\,\omega_2\right]^{1/2}$$

$$\omega_1 = (A_{jj}\, B_{ij} - B_{jj}\, A_{ij})_{k,r}$$

$$\omega_2 = (A_{ii}\, B_{ij} - B_{ii}\, A_{ij})_{k,r} \tag{20}$$

$$\omega_3 = (A_{ii}\, B_{jj} - B_{ii}\, A_{jj})_{k,r}$$

A single transformation as defined above will result in changing only the row and column pairs of $A_k$ and $B_k$ corresponding to the ij pair of Equation (19) in the manner listed in Table (1). All remaining terms of $A_{k,r}$ and $B_{k,r}$ remain unchanged, until subsequently operated upon by a transformation involving their row or column pair. In the "cyclic" generalized Jacobi technique used here, no attempt is made to determine which off-diagonal term is largest so

TABLE (1)

Changes in the i,j rows and columns of $A_{k,r+1}$ and $B_{k,r+1}$ due to a single transformation using $P_r$ of Equation (19)

| Element | $P_r^T A_{k,r} P_r$ | $P_r^T B_{k,r} P_r$ |
|---|---|---|
| ii | $(A_{ii} + \beta_{ji}^2 A_{jj} + 2\,\beta_{ji} A_{ij})_{k,r}$ | $(B_{ii} + \beta_{ji}^2 B_{jj} + 2\,\beta_{ji} B_{ij})_{k,r}$ |
| jj | $(A_{jj} + \alpha_{ij}^2 A_{ii} + 2\,\alpha_{ij} A_{ij})_{k,r}$ | $(B_{jj} + \alpha_{ij}^2 B_{ii} + 2\,\alpha_{ij} B_{ij})_{k,r}$ |
| ij = ji | 0 | 0 |
| $\delta = 1,2,\ldots,m$ ; $\delta \neq i$ , $\delta \neq j$ | | |
| $i\delta = \delta i$ | $(A_{i\delta} + \beta_{ji} A_{j\delta})_{k,r}$ | $(B_{i\delta} + \beta_{ji} B_{j\delta})_{k,r}$ |
| $j\delta = \delta j$ | $(A_{j\delta} + \alpha_{ij} A_{i\delta})_{k,r}$ | $(B_{j\delta} + \alpha_{ij} B_{i\delta})_{k,r}$ |

as to reduce it to zero first. Instead, all off-diagonal terms are operated upon in row major order, sweep after sweep. As such, diagonalizing the m x m matrices $A_k$ and $B_k$ of (14) will require several sweeps, $J_{max}$; each sweep consisting of m(m-1)/2 orthogonal transformations of the type in (19). As the number of sweeps increases, both $A_{k,r+1}$ and $B_{k,r+1}$ will approach their diagonal form, in which case the eigenpairs are simply:

$$\mathrm{diag}\,(\Omega_k) \simeq \mathrm{diag}\,(A_{ii}/B_{ii})_{k,r+1} \qquad (21)$$
$$Q_k \simeq P_1\, P_2 \,\cdots\, P_r\ \mathrm{diag}\,(1/\sqrt{B_{ii}})_{k,r+1}$$

## 4. Parallel Implementation of Simultaneous Iteration

Preliminaries:

The steps of the algorithm described in Section 2 are summarized in Table (2). The algorithm consists of four essential operations: (i) decomposing a banded Hermitian matrix of large order n into upper and lower triangular factors; (ii) forming the product of matrices that may be banded, rectangular or square; (iii) extracting all eigenpairs of the m-order problem by a generalized Jacobi and (iv) solving for the unknowns of an algebraic set of equa-tions by a forward pass, and then by a backward pass.

The objective of this section is to construct parallel implementation strategies for the above steps, and to derive expressions for the speedup and efficiency of the individual steps and of the complete algorithm. The speedup and efficiency are the most common measures for evaluating the performance of algorithms on N-identical processors operating in parallel. Both measures are related. The speedup is the ratio of the time required to execute a given algorithm on a single processor computer to the time required to execute the same algorithm on a parallel processing computer composed of N processors of the same type. The efficiency is defined as the speedup per processor. Equivalently, the efficiency is the ratio of time spent in computation to the total time required for computation, interprocessor communication and idling, if any.

TABLE (2)

Simultaneous Iteration Algorithm

| Solution Step | Comments |
|---|---|
| 1. Obtain the triangular factors of $(A-\lambda_o B) = U^H U$ |  |
| 2. Choose m-independent vectors $V_o = [v_1, v_2, \ldots, v_m]_o$ and set diag $(\Omega)_{-1} = 0$ | |
| 3. Construct the product $Z_{k-1} = (A - \lambda_o B) V_k$, k=0 |  |
| 4. Compute $A_k = V_k^H Z_{k-1}$ |  |
| 5. $W_k = B V_k$ |  |
| 6. $B_k = V_k^H W_k$ |  |
| 7. Extract m orthonormal eigenpairs of $A_k Q_k = B_k Q_k$ diag $(\Omega_k)$ |  |
| 8. Compute $U_k = V_k Q_k$ |  |
| 9. Convergence check: if $\|(\Omega_k - \Omega_{k-1})/\Omega_k\|_{ii} < \epsilon$, set $U_k = [x_1, x_2, \ldots, x_m]_k$<br>diag$(\Omega_k + \lambda_o)$ = diag$(\lambda_1, \ldots, \lambda_m)_k$, exit otherwise continues | |
| 10. Form $Z_k = B U_k$ |  |
| 11. With a forward pass compute $Y_{k+1}$ from $U^H Y_{k+1} = Z_k$ |  |
| 12. With a backward pass compute $V_{k+1}$ from $U V_{k+1} = Y_{k+1}$ |  |
| 13. Set k <-- k+1, and go to 4 | |

To quantify the complete processing costs, two architectural parameters, q and $\mu$, are used. The computational cost is characterized by q, which is defined as the time required to perform a floating point operation. One floating point operation is assumed, on the average, to consist of a multiplication followed by an addition. The cost of interprocessor communication is characterized by $\mu$, which is defined as the ratio of the time required to transmit one floating point number from one processor to its nearest neighbor, to the time required to perform a floating point operation. In the current state-of-the-art computers, $\mu$ is of order unity. The cost of propagating data through a network of N-processors depends on the transmission speed $\mu q$, communication topology among processors, the number of data items to be transmitted, and whether all processors should receive the same data or each should receive different data. In computers such as the Cosmic Cube, the time required for transmitting $\nu$ floating point numbers to N-processors is[5]:

$$T_1 = \nu(\log_2 N)\,\mu q \qquad (22)$$

if the same $\nu$ data items are sent to all N processors, and

$$T_2 = (\nu + N - 2)\,\mu q \qquad (23)$$

if different processors are sent different sets of $\nu$ data items each.

In the following, operations on matrices of large order are reduced to operations on smaller partitions of size s. It will be assumed that 1<s<<b. Further, by proper padding with zeros:

$$\mathrm{Mod}(n,s) = 0$$
$$\mathrm{Mod}(b,N) = 0$$
$$\mathrm{Mod}(b,s) = 0$$

and

$$\begin{aligned} b &= 2Ns \ll n \\ n_s &= n/s \\ b_s &= b/s = 2N \\ n_N &= 1 + \mathrm{Int}\,((n_s-1)/N) \end{aligned} \tag{24}$$

i. Parallel Matrix Decomposition

Two strategies were given in Reference [6] for the parallel implementation of decomposition of a banded Hermitian matrix of large order, n, into its triangular upper and lower factors $\underset{\sim}{U},\underset{\sim}{U}^H$. These stratagems use two different interpretations of the Cholesky factorization. Their performance is nearly equal. With the definitions and notations outlined above, the time required to factor an n x n matrix with half bandwidth b using N-processors is [6]:

$$T_i \approx qns^2N\,[2(1 + \frac{1}{N}) + \frac{\mu}{s}\,(10 + \frac{1}{N})] \tag{25}$$

where the coefficient of $\mu$ is due to interprocessor transmission of data. Expression (25) as well as others to be developed in subsequent sections are required for estimating the efficiency of the entire algorithm.

ii. Matrix Product

Three schemes for performing the matrix product $\underset{\sim}{C} = \underset{\sim}{A}^H\underset{\sim}{B}$ are given in this section, depending on whether $\underset{\sim}{A}$ and $\underset{\sim}{B}$ are banded, square or rectangular.

a. Inner Product of Two Rectangular Matrices

Let $\underset{\sim}{A}$ and $\underset{\sim}{B}$ be n x m matrices, each of which is partitioned into blocks $\underset{\sim}{A}_i$, $\underset{\sim}{B}_i$; $i = 1,\ldots,n_s$ with block size s x m. Assuming that each of the N-processors can store ($2ms+m^2$) floating point numbers, the inner product may be expressed by:

$$\underset{\sim}{C} = \sum_{\ell=1}^{N} \underset{\sim}{C}_\ell \tag{26}$$

where

$$\underset{\sim}{C}_\ell = \sum_{k=1}^{n_N} \underset{\sim}{A}^H_{(k-1)N+\ell}\;\underset{\sim}{B}_{(k-1)N+\ell} \tag{27}$$

or

$$\underset{\sim}{C}_\ell = \sum_{k=1}^{n_N} \underset{\sim}{A}^H_{(\ell-1)n_N+k}\;\underset{\sim}{B}_{(\ell-1)n_N+k} \tag{28}$$

The choice between placing the operands $\underset{\sim}{A}_i$ and $\underset{\sim}{B}_i$ in the N processors according to $i = (k-1)N + \ell$ of Equation (27), or $i = (\ell-1)n_N + k$ of Equation (28) may be dictated by the step previous to the matrix multiplication. With N processors, N values of $\underset{\sim}{C}_\ell$, $\ell=1,\ldots,N$ can be computed in parallel. Each processor performs $n_N$ serial floating point operations on their operands. No interprocessor communication is needed, and all $\underset{\sim}{C}_\ell$ are completed in a time of order $n_Nm^2q(1+s)$. The cascade sum of all $\underset{\sim}{C}_\ell$ is performed next according to Equation (26) in a time proportional to $m^2q(1+\mu)\log_2N$ during which the final results are collected in the host computer. The total cost of the inner matrix product is, therefore:

$$T^a_{ii} \approx m^2q\;[n_N\;(1 + s) + (1 + \mu)\;\log_2 N] \tag{29}$$

b. Product of a Rectangular Matrix by Square Matrix

Let $\underset{\sim}{A}$ and $\underset{\sim}{B}$ denote n x m and m x m matrices, respectively. Again, assuming that each processor can hold ($2ms+m^2$) floating point numbers, and that only $\underset{\sim}{A}$ is partitioned into s x m blocks $\underset{\sim}{A}_i$; $i=1,\ldots,n_s$, the product may be written as:

$$\underset{\sim}{C}_i = \underset{\sim}{A}_i\underset{\sim}{B} \tag{30}$$

where the resulting product $\underset{\sim}{C}$ is conformably partitioned as $\underset{\sim}{A}$ into $\underset{\sim}{C}_i$ blocks. Since $n_s>N$, the parallel implementation of Equation (30) can be accomplished by assigning each processor the task of computing $n_N$ of the $\underset{\sim}{C}_i$ partitions according to either

$$\underset{\sim}{C}_\ell = \underset{\sim}{A}_{(k-1)N+\ell}\;\underset{\sim}{B} \quad \text{or} \quad \underset{\sim}{C}_\ell = \underset{\sim}{A}_{(\ell-1)n_N+k}\;\underset{\sim}{B} \tag{31}$$
$$k = 1,2,\ldots,n_N$$

To begin with, the same $\underset{\sim}{B}$ and the appropriate partition of $\underset{\sim}{A}$ as defined by Equation (31) must reside in each processor. Then all processors perform their products simultaneously in a time of order ($n_Nm^2sq$). The final results, now available in N partitions in the N-processors may be transmitted to the host computer in a time proportional to $\mu q(sm+N-2)$. Therefore, the total cost is:

$$T^b_{ii} \approx q\;[n_N\;m^2s + \mu\;(sm + N - 2)] \tag{32}$$

c. Product of Banded by Rectangular Matrix

Here $\underset{\sim}{A}$ is n x n banded matrix with half bandwidth, b, partitioned into $n_s$ x $n_s$ square blocks according to Equation (24). On the other hand, $\underset{\sim}{B}$ is rectangular n x m partitioned row-wise into $n_s$ rectangular blocks, each s x m. For parallel implementation, the product $\underset{\sim}{C} = \underset{\sim}{A}\underset{\sim}{B}$ may be written as:

$$\underset{\sim}{C}_i = \sum_{\ell=1}^{N} \underset{\sim}{C}_{i\ell} \quad ; \quad \underset{\sim}{C}_{i\ell} = \sum_{k=1}^{4} \underset{\sim}{A}_{ij}\;\underset{\sim}{B}_j \tag{33}$$
$$i=1,\ldots,n_s;\; j=i-2N+4(\ell-1)+k;\; \text{and } \ell=1,\ldots,N$$

For a given row partition i, the appropriate s x s partition $\underset{\sim}{A}_{ij}$ and s x m partition of $\underset{\sim}{B}_j$ corresponding to k=1 must reside in the appropriate processor $\ell=1,\ldots,N$ according to the indices above. The product and partial sum defined by Equation (33) are then computed in parallel using N processors. When this is repeated sequentially for k=2, 3 and 4, one obtains the results of the ith row partition of $\underset{\sim}{C}$. Other row partitions are processed in sequence for all $i=1,\ldots,n_s$ and the final sum is continually accumulated in one processor. The completed results are performed in time

$$T^{c}_{ii} = nmq\ (4s + \mu \log_2 N) \qquad (34)$$

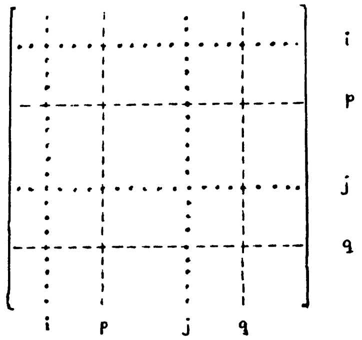
iii. Parallel Generalized Jacobi for Extracting the Eigenpairs

The fact that each of the (m/2)(m-1) transformations of (18) and (19) systematically annihilates the ij,ji terms of $\underset{\sim}{A}_{k,r+1}$ and $\underset{\sim}{B}_{k,r+1}$, and thereby causes only their respective ith and jth rows and columns to change, suggests considerable concurrency in a parallel implementation of the generalized Jacobi. By selecting a set of m/2 non-overlapping pairs of i,j indices, it is possible to perform m/2 parallel transformations on $\underset{\sim}{A}_{k,r}$ and m/2 similar transformations on $\underset{\sim}{B}_{k,r}$. The process is repeated (m-1) times, each time using a different set of non-overlapping indices. Completion of all (m/2)(m-1) transformations constitutes a typical Jacobi sweep that may be repeated until diagonalization is achieved.

For example, the first set of m/2 transformations may be $P_1(1,2)$, $P_2(3,4)$,..., $P_{m/2}(m-1,m)$. Their execution will result in:

$$\underset{\sim}{A}_{k,r+m/2} =$$
$$\underset{\sim}{P}^T_{m/2}(m-1,m) \ldots \underset{\sim}{P}^T_2(3,4)\ \underset{\sim}{P}^T_1(1,2)\ \underset{\sim}{A}_{k,r}\ \underset{\sim}{P}_1(1,2)\ \underset{\sim}{P}_2(3,4) \ldots \underset{\sim}{P}_{m/2}(m-1,m)$$
$$\underset{\sim}{B}_{k,r+m/2} = \qquad (35)$$
$$\underset{\sim}{P}^T_{m/2}(m-1,m) \ldots \underset{\sim}{P}^T_2(3,4)\ \underset{\sim}{P}^T_1(1,2)\ \underset{\sim}{B}_{k,r}\ \underset{\sim}{P}_1(1,2)\ \underset{\sim}{P}_2(3,4) \ldots \underset{\sim}{P}_{m/2}(m-1,m)$$

Suppose that N=m/2 processors are used to perform Equation (35). Each processor may be assigned one pair of the (1,2),(3,4),... indices, for which it needs to store only the corresponding row and column pairs of $\underset{\sim}{A}_{k,r}$ and $\underset{\sim}{B}_{k,r}$; i.e., a total of 4m values. Considering any two processors $\eta$ and $\xi$, the interaction between any two transformations $\underset{\sim}{P}_\eta(i,j)$ and $\underset{\sim}{P}_\xi(p,q)$ of the m/2 transformations in (35) is visualized schematically by the dotted (i,j) and dashed (p,q) rows and columns in (36):



(36)

As indicated by Table (1), the ii,jj,ij, and ji terms of rows i and j residing in processor $\eta$ are affected only by transformation with $P_\eta(i,j)$. However, all other i$\delta$ and j$\delta$ terms ($\delta$=1,...,m; $\delta \neq i \neq j$) are affected by column changes stemming from the remaining [(m/2)-1] transformations. For example, the ip, iq, jp, jq terms are changed not only by $P_\eta(i,j)$, but also by $P_\xi(p,q)$, thus becoming:

$$(A_{ip})_{k,r+m/2} = A'_{ip} + \beta_{qp} A'_{iq}$$
$$(A_{iq})_{k,r+m/2} = A'_{iq} + \alpha_{pq} A'_{ip}$$
$$(A_{jp})_{k,r+m/2} = A'_{jp} + \beta_{qp} A'_{jq} \qquad (37)$$
$$(A_{jq})_{k,r+m/2} = A'_{jq} + \alpha_{pq} A'_{jp}$$

where from Table (1), $\delta$ assumes p or q:

$$A'_{ip} = (A_{ip} + \beta_{ji} A_{jp})_{k,r}\ ; A'_{jp} = (A_{jp} + \alpha_{ij} A_{ip})_{k,r}$$
$$A'_{iq} = (A_{iq} + \beta_{ji} A_{jp})_{k,r}\ ; A'_{jq} = (A_{jq} + \alpha_{ij} A_{iq})_{k,r}$$

However, because the m/2 indices do not overlap, each of the [(m/2)-1] transformations affect different terms of rows i and j.

Instead of computing the eigenvectors at the end of the last sweep according to (21), data transmission can be eliminated if the eigenvectors are continuously updated at the same time that $\underset{\sim}{A}_k$ and $\underset{\sim}{B}_k$ are transformed by the P's. Only the simple scaling by diag $(1/\sqrt{B_{ii}})_{k,r+1}$ is deferred to the end. Similar to (35), an intermediate matrix of eigenvectors $\underset{\sim}{Q}_k$ is updated by m/2 transformations $\underset{\sim}{P}_1,\ldots,\underset{\sim}{P}_{m/2}$:

$$\underset{\sim}{Q}_{k,r+m/2} = \underset{\sim}{Q}_{k,r}\ \underset{\sim}{P}_1\ \underset{\sim}{P}_2 \cdots \underset{\sim}{P}_{m/2} \qquad (38)$$

In a parallel implementation of Equation (38), using m/2 processors each storing a row pair $\underset{\sim}{Q}_{i\delta}$, $\underset{\sim}{Q}_{j\delta}$, $\delta$=1,...,m with non-overlapping i and j indices, each processor updates four terms associated with each of the m/2 transformations. For example, the following four terms of the i,j row pair residing in any of the m/2 processors will be changed by a typical transformation $\underset{\sim}{P}_\xi(p,q)$:

$$(Q_{ip})_{k,r+m/2} = (Q_{ip} + \beta_{qp} Q_{iq})_{k,r}$$
$$(Q_{iq})_{k,r+m/2} = (Q_{iq} + \alpha_{pq} Q_{ip})_{k,r}$$
$$(Q_{jp})_{k,r+m/2} = (Q_{jp} + \beta_{qp} Q_{jq})_{k,r} \qquad (39)$$
$$(Q_{jq})_{k,r+m/2} = (Q_{jq} + \alpha_{pq} Q_{jp})_{k,r}$$

Again, since the m/2 indices do not overlap, the transformations in (39) affect different terms of rows i and j of $\underset{\sim}{Q}$. All processors can perform Equation (39) simultaneously on different rows. Thus, with N=m/2 processors, each storing two rows of each of $\underset{\sim}{A}_k$, $\underset{\sim}{B}_k$ and $\underset{\sim}{Q}_k$ corresponding to a pair of non-overlapping indices, the steps of the parallel generalized Jacobi technique are summarized as follows:

1. Each of the m/2 processors computes one pair of rotation coefficients $\alpha_{ij}$ and $\beta_{ji}$ according to (20). This requires 12q computational resources.

2. Each processor sends the two values of $\alpha_{ij}$, $\beta_{ji}$ of Step (1) to all other [(m/2)-1] processors in the network. In doing so, (m/2)$\mu$q resources are consumed.

3. Each processor updates: (a) its ii and jj values of the current rows of $\underset{\sim}{A}_k$ and $\underset{\sim}{B}_k$ according to the first two expressions of Table (1) using its own $\alpha_{ij}$ and $\beta_{ji}$; (b) the remaining terms of its current rows of $\underset{\sim}{A}_k$ and $\underset{\sim}{B}_k$ having column indices pq that match the rotation coefficients supplied by other processors in Step (2). Equations (37) are used for this purpose; (c) all terms of the stored pair of rows of $\underset{\sim}{Q}_k$ having column indices which match the m/2 pair of rotation coefficients. This is done according to Equation (39).

This 3-part step requires (12+12m+2m)q resources.

4. A new set of m/2 pairs of rows with unique non-overlapping indices is acquired by the m/2 processors. This may be done by a systematic row exchange according to the scheme described in Appendix (A). According to this scheme, corresponding rows of $\underset{\sim}{A}_k$ and $\underset{\sim}{B}_k$ are exchanged among processors, while the $\underset{\sim}{Q}_k$ rows remain stationary in their original processors. This requires 2m$\mu$q resources.

5. One Jacobi sweep is completed when Steps (1) to (4) are repeated (m-1) times, at which time the current values of off-diagonals in the current rows of $\underset{\sim}{A}_k$ and $\underset{\sim}{B}_k$ are tested for smallness according to:

$$(A^2_{i\delta}/A_{ii}\ A_{jj})_k \le 10^{-\varepsilon} \quad ; \quad (A^2_{j\delta}/A_{ii}\ A_{jj})_k \le 10^{-\varepsilon}$$

$$(B^2_{i\delta}/B_{ii}\ B_{jj})_k \le 10^{-\varepsilon} \quad ; \quad (B^2_{j\delta}/B_{ii}\ B_{jj})_k \le 10^{-\varepsilon}$$

$$\delta = 1,2,\ldots,m \quad ; \quad \delta \ne i \ne j \tag{40}$$

A "pass" is reported to halt the sweeps when all off- diagonals are small enough, and when all eigenvalues computed according to Equation (21) pass the convergence test

$$\|\Omega^J_{ii} - \Omega^{J-1}_{ii}/\Omega^{J-1}_{ii}\|_k \le 10^{-\varepsilon} \tag{41}$$

A total of 12mq resources are required each time the above convergence tests are performed.

6. Final collection of the converged eigenvalues and vectors from all N=m/2 processors requires 2.5 m$\mu$q resources.

Assuming that on the average $J_{max}$ - sweeps are needed for convergence, computation of the m eigenvalues and vectors by the parallel generalized Jacobi requires total computer time of the order:

$$T_{iii} \simeq m^2q\ (14 + 2.5\ \mu)\ J_{max} \tag{42}$$

iv. <u>Forward and Backward Passes</u>

When solving for the n x m unknowns $\underset{\sim}{X}$ in

$$\underset{\sim}{U}^H\underset{\sim}{U}\underset{\sim}{X}=\underset{\sim}{C} \tag{43}$$

a forward pass is first required to find $\underset{\sim}{Y}$, then a backward pass is performed to compute $\underset{\sim}{X}$;

$$\underset{\sim}{U}^H\underset{\sim}{Y}=\underset{\sim}{C} \quad ; \quad \underset{\sim}{U}\underset{\sim}{X}=\underset{\sim}{Y} \tag{44}$$

All $\underset{\sim}{A}$, $\underset{\sim}{U}$,$\underset{\sim}{U}^H$ are n x n with half bandwidth $b_s$ partitioned into $n_s$ rows. Each row is partitioned into $b_s$ column blocks of size s x s. Similarly, $\underset{\sim}{C}$, $\underset{\sim}{Y}$ and $\underset{\sim}{X}$ are n x m rectangular matrices, also partitioned into $n_s$ rows $\underset{\sim}{C}_i$, $\underset{\sim}{Y}_i$ and $\underset{\sim}{X}_i$; i=1,...,$n_s$, each of size s x m. From Equations (44):

$$\underset{\sim}{Y}_i = \underset{\sim}{U}^{-1}_{ii}\left[\underset{\sim}{C}_i - \sum_{k=i-b_s+1}^{i-1} \underset{\sim}{U}_{ik}\ \underset{\sim}{Y}_k\right] \tag{45}$$

and

$$\underset{\sim}{X}_i = \underset{\sim}{U}^{-1}_{ii}\left[\underset{\sim}{Y}_i - \sum_{k=i+1}^{i+b_s-1} \underset{\sim}{U}_{ik}\ \underset{\sim}{X}_k\right] \tag{46}$$

With N=$b_s$ /2 processors, Equation (45) may be executed in parallel for a typical row partition i=1,...,$n_s$ in five substeps. To begin with, as a result of performing the forward pass of Equation (45) on the (i-1)<u>th</u> row partition, two sets of $\underset{\sim}{Y}$ and $\underset{\sim}{U}$ partitions will have been stored in each processor (except the first). For example, processor #1 will have stored $\underset{\sim}{C}_i$, $\underset{\sim}{U}_{ii}$, $\underset{\sim}{Y}_{i-1}$, and $\underset{\sim}{U}_{i,i-1}$; processor #2 will have stored $\underset{\sim}{Y}_{i-2}$, $\underset{\sim}{U}_{i,i-2}$, $\underset{\sim}{Y}_{i-3}$ and $\underset{\sim}{U}_{i,i-3}$; and processor #N will have stored $\underset{\sim}{Y}_{i-bs}$, $\underset{\sim}{U}_{i,i-bs}$, $\underset{\sim}{Y}_{i-bs+1}$, and $\underset{\sim}{U}_{i,i-bs+1}$. During the first substep, all processors simultaneously multiply and add their contents. Thus, a typical processor such as #2 computes $-(\underset{\sim}{U}_{i,i-2}\ \underset{\sim}{Y}_{i-2} + \underset{\sim}{U}_{i,i-3}\ \underset{\sim}{Y}_{i-3})$, and #N computes $-(\underset{\sim}{U}_{i,i-bs}\ \underset{\sim}{Y}_{i-bs} + \underset{\sim}{U}_{i,i-bs+1}\ \underset{\sim}{Y}_{i-bs+1})$. The exception is processor #1 which performs $-(-\underset{\sim}{C}_i + \underset{\sim}{U}_{i,i-1}\ \underset{\sim}{Y}_{i-1})$. The time required for the first substep is of order 2ms$^2$, and the result is a partial sum residing in each processor. In the second substep, the cascade sum of the partial sums in all N processors is formed by adding the m x s contents of pairs of processors in the lower-numbered processor of each pair. This requires simultaneous passing of one m x s data block between the next neighbor processors of each pair. As a result, the full cascade sum of the quantity in parenthesis in Equation (45) is readily accumulated in processor #1 in total time of the order (1+$\mu$(msq)log$_2$N.

In the third substep, processor #1 computes $\underset{\sim}{Y}_i$ by multiplying $\underset{\sim}{U}_{ii}$ by the total sum obtained in the second substep in time of order ms$^2$q/2. All other processors remain idle during this substep. The purpose of the last two substeps is to store the needed data in the appropriate processors in preparation for performing the forward pass on the (i+1)<u>th</u> row partition.

Thus in the fourth substep, all $\underset{\sim}{Y}_i$ blocks are shifted one storage location toward the higher-numbered neighboring processor. For example, $\underset{\sim}{Y}_{i-1}$ is transferred from processor #1 to processor #2; $\underset{\sim}{Y}_{i-2}$ replaces $\underset{\sim}{Y}_{i-3}$ in the same #2 processor, while $\underset{\sim}{Y}_{i-3}$ is transferred to processor #3 to replace $\underset{\sim}{Y}_{i-4}$; simultaneously $\underset{\sim}{Y}_{i-4}$ replaces $\underset{\sim}{Y}_{i-5}$ in processor #3 while $\underset{\sim}{Y}_{i-5}$ is transferred to processor #4 to replace

$\underset{\sim}{Y}_{i-6},\ldots$,etc. This is done in parallel by all processors on s x m data blocks in time proportional to msq$\mu$. In the last substep, two s x s blocks ($\underset{\sim}{U}_{ik}$ and $\underset{\sim}{U}_{i,k-1}$) are downloaded from the host computer to each of the N-processors, where $k=i,\ldots,i-b_s+1$. This requires communication time proportional to $(2s^2+N-2)q\mu$. The total time required for performing the forward pass of (45) on $n_s$ row partitions consists of the above five substeps repeated $n_s$ times, and is denoted by $T_{iv}^{F}$.

$$T_{iv}^{F} \simeq mnq\ [\frac{5}{2}\ s + \log_2 N + \mu\ (2 + \log_2 N)] \qquad (47)$$

As can be seen from Equations (45) and (46), the time required for the backward pass $T_{iv}^{B}$ is essentially the same as (47), i.e., $T_{iv}^{B}=T_{iv}^{F}$.

## 5. Algorithm Efficiency and Speedup

By summing the results of Equations (25, 29, 32, 34, 42, and 47), the total time, T, required to complete the algorithm is found to be of order:

$$T \simeq mnq\ [(\alpha_0 + \alpha_1\ K_{max}) + \mu\ (\beta_0 + \beta_1\ K_{max})] \quad (48)$$

where $\alpha_0 = 2s\ (2 + s/m)$

$$\alpha_1 = [13s + 2\ \log_2 N + \frac{m}{n}\ (\frac{3n}{N} + 14\ J_{max} + 2\ \log_2 N)]$$

$$\beta_0 = (\log_2 N + 10s/m)$$

$$\beta_1 = [4(1 + \log_2 N) + \frac{m}{n}\ (2.5\ J_{max} + 2\ \log_2 N)]$$

The coefficients $\alpha_o$ and $\beta_o$, respectively, are computation and communication costs associated with Steps 1 through 3 of Table (2). These are fixed and do not depend on the convergence rate. On the other hand, $\alpha_1$ and $\beta_1$ are, respectively, computation and communication cost per simultaneous iteration $k=1,2,\ldots,K_{max}$. Both $\alpha_1$ and $\beta_1$ are functions of the parameters b,m,n,s,N as well as the maximum number of Jacobi sweeps, $J_{max}$.

According to our previous definitions, the algorithm efficiency $\epsilon^*$ and speedup $g^*$, are:

$$\epsilon^* = \frac{\alpha_0 + \alpha_1\ K_{max}}{(\alpha_0 + \alpha_1\ K_{max}) + \mu\ (\beta_0 + \beta_1\ K_{max})}, \qquad (49)$$

$$\text{and } g^* = \epsilon^* N$$

To illustrate the behavior of the efficiency $\epsilon^*$ in Equation (49), the representative values of problem parameters in Table (3) are considered. Because contributions of the maximum number of required Jacobi sweeps, $J_{max}$, to the coefficients $\alpha_1$ and $\alpha_2$ (and consequently to $\epsilon^*$) is made negligibly small by the small ratio of m/n, $J_{max}$ is arbitrarily taken equal to ten in subsequent discussions of $\epsilon^*$ and $g^*$. However, contributions of the maximum number of simultaneous iterations, $K_{max}$, to $\epsilon^*$ is not as obvious. In Figure (1), the efficiency $\epsilon^*$ is depicted for the three sets of parameters labled "A" in Table (3) for the range of $K_{max}$=0,1,2,5,10. As is observed from Figure (1), the efficiency of the parallel algorithm becomes rather insensitive to values of $K_{max}$ in their upper range. The total time, T, of Equation (48) behaves linearly with $K_{max}$ beyond the initial Steps 1 through 3 of Table (2).

TABLE (3)

Selected Problem Parameters

| | A | | | B | | | C | | |
|---|---|---|---|---|---|---|---|---|---|
| n | 16384 | | | 4096 | | | 4096 | | |
| b | 2048 | | | 512 | | | 256 | | |
| N | 128 | 64 | 32 | 64 | 32 | 16 | 64 | 32 | 16 |
| s | 8 | 16 | 32 | 4 | 8 | 16 | 2 | 4 | 8 |
| m | 256 | 128 | 64 | 128 | 64 | 32 | 128 | 64 | 32 |

In Figure (2), $K_{max}$=10 is used to construct Equation (49) graphically for cases A, B and C of Table (3). As illustrated, the algorithm is more efficient for larger problem order n and bandwidth b. The speedup can readily be obtained from Figure (3) by the simple multiplication $g^*=N\epsilon^*$. For example, using 128 processors in parallel, Case A can be solved more than 100-times faster than with a single processor.

## 6. Conclusions

A parallel algorithm is described for extracting m eigenpairs of generalized eigenvalue problems of large order n>>m. The algorithm combines power methods with a generalized Jacobi technique, both of which are known to have good convergence properties. Concurrency is introduced by partitioning the computational work load among N-processors during an initial one-time factorization step and during successive iterations. As Equation (48) indicates, the first is functionally dependent upon $\alpha_o$ and $\beta_o$ while the second is dependent upon $\alpha_1$ and $\beta_1$. As the number of required iterations $K_{max}$ increase, the iterative part of the calculations dominates the required computational resources as well as the efficiency and speedup of the algorithm. This is illustrated by Figure (1). In terms of efficiency and speedup, the algorithm performs best for problems with larger order n and bandwidth b.

### APPENDIX A

Five basic operations are defined in the following table:

| Oper # | Description | Example: $m=8$, $r^2=m/2$, $x=1$ |
|---|---|---|
| 1 | shift j indices to the right<br>$P_{\lambda,\nu} \Rightarrow P_{\lambda,\nu+x}$ if $\nu+x \le r$<br>$\Rightarrow P_{\lambda,\nu+x-r}$ if $\nu+x > r$ | 11: $1,\overrightarrow{2}$ 12: $3,\overrightarrow{4}$<br>21: $5,\overrightarrow{6}$ 22: $7,\overrightarrow{8}$<br>⇒<br>11: 1,4 12: 3,2<br>21: 5,8 22: 7,6 |
| 2 | shift j indices up<br>$P_{\lambda,\nu} \Rightarrow P_{\lambda-x,\nu}$ if $\lambda-x \ge 1$<br>$\Rightarrow P_{r+\lambda-x,\nu}$ if $\lambda-x < 1$ | 11 ↑ 1,2 12 ↑ 3,4<br>21 ↑ 5,6 22 ↑ 7,8<br>⇒<br>11: 1,6 12: 3,8<br>21: 5,2 22: 7,4 |
| 3 | shift j indices down<br>$P_{\lambda,\nu} \Rightarrow P_{\lambda+x,\nu}$ if $\lambda+x \le r$<br>$\Rightarrow \lambda+x-r,\nu$ if $\lambda+x > r$ | 11 ↓ 1,2 12 ↓ 3,4<br>21 ↓ 5,6 22 ↓ 7,8<br>⇒<br>11: 1,6 12: 3,8<br>21: 5,2 22: 7,4 |
| 4 | exchange j of $P_{\lambda,\nu}$ with i of $P_{\lambda,\nu+x}$ | 11: $1,\overrightarrow{2}$ 12: $\overleftarrow{3},4$<br>21: $5,\overrightarrow{6}$ 22: $\overleftarrow{7},8$<br>⇒<br>11: 1,3 12: 2,4<br>21: 5,7 22: 6,8 |
| 5 | diagonally exchange i of $P_{\lambda,\nu}$ with j of $P_{\lambda+x,\nu}$ | 11: 1,2 12: 3,4<br>21: 5,6 22: 7,8<br>⇒<br>11: 6,2 12: 8,4<br>21: 5,1 22: 7,3 |

I. Start with a set of m/2 non-overlapping set of i,j indices in each processor $P_{\lambda,\nu}$, e.g., $m=32$, $N=m/2=r^2$, $r=4$, $\lambda=1,2,\ldots,r$, $\nu=1,2,\ldots,r$, so that $P_{11}(1,2)$, $P_{12}(3,4)$,... $P_{44}(31,32)$. This is the first of the (m-1) combinations.

II. Generate $(r^2-1)$ combinations of (i,j) as follows:
   1. Do (r-1) times
      a. apply operation #1, (r-1) times with x=1
      b. apply operation #3, once with x=1
   2. Repeat operation #1, (r-1) times with x=1

III. Generate $(r^2-1)$ combinations as follows.
   1. Apply operation #4, once with x=1.
   2. Do (r-2) times
      a. apply operation #2, (r-1) times
      b. apply operation #4 with x=(r-2), or #1 with x=(r-2) (alternate between the two).
   3. Apply operation #2, (r-1) times with x=1.
   4. Apply operation #5 with x=1,2,..., (r-2).
   5. Apply operation #2 with x=(r-2).

# MATHEMATICAL MODEL PARTITIONING AND PACKING FOR PARALLEL COMPUTER CALCULATION

Dale J. Arpasi and Edward J. Milner

National Aeronautics and Space Administration
Lewis Research Center
Cleveland, Ohio 44135

Abstract -- This paper deals with the development of multiprocessor simulations from a serial set of ordinary differential equations describing a physical system. The identification of computational parallelism within the model equations is discussed. A technique is presented for identifying this parallelism and for partitioning the equations for parallel solution on a multiprocessor. Next, an algorithm which packs the equations into a minimum number of processors is described. The results of applying the packing algorithm to a turboshaft engine model are presented.

## Introduction

Multiple processors, operating together to solve a single problem, can, in many cases, decrease the time of calculation. This is important in time-critical applications, such as real-time simulation, where this technique can provide computational rates unachievable on a single processor or allow the use of lower cost hardware to provide the necessary computational capabilities. For certain classes of problems it is possible to configure a network of microcomputers to achieve the same throughput rate as a large mainframe computer at a lower initial and ongoing maintenance cost.

The parallel processing concept has opened new areas of research and development in hardware, software and theory. Some efforts sponsored by NASA Lewis are described in Refs. [1] to [6]. Techniques for developing mathematical models that can be solved efficiently on parallel processors is a key area of study. The first step in developing these multiprocessor models is to identify parallelism within the mathematical formulation of the problem. This requires a data flow analysis of the problem's equations and will identify the "critical path" and the minimum achievable calculation time. The next step is to arrange, or "pack" the noncritical path computations on the minimum number of processors so as to make maximum use of the available computing resources.

This paper presents a method of partitioning and packing equations for multiprocessor solution. Reference [6] gives a more detailed discussion of these techniques, including a comprehensive example of applying them to a turboshaft engine model.

## Computational Parallelism

A mathematical model of a physical system consists of a set of equations which describe, to some degree of accuracy, the response of that system to external influences (driving functions) over a limited range of operation. This range is defined in terms of the maximum and minimum values of the driving functions and, if time dependent, the maximum frequency or maximum rate of change of these functions. Generally, the object of this modeling effort is to provide a simulation of the physical system.

The prerequisite to developing parallel processor simulations is to be able to identify the parallel computational paths contained in the model. In general, a dynamic model can be programmed on a digital computer as a set of N computationally sequential equations of the form

$$X_K(ih) = f_K[X_m(ih),\ X_m((i - 1)h),\ \ldots,\ u(ih)]$$

where $X_K(ih)$ is the result of the $K^{th}$ equation at time ih. Here, h denotes the simulation time step or update interval of the model calculations. The arguments $X_m(ih)$ are the current values of the results of preceding equations in the model (i.e., m = 1 to K - 1), and $X_m((i - 1)h)$ are the past values of the results of all equations in the model. The argument u represents values obtained from sources external to the model which are always available at the start of the model computation sequence. The functional relationship between $X_K$ and its arguments is represented by $f_K$. Assuming an equation is an indivisible computational unit, then the parallelism in the model is determined by the arguments of each equation. That is, two equations, or sets of equations, can be computed in parallel within an update interval if their arguments are independent of the results of the others computed in that interval.

For example, a model of the form

$$X_1(ih) = f_1[X3((i - 1)h)]$$

$$X_2(ih) = f_2[X_1(ih)]$$

$$X_3(ih) = f_3[X_2(ih),\ X_3((i - 1)h)]$$

contains no parallelism since $X_3(ih)$ requires $X_2(ih)$ and $X_2(ih)$ requires $X_1(ih)$. These calculations must be done serially. However, the model

$$X_1(ih) = f_1[X_3((i - 1)h)]$$

$$X_2(ih) = f_2[u(ih)]$$

$$X_3(ih) = f_3[X_1(ih),\ X_2(ih),\ X_3((i - 1)h)]$$

does contain parallelism since $X_1$ can be computed at the same time as $X_2$.

Parallelism due to decoupled or loosely coupled equation sets is easily identified from the physical nature of the model. A more difficult task is the identification of parallelism in a set of closely coupled equations, where the process dynamics dictate the use of current arguments in solving for equation results. For instance, suppose a model contains the following set of equations:

$$X_1(ih) = f_1[X_5((i - 1)h), u(ih)]$$

$$X_2(ih) = f_2[X_5((i - 1)h)]$$

$$X_3(ih) = f_3[X_2(ih)]$$

$$X_4(ih) = f_4[X_1(ih), X_2(ih)]$$

$$X_5(ih) = f_5[X_3(ih), X_4(ih), X_5((i - 1)h)]$$

The variable $X_1$ can be computed at the start of the calculation interval, since it is a function of the past value of $X_5$ and the external variable u. $X_2$ may also be computed at the start of the interval. However, the calculation of $X_3$ must be delayed until $X_2$ has been determined, the calculation of $X_4$ must be delayed until both $X_1$ and $X_2$ are determined, and the calculation of $X_5$ must be delayed until both $X_3$ and $X_4$ have been determined. As shown in Fig. 1(a), three computational paths can be identified which can be assigned to three different computers in the simulation. Note that "wait states" have been inserted to insure the currency of the arguments. That is, equation calculation is delayed until current argument values become available. The $X_3$ calculation is shown to be delayed slightly for the transfer of $X_2$. The shaded areas (time slots) in Fig. 1(b) indicate the time available for result transfer to computer number 1. The calculation of $X_1$ and $X_3$ can take place anywhere in the time slot.

The detection of this type of computational parallelism can become burdensome when the equation set becomes large. The technique, however, can be automated. Related to this problem of partitioning is the problem of allocation (i.e., packing these paths into a minimum number of computers without extending the update time). Figure 1(b) demonstrates packing of the paths defined in Fig. 1(a). Arbitrary calculation times of $TX_1$, $TX_2$, $TX_3$, $TX_4$, and $TX_5$ have been assigned to the equations producing results $X_1$ through $X_5$, respectively. The time $TX_1$ includes the time required to obtain the value of u. Note in Fig. 1(b), that, because of the calculation times, the $X_2$ - $X_4$ - $X_5$ path is critical in that it contains no idle states. This path, therefore, dictates the minimum possible update time ($\Delta T = TX_2 + TX_4 + TX_5$). The paths $X_1$ and $X_3$ are assigned to separate computers. Packing in this example is a trivial task, since the $X_3$ calculation can be moved onto computer number 2 to be calculated during the idle period, as shown in the figure.

In many cases, efficient packing requires shifting equations in their time slots. This causes a ripple effect on the time slots of other equations which can complicate the packing problem. Because of the nature of the packing problem, a unique solution to the development of a packing algorithm does not exist. There are many ways to pack most parallel models.

In the following sections partitioning and packing algorithms that have been developed at NASA Lewis are discussed. These algorithms were tested with a model of a turboshaft engine and detailed results are presented in Ref. [6].

## Partitioning

To begin the discussion of the partitioning algorithm, certain terms should be defined. A mathematical model is a set of equations, written to define the characteristics of a physical system to some desired degree of accuracy. A program is a sequential set of digital equations and supporting information (e.g., variable and constant definition) which define the mathematical model within the constructs of a programming language. A path is a subset of these equations which, because of interrelationships between arguments and results, contains no parallelism. Partitioning is the transformation of the program equations into a number of paths which may be calculated in parallel. Packing is the combination of paths into a minimum number of processors (computers) which provide computation of the model within a prescribed update interval. The critical path is the longest path and the prescribed update interval must be greater than or equal to the calculation time of the critical path.

In this discussion of partitioning it is assumed that a program is given. That is, these equations, when executed serially, provide the required results. No assumptions are made concerning the parallelism of computational operations contained in the program equations.

$$x = a*y + b*z$$

contains parallelism (i.e., a*y can be calculated in parallel with b*z) which will be ignored since we are concerned with partitioning at the equation level and not parsing. For purposes of this discussion, the above equation will be considered as

$$x = f(a, y, b, z)$$

where f is some single operation. Therefore, equations will be assigned to paths in their entirely and not broken up into more primitive result-argument relationships.

As indicated in the last section, partitioning requires the establishment of result-argument relationships for the serial set of equations in order to develop computational paths. It is also necessary to know the calculation time of each equation. The program must be processed to provide this information. For this effort, the result-argument relationships and the calculation time information are outputs of the multiprocessor programming utility RTMPL [2], [3]. The primary function of this utility is to translate a structured program of the mathematical model into assembly language for the simulation processor(s). As an option, the utility also provides information on the result and arguments of each equation, the processor operations necessary to obtain the result, and the processor calculation time for each operation. For the equation

$$X = y + z$$

The processor operations to compute the equation are: load register R1 with z (requires 8 time units), add variable y to R1 (16 time units) and store R1 as the value of variable X (8 time units). This type of information is generated for each equation in the program.

Consider the close-coupled example in the previous section. The first step in the partitioning process is to convert utility generated information into the form needed for partitioning. Dependent arguments are those which are the results of previous program equations calculations in the update interval (e.g., $X_1$ is a dependent argument of $X_4$). These are the drivers for partitioning since their current values are required before the computation sequence can continue. The independent arguments u and $X_5$ do not affect partitioning since only past values are used. The calculation time for each equation is determined by adding the calculation times of the given processor operations.

The time at which an equation can start is determined by the arguments and calculation time of each equation. The first equation of a set only has independent arguments and thus, can always start at time 0 (measured from the beginning of the calculation update interval). It can never require results from calculations in the current update interval since none are yet available. An equation can end at the time obtained by adding its calculation time to the time it can start. The general formula for obtaining this time is

$$\text{CANSTART(RESULT)} = \text{MAX(CANEND(ARG 1), CANEND(ARG 2), ..., 0)}$$

$$\text{CANEND(RESULT)} = \text{CANSTART(RESULT)} + \text{CALCTIME(RESULT)}$$

where ARG1 is the first dependent argument, etc. This formula is applied sequentially to each equation in the program.

Once these attributes have been established for each program equation, the identification of computational paths contained in the program can begin. The algorithm used for path identification is shown in Fig. 2. Its purpose is to identify all sequences of equations which contain no parallelism and which must be computed serially. These paths are organized into a linked list called PATHLIST. The paths in PATHLIST are ordered in terms of decreasing path calculation time. Therefore, the first path in PATHLIST is the critical path. To form a path, the algorithm selects the program equation, having the maximum CANEND time, and which has not already been assigned to a path. This is the result equation of the path. The next equation selected is the one which produces a result used as a dependent argument of the result equation. If more than one equation result is used as a dependent argument, then the one with maximum CANEND time is selected. The selected equation then is inserted in front of the result equation in the path. The path formation process continues until an equation is inserted which has no dependent argument equations which are not already assigned to a path. Paths are formed until all program equations have been assigned.

Partitioning has been discussed in terms of equations that produce values of variables. Often, mathematical models contain statements that do not produce values. Two common examples are conditional statements (e.g., IF ... THEN ... ELSE) and command statements (e.g., I/O operations). The calculation time of such a statement must be combined with a preceding or following equation. This could impose limitations on program structure and is a subject for future study.

## Packing

The partitioning process produces a number of paths consisting of equations which must be computed serially and a table of information on each equation. The final task in the process of formulating a multiprocessor model is to pack the paths for assignment to a minimum number of processors. The first path in our list has the largest calculation time due to the partitioning algorithm. This is called the critical path and its calculation time is the minimum time in which the model can be computed no matter how many processors are used. The number of paths identified through partitioning is usually greater than the minimum number of processors necessary.

The minimum number of processors necessary to implement a multiprocessor simulation depends on how fast the simulation must be computed. This update time must be specified prior to packing. The simulation time step h is usually based on stability and dynamic accuracy requirements. For real-time applications, the update time $\Delta T$ must be equal to h. The update time also specifies when the computations must end. The first step in packing is to determine when each equation must end using the specified update time.

To determine when an equation must end, we begin with the state variables (defined here as those variables whose current values are not used as arguments in the model, but appear as results of model equations). The state variable computations will be the last computations performed, and thus must end at the prescribed update intervals. The calculation of equations which are dependent arguments of these variables must end no later than the time at which the state variable calculations must start. The times when subsequent equations in the result/argument string must end are similarly determined. Since a variable can be used as a dependent argument in more than one equation, care must be taken that the earliest time, arrived at after all paths are analyzed, is used to specify when that equation must end.

We now have determined when an equation can start, can end, and must end. These are termed equations attributes. Since the paths are serial they can also be assigned these attributes: A path can start when its first equation can start, a path can end when its last equation can end, a path must end when its last equation must end, and additionally, the calculation time of a path is the summation of the calculation times of its equations. This is sufficient information to pack the paths.

The solution to the packing problem is not unique in that many arrangements of paths in processors can result in a satisfactory solution.

The packing algorithm, shown in Fig. 3, was designed to achieve the minimum number of processors. Other requirements which may be imposed, such as memory size limitations and interprocessor data transfer limitations were not imposed on the algorithm.

As input, the algorithm requires: (1) that all paths be specified in a linked list called PATHLIST in order of decreasing calculation time; (2) that the required update time of the simulation, ΔT, is specified and that the attributes of each equation and path (CANSTART, CANEND, MUSTEND, CALCTIME) have been determined as described above.

The packing algorithm creates processors as needed and inserts paths from PATHLIST according to a hierarchy of relationships between existing equations in a processor and the equations in the unpacked paths. When a processor is created, the path with the longest calculation time in PATHLIST is inserted. Next, the paths which are related to paths already in a processor are tested to see if they fit (see discussion of TESTFIT algorithm below). If so, they are inserted, if not, they are placed in a carry-over list.

Then, paths in pathlist which are unrelated to the equations in the processor are tested. If one of these is inserted, unrelational testing is ended and relational testing begins again. When no other paths can be inserted into a processor, another processor is created. This process continues until all paths in PATHLIST are inserted into a processor.

Relational testing is prioritized. All unpacked paths which provide critical arguments are tested first. (A path is considered to provide a critical argument if the result of the last equation in the path (EL) is an argument of a processor equation (EP) and

MUSTEND (EL) = MUSTEND (EP) - CALCTIME (EP)

Next, other related paths are tested. Then paths in the carry over list (which was formed from paths which were related to equations packed into previously formed processors, but not yet packed) are tested.

Paths are tested for insertion on an equation by equation basis using the test fit algorithm shown in Fig. 4. First the attributes (CANSTART, CANEND, MUSTEND, AND, CALCTIME) of all program equations are saved. This is necessary because inserting an equation into a processor can cause a ripple effect on the attributes of other equations. If the whole path does not fit, any equation of the path, inserted into the processor, must be removed and the attributes of affected equations restored.

The ripple effect is illustrated in Fig. 5. Assume a processor contains two equations (A and B) and that it has been determined that equation (C) can be inserted between them. The calculation time of each equation is shown as the shaded areas. For packing purposes, the calculation of each equation can take place anytime between its CANSTART time and its MUSTEND time.

The space available for C is the difference between the time at which B must end and A can end minus the calculation time of B. Equation C will be inserted to start directly after A can end. The calculation of B will be delayed until C can end. Note that the difference between the MUSTEND and CANEND times of A and C have been reduced to zero by the positioning of C, and that the time difference for B has been reduced. The primary impact of these changes is to reduce the space in the processor available for packing other paths. There is also a secondary impact of equal importance. By increasing the times at which C and B can end, any unpacked equations which use these equations as arguments have their starting times delayed. Similarly, by reducing the MUSTEND times of A and C, the MUSTEND times of any unpacked arguments of these equations are moved up. These effects tend to reduce the slot sizes of unpacked equations restricting the range of time into which they can be packed into a processor. Also, these ripple effects may introduce computational gaps within unpacked paths.

After the attributes are saved (Fig. 4), the equations within a path are ordered in terms of decreasing CANEND times for insertion testing. That is the latest equation will be tested first and the earliest last.

The processor equations are arranged in sequential order where EP(1) is the earliest equation and EP(n) is the latest equation. Testing to determine if a path equation (E(i)) can be inserted into the processor involves the identification of all slots between any two processor equations (EP(j - 1), EP(j)) where the equation fits. The processor end points (i.e., EP(j) = EP(1) and EP(j - 1) = EP(n)) must also be considered. Because of the argument and result relationships between E(i) and the processor equations it is required that the range of processor equations be limited for testing purposes. Let the end points of the range be designated by EPE and EPL (the earliest and latest processor equations respectively, before which E(i) may be inserted). This range is established as follows: If E(i) is an argument of a processor equation, then EPL is the earliest processor equation of which E(i) is an argument (EPE = EP(1)); if any processor equation is an argument of E(i), then EPE is the one following the latest of these and EPL is the last processor equation plus one (end point); if E(i) is unrelated to any processor equation, then EPE = EP(1) and EPL is the last processor equation plus one.

Once the range of testing has been established, all slots within that range are tested to determine if E(i) fits. The fit criterion is as follows:

1. If EP(j) = EP(1) then CANEND* (E(i)) = CALCTIME (E(i)) else CANEND* (E(i)) = CANEND (EP(j - 1)) + CALCTIME (E(i));

2. If CANEND* (E(i)) < CANEND (E(i)) then CANEND* (E(i)) = CANEND (E(i));

3. If EP(j - 1) = EP(n) then MUSTEND* (E(i)) = ΔT else MUSTEND* (E(i)) = MUSTEND (EP(j)) - CALCTIME (EP(j));

4. If MUSTEND* (E(i)) > MUSTEND (E(i)) then MUSTEND* (E(i)) = MUSTEND (E(i));

5. If [[CANEND* (E(i)) < = MUSTEND (E(i))] and [CANEND* (E(i)) < = MUSTEND* (E(i))]], then E(i) fits.

The asterisk indicates the attributes of E(i) if it were inserted into the slot between EP(j - 1) and EP(j).

If it is established that E(i) can fit in more than one slot, the testfit algorithm proceeds to select the slot into which E(i) best fits. The best fit criterion is as follows:

If a slot exists such that

$$\text{CANEND* (E(i)) - CALCTIME (E(i)) - CANEND (EP(j - 1)) = 0}$$

then this slot is selected. Otherwise, the latest slot which maximizes

$$\text{[MUSTEND* (E(i)) - CANEND* (E(i))]}.$$

is selected.

This criterion provides for efficient packing by eliminating processor idle time if possible, and if not, then the ripple effect from insertion is minimized.

Once a slot is selected, the equation is inserted and the attributes of all program equations are updated to reflect the insertion. If any path equation cannot be inserted into the processor, path equations which have already been inserted are removed from the processor, the original attributes are restored to the program equations and the Test Fit algorithm ends.

## Results

The packing algorithm was programmed in Pascal, along with the partitioning algorithm. It was then tested on a turboshaft engine model. The results, in terms of percent processor utilization, are presented in Table I. The first column is the update time ΔT specified prior to packing. It is given in terms of machine cycles. In this case, four processors were required. The second column gives the number of processors required for packing. The remaining columns show the percent utilization of the update time in calculating each processor's assigned equations. The first specified update time (5666 cycles) was the minimum possible time and corresponds to the critical path calculation time. The second update time selection (10 000 cycles) required two processors. Note that the percent utilization of the last processor in each case exceeds the summation of time available on the other processor(s). The algorithm, therefore, functioned satisfactorily.

Since the packing algorithm does not account for data transfer times, it is possible that the available time between when a variable is computed on one processor and when its value is required for computation on another processor will be less than the time required to transfer the variable between the processors. The effect of this will be to increase the effective calculation time of the packed simulation, and therefore, to increase the minimum achievable update time. Data transfer effects may be significant for multiprocessor systems with inefficient data transfer mechanisms or for simulations that require large volumes of data transfer between processors. Future work in the development of a packing algorithm should include a study of the effects of data transfer. While these effects will increase the critical path time, and therefore, the minimum update time, proper consideration of data transfer will minimize this increase and provide far more efficient packing.

## Concluding Remarks

The algorithms and considerations presented for partitioning and packing mathematical models for calculation on parallel processors have simplified the development of multiprocessor simulations at Lewis. Evaluation of the packing algorithm will continue as other multiprocessor simulations are developed. Work on a completely automated programming package is in progress, which will take a structured serial statement of a mathematical model, detect this parallelism, and provide load modules for the required number of processors.

The authors welcome discussions of the techniques presented in the paper, related techniques, and developments in the many other aspects of multiprocessor simulation.

## Abstract

The specification of arithmetic expressions by means of (i) ambiguous context free grammars and (ii) context sensitive grammars is considered. A CSG is developed which selects the balanced tree most suitable for parallel execution. The possibilities of parsing an arithmetic expression by using the grammar and constructing a replacement syntaxanalyser module for a parallel compiler are discussed.

## Introduction

In recent years much work has been done on the problem of "balancing arithmetic trees, Ashoke [4] Evans and Williams [8] and Evans and Abdollazadeh [7]. The principle behind this process being to divide an arithmetic expression into two parts of comparable computational 'size' which can then be evaluated at the same time on different processors and thus reduce the time required to evaluate the entire expression. The smaller subexpressions formed as a result of this dissection can then be treated in a similar fashion until we reach a level at which such processing is uneconomical or unnecessary.

Until now the algorithms have relied on explicit knowledge of the special (algebraic) properties of the arithmetic operators involved. Because we would like to be able to apply our tree manipulations to parts of a program other than arithmetic expressions we restrict the properties used to (i) associativity of certain like operators and (ii) precendence of multiplicative operations over additive ones. These properties not only prove to be the most useful, but also appear in numerous other constructions within high-level languages and lend themselves to specification by formal grammars.

After preliminary discussion of relevent segments of language theory and of the structure of arithmetic expressions we derive suitable grammars for two classes of arithmetic expressions. We conclude the paper with a discussion of how this work may be extended to more general situations and the problem assoicated with parsing the languages generated by these grammars.

## Some Elements of Language Theory

The grammars presented later in this paper are related to a new class of operator precedence grammars. In order to facilitate their description some terminology is required. This is fairly standard and can be found elsewhere (eg Aho and Ullman [3])) but is included here for completeness. In these definitions we assume familiarity with basic set theory.

A phrase-structure grammar (PSG) is an algebraic structure consisting of an ordered 4-tuple (N,T,P,S) where N and T are non-empty finite alphabets of non-terminal symbols and terminal symbols respectively such that $N \cap T = 0$ and $N \cup T = V$ where V is called the vocabulary of G. P is a set of productions, $P \subseteq V^+ x V^*$ and, assuming the symbol → not to be in V, $(\alpha, \beta) \epsilon P$ is usually written as

$$\alpha \rightarrow \beta$$

Finally $S \epsilon N$ and S is called the start symbol.

Given $w,y \epsilon V^*$, then w directly derives y if $w=z_1uz_2$ and $y=z_1vz_2$ where $z_1,z_2,v \epsilon V^*$, $u \epsilon V^+$ and $u \rightarrow v \epsilon P$ and is written as $w \Rightarrow y$.

If now w and y are words over V and there is a finite sequence $w_0,w_1,w_2, \ldots w_r$ where $w_0=w$, $w_r=y$ and $w_{i-1} \Rightarrow w_i$ $(i=1,\ldots,r)$ then we say that w derives y, written as $w \overset{*}{\Rightarrow} y$. Moreover if $\alpha \epsilon T^*$ and $S \overset{*}{\Rightarrow} \alpha$ then $\alpha$ is a sentence generated by G. Thus the language, L(G) generated by G is $\{x : x \epsilon T^* \alpha \nu \phi\ S \overset{*}{\Rightarrow} x\}$. Where G is understood we can define $L(X) = \{x : x \epsilon T^*, X \epsilon N \text{ and } X \overset{*}{\Rightarrow} X\}$.

Let G=(N,T,P,S) be a PSG as described above. such a grammar is called Chomsky Type 0. If each element of P is of the form $z_1uz_2 \rightarrow z_1vz_2$ where $z_1,z_2\ \epsilon V^*$, $u \epsilon N$ and $v \epsilon V^+$ then G is said to be context sensitive (a CSG), or Chomsky Type 1. An alternative restriction is that if $w \rightarrow y\ \epsilon P$ then w and y should be such that $1 \leq |w| \leq |y|$.

If the replacements may be carried out regardless of context then we may replace 'contexts' $z_1$ and $z_2$ by the empty string, $\Lambda$, and obtain the weaker restriction that if $w \rightarrow y \epsilon p$ then $w \epsilon N$ and $y \epsilon V+$. This restriction is satisfied by context-free or Chomsky Type 2 grammars, (CFG'S).

An important subset of CFG's is the so called operator grammars. These are grammars in which all productions are such that no two non-terminals are adjacent in any right-hand side of a production. For the definition of precedence relations and operator precedence grammars, see [3]. The symbols <•, = and •> denote precedence relations and provided that at most one such relation holds between any two elements of $T \cup \{\$\}$ then the associated operator grammar is called an operator precedence grammar.

## Structure of Arithmetic Expressions

For any expression we need to consider all admissible tree structures and from these select one most suitable for parallel execution. We say a tree is admissible if, by evaluating the subexpressions in the order defined by corresponding subtreees, evaluation of the expression associated with the entire tree is arithmetically correct for all legal assignments of numerical values within the expression.

Example: For the expressions 7 - 3 + 2 the tree in Figure 1 (a) corresponds to the valuation (7 - 3) + 2 = 6 and is admissible, but the tree in 1 (b) infers the calculation 7 - 3(+2) = 2 and is inadmissible.

Eventually it will be necessary to specify the processing of arbitrary well-formed arithmetic expressions consisting of identifiers a, b, c, ... etc., each associated with a numeric quantity, the operators +,-,* and /, and the usual parentheses.

However, mindful of the desire to be able to extend this methodology to manipulation of other aspects of programming languages we shall concentrate on expressions most amenable to the process being developed here. Identification of the relevent algebraic properties is readily achieved by examination of the rules of elementary arithmetic.

Our concern is with expressions involving quantities of type real. Mathematically, the reals are an infinite set of numbers on which the two operations of addition (+) and multiplication (*) are defined. Computationally, any implementation of real arithmetic uses only a (comparatively, very small) finite set of numbers and often encounters situations where the result of an addition or multiplication is simply not defined; resulting in overflow conditions[a] and hopefully a halt in the proceedings.

Using parentheses to indicate the desired order of evaluation, the field of real numbers R is subject to the following 9 axioms:

1. Addition is commutative
   a+b = b+a for all a,b $\epsilon$R
2. Addition is associative
   (a+b)+c = a+(b+c) for all a,b,c $\epsilon$R
3. There is a specific x$\epsilon$R such that
   x+a = a for all a$\epsilon$R
   x is called zero and usually written 0.
4. For each a$\epsilon$R there corresponds an element b$\epsilon$R such that
   a+b = 0
   b is the additive inverse of a, usually written -a or (-a).
5. Multiplication is commutative
   a*b = b*a for all a,b$\epsilon$R
6. Multiplication is associative
   (a*b)*c = a*(b*c) for all a,b,c$\epsilon$R
7. There is a specific y$\epsilon$R\{0} such that
   y*a = a for all a$\epsilon$R
   y is the multiplicative identity and is usually denoted by 1.
8. For each a$\epsilon$R\{0} there is an element c$\epsilon$R such that a*c = 1
9. Multiplication distributes over addition
   a*(b+c) = (a*b)+(a*c) for all a,b,c$\epsilon$R.

Subject to the calculations being carried out within the limits determined by an implementation, the arithmetic is fully and strictly as defined by these nine rules. However, in order to make the expressions more easily understood various conventions are adopted. First, subtraction and division are introduced and defined in terms of additive and multiplicative inverses viz.

$$a-b \overset{def}{=} a+(-b) \qquad a/b \overset{def}{=} a*(b^{-1})$$

Second, in order to reduce the necessity for some parentheses, it is assumed that multiplication (and hence division) take precedence over addition (and subtraction)
ie a*b+c means (a*b)+c and a+b*c means a+(b*c)

Following the concepts of admissibility and generalization we choose not to allow tree transformations based on commutativity or distributivity. This is because these properties are very special and hence do not easily generalize. They are also of questionable benefit in reducing execution time of expressions, (see Abdollahzadeh [1] for details). In terms of tree transformations the manipulations are as in Figures 2 and 3 respectively; commutativity requires reordering of leaves in the trees and distributivity involves deletion/creation of terminal and non-terminal nodes.

Axioms 3,4,7 and 8, involving identities and inverses, serve to define the auxiliary operations of subtraction and division. If these operations are not implemented directly but via the process of constructing inverses then they need not be considered further. Notwithstanding this fact most computers have explicit subtraction (and, getting away from most micro-processors, division) instructions which are more awkward to manipulate. The subtraction operation being subject to the derived rules as follows. By definition

$$x-y-z = x+(-y)+(-z)$$

This second expression can then be evaluated either as

$$(x+(-y))+(-z) = (x-y)-z$$

or, as

$$x+((-y)+(-z)) = x+((-1)*y+(-1)*z)$$
$$= x+(-1)*(y+z) = x-(y+z)$$

It therefore follows that both the trees in Figure 4 are admissible for this expression and to be consistent with our earlier remarks on tree tramsformations we reject the form in Figure 4 (b). This emphasises the left associativity of subtraction. Similar arguments apply to division.

[a] This is in contrast to calculations suffering loss of accuracy due to round-off error. When specific orders of evaluation are required in order to minimize this effect, parentheses can be used as noted below.

This leaves us with the associativity of addition and multiplication, and the precedence of multiplication over addition.

We now turn our attention to the grammatical specification of admissible trees for arithmetic expressions that allow associative transformations and assist in the selection of the admissible tree most suitable for parallel execution.

### Expressions Involving a Single Associative Operator

The classical grammar central to our considerations is:

$E \to E+T \mid T$ , $T \to T*P \mid P$ , $P \to (E) \mid I$ (Grammar $G_1$)

$G_1$ involves two operators and hence we shall initially only use one layer of it, namely the sub-grammer $G_2$.

$E \to E+T \mid T$ (Grammar $G_2$)

The sentences derived from E in $G_2$ are of the form
T, T+T, T+T+T, ... etc.

Moreover a typical derivation in $G_2$ is

$$E \Rightarrow E+T \Rightarrow E+T+T \Rightarrow E+T+T+T \Rightarrow E+T+T+T+T \Rightarrow T+T+T+T$$

with the derivation tree in Figure 5 (a).

The corresponding arithmetic tree is given in Figure 5 (b).

Symbolically (ie syntactically rather than arithmetically). $L(G_2)=\{T(+T)^n : n \geq 0\}$. Now this language can also be written as $\{(T+)^n T : n \geq 0\}$ and this gives rise to a syntactically equivalent grammar $G_3$.

$E \to T+E \mid T$ (Grammar $G_3$)

However the underlying syntactic structure, and therefore any 'natural' semantic ordering, associated with $G_3$ is as shown in Figure 6. Figure 6 depicts the $G_3$ derivation of the same sentence as in Figure 5.

In grammar $G_2$ the left recursion [3] indicates the left associativity of addition and gives rise to the precedence relation + •> +. Similarly the right recursion in $G_3$ yields right associativity and + <• +. Notice also that both $G_2$ and $G_3$ are unambiguous and hence there is only one admissible semantic structure for any sentence in each of the grammars. However, since addition is associative (rather than just left- or right-associative), there are, in non-trivial examples, very many admissible trees. To enable syntactic generation of these trees we combine $G_2$ and $G_3$ into $G_4$

$E \to E+T \mid T+E \mid T$ (Grammar $G_4$)

Now $G_4$ is ambiguous and gives rise to, amongst others, the five semantic trees depicted,in Figure 7.

$G_4$ incorporates the precedence relations + <• + and + •> + and leads to the definition of an extended precedence relation, namely $^{\bullet>}$ . Formally: within an operator grammar, given terminal (operator) symbols a and b, we say that a and b are of comparable precedence (written a $^{\bullet>}$ b) iff a <• b and a •> b. Thus, from $G_4$ we may obtain the precedence table in Figure 8.

In fact $G_4$ can generate all admissible trees for sentences in $L(G_2)$ but by the deterministic nature of context-free parsing algorithms, even when acting on ambiguous grammars, such algorithms will always give a tree similar to those in Figure 5 (b) or 6 (b). It is argued elsewhere, Evan and Adbollazadeh [7] that the most suitable tree for parallel execution of the expression T+T+T+T+T is that given in Figure 7 (b) and we now set about the problem of isolating this particular tree from all admissible trees for the expression.

Limiting consideration to expressions built from the addition of terms (T) we can always overcome the selection problem by the inclusion of syntactic sugar in the form of parentheses. Of course, this is cheating, expecting the programmer to analyse the expression for himself, however it helps to motivate the grammatic constructions that will eventually lead to automatic balancing.

Explicitly, using parentheses to indicate the tree structure, the expressions $E_n$ involving n terms ($T_i$) and n-1 operators are:

$$E_1 = T_1,\quad E_2 = (T_1+T_2),\quad E_3 = (T_1+T_2)+T_3,$$
$$E_4 = ((T_1+T_2)+(T_3+T_4))$$
$$\ldots\ E_n = ((\ldots(T_1+T_2)+(T_3+T_4))+\ldots\ldots+T_n)\ldots)$$

Obviously, when the value of n is not a power of 2, we cannot represent the structure of the expression $E_n$ by a tree which is balanced and in which all subtrees are balanced. In such cases we balance the subtrees from left to right, (the rationale for this is given in Evans and Abdollazadeh [7]). To particularize our use of the word 'balanced' we define its use in two technical terms. Both of these are recursive and they recurse with respect to the height of a tree.

The height, h(t) of the binary tree t is such that,

(i) $h(t) = 0$ if t is a tree associated with an expression involving no operators,

and (ii) $h(t) = \max(h(t_1), h(t_2))+1$ if t is composed of two subrees $t_1$ and $t_2$, joined by the binary operator op, ie $t=t_1$ op $t_2$.

A complete balanced binary tree (CBBT) of height n is (i) any tree of height n=0, or (ii) a tree corresponding to the expression $t_1$ op $t_2$ where $t_1$ and $t_2$ are CBBT's of height n-1.

It follows immediately that the CBBTs associated with the language $\{T(+T)^n : n \geq 0\}$ are those derived from expressions $E_n$ where $n=2^m$ for some m, ie trees of height m involving n operands.

A (left-to-right) balanced binary tree (BBT) is either (i) a trivial tree of height 0 or (ii) $t_1$ op $t_2$ where $t_1$ is a CBBT and $t_2$ is a BBT and $h(tl) \geq h(t_2)$.

A consequence of the definition of BBTs is that the BBT involving n operands is of height p where $2^{p-1}<n\leq 2^p$; moreover, by isolating non-trivial CBBTs in parentheses as soon as such a structure is recognized, we can deduce the form of any BBt while processing it from left to right. Using multiplicative notation to indicate duplicity of structure the process can be written explicitly as:

$E_1 = T,\ E_2 = T+T=(E_1+E_1)=2E_1,\ E_3 = 2E_1+E_1=(E_2)+E_1$

$E_4 = (E_2)+E_1+E_1=(E_2)+(E_1+E_1)=E_2+E_2)=2E_2$

$E_5 = (E_4)+E_1,\ E_6 = (E_4)+(E_1+E_1)=(E_4)+2E_1=(E_4)+(E_2)$

$E_7 = (E_4)+(E_2)+E_1\{=(E_4)+E_3\},\ E_8 = (E_4)+(E_2)+(E_1+E_1$

$=(E_4)+(E_2)+(E_2)=(E_4)+2E_2=(E_4)+(E_4)=2E_4$

$$\text{and } E_n = \{ \begin{array}{ll} 2E_{2^{p-1}} & \text{when } n=2^p \\ E_{2^{p-1}}+E_q & \text{where } 2^{p-1}<n<2^p \\ & \text{and } q<2^{p-1} \end{array}$$

Diagrammatically the balanced structure of $E_6$, $E_7$ and $E_8$ is indicated in Figure 9.

As will be seen from the right subtrees of the diagrams in Figure 9, if the tree is complete ($E_2$ in Figure 9) but of a smaller height then the left subtree ($E_4$ in Figure 9 (a), then the height of the right tree is increased by one ($E_3$ in Figure 9 (b)) and the previous subtree inserted as the left part ($E_2$ in Figure 9 (b)). Otherwise we step down the right subtree to find its largest complete component and perform the same process at a lower level. It therefore follows that a 'balancing' grammar needs to keep track of the heights (or at least the difference between heights) of adjacent subtrees.

Recall that the height of the balanced tree for $E_n$ is p where $2^{p-1}<n\leq 2^p$ and its structure is given by $E_{2p-1}+Eq$ where $q<2^{p-1}$. Hence the $(2^{p-1})$th operator is at the top of the tree, the $(2^{p-2})$th operator is one level lower, the $(2^{p-3})$th operator is two levels lower, and so on.

The grammar, $G_5$ mimics our structuring process in so far as whenever a BBT is completed it is surrounded by '(' and ')'. Also, when it is required to increase the height of a tree to accommodate more operands (as in Figure 9 (a) and (b)) this is effected by joining two trees thus:

(CPBT) + (BBT)

- even trivial trees, ie terms, are bracketed by our grammar -, grammatically we reduce ')+(' to + by a suitable production. Before giving the grammar and describing its use, we note that in order to clarify the difference between actual and terminal symbols and synthetic structure-indicators we have used 0 and C (open and close) in place of '(' and ')'. To aid parsing \$ is used as an end marker.

$$G_5 = (\{X,S,E,P,O,C\},\ \{+,T,\$\},\ Q,X)$$

where Q = {(1) E→T, (2) P→+, (3) OEC→EPE,
(4) P→CPO, (5) \$→C\$, (6) PE\$→CPE\$,
(7) S\$→OE\$, (8) S\$→OS\$, (9) X→S\$ }

Now we apply $G_5$ to the reduction and structuring of $E_7$. Recall $E_7$ = T+T+T+T+T+T+T \$ and that it should be structured (see Figure 9 (b)) as $E_7$ = ((T+T)+(T+T))+((T+T)+T)\$ in which the right subtree is a CBBT of height 2 and the left subtree is a BBT of height 2 resulting in $h(E_7)=3$. The expression can be analysed (the reverse process to derivation) as follows:

```
(1) T+T+T+T+T+T+T$       (9) OOEC P ECPE$
(2) EPE+T+T+T+T+T$      (10) OOEC P EPE$
(3) OEC+T+T+T+T+T$      (11) OOEC P OEC$
(4) OECPOEC+T+T+T$      (12) OOE P EC$
(5) OEPEC +T+T+T$       (13) OO OEC C$
(6) OOECC PEPE+T$       (14) OO OE $
(7) OOECC POEC+T$       (15)    S$
(8) OOEC P EC+T$        (16)    X
```

Productions (1) and (2) of Q (which we shall refer to as $Q_1$ and $Q_2$ ...) simply encode $T_5$ and '+' symbols and are used freely throughout the reduction. Stages 1, 2 and 3 transform 'T+T' into 'OEC' represesnting a CBBT of height 1 by means of $Q_3$. The next 'T+T' is similarly treated giving (No 4) 'OECPOEC'. Production Q4 now removes the reverse brackets ')+(' represented by 'CPO' and then using $Q_3$ again we obtain (No. 6) 'OOECC' which corresponds to a CBBT of height 2.

Now the string generated by $E_2$ in Figure 9 (b) is transformed into 'EPE' and then 'OEC' in stages 6 and 7. The central plus, now P, then causes partial combination of these CBBTs. However, the two E's in No. 8 do not combine because they are not of the same height, the second being too low.

The last term comes into play at No. 9. Because $E_7$ cannot be completely balanced we need to apply special productions to cater for the incomplete subtree $E_3$. Production $Q_6$ erases the superfluous 'C' enabling the right-hand subtree to be incorporated with the preceding E (No. 11) $Q_4$ then performs the last proper reduction with two trees of height 2 (No. 12). The final stages using $Q_5$, $Q_8$ and $Q_9$ remove peripheral bracket tokens and achieve the start symbol X.

Pictorially the parse is set out in Figure 10.

We can now extract the desired admissible tree structure from this parse by translating from Q to a related set of context-free productions Q'. This is simply done by ignoring all structuring symbols and trivial productions. Hence we have:

| Q | Q' |
|---|---|
| E → T | E → T |
| P → + | P → + |
| OEC → EPE | E → EPE |
| P → CPO | |
| \$ → C\$ | |
| PE\$ → CPE\$ | |
| S\$ → OE\$ | S → E |
| S\$ → OS\$ | |
| X → S\$ | X → S |

Applying this translation to Figure 10 gives the context-free parse in Figure 11 and further simplication trivially gives us $G_6$ defined by the productions

$$E \to E+E \mid T \qquad \text{(Grammar } G_6\text{).}$$

Consequently the sequence of applications of reductions $Q_3$ and $Q_1$ in grammar $G_5$ gives a balanced parse from the grammar $G_6$. Figure 11 is, as required, a syntactic equivalent of the semantic structure in Figure 9 (b).

Expressions Involving Two Associative Operators

The construction of the context-sensitive grammar $G_5$ from the context-free grammar $G_4$ can be mirrored for any language based on a single associative operation. Hence, we could for instance take $G_1$

$$E \to E+E \mid T \text{ , } T \to T*P \mid P, \quad P \to (E) \mid I \qquad \text{(Grammar } G_1\text{).}$$

and slice off the second, multiplicative, layer

$$T \to T*P \mid P$$

and then add extra productions to allow both left and right-associativity. Thus, to generate L(T)

we have $\quad T \to T*P \mid P*T \mid P$

or alternatively $\quad T \to T*T \mid P$ .

To deal with more than one such operator is more complicated and methods for the construction of grammars to cope with the general situation are currently under review. Of more immediate concern is the case noted above. We know that, by convention, multiplication has a higher precedence than addition and hence whenever these operators are adjacent in an expression we need to ensure that any tree balancing takes account of these precedence relations. Of course for any sub-expression involving only one kind of operator the method of section 3 can be used.

To illustrate how these operators inter-relate with each other and with the tree-balancing processes we give an example. To aid description of multiplicative sub-structure we shall use $T_n$ to represent a sub-expression involving n operands combined multiplicatively, and to aid analysis we use '\$' as a delimiter rather than just a terminator for the entire expression.

Example: Consider the expression, $I_1+I_2+I_3*I_4*I_5$ which should be parenthesised thus:

$$(I_1+I_2) + ((I_3*I_4)*I_5)$$

As before the reduction starts by forming $I_1+I_2$ into a (C)BBT of height 1. However, the '*' following $I_3$ prevents $I_3$ from being immediately included in an additive BBT of height 2, and causes a multiplicative tree to be formed from $I_3$ and $I_4$ and subsequently $I_5$ is also included. In order that the correct combination should be achieved we need to check both operators adjacent to non-peripheral operands. In this particular situtaion we could use productions such as

$$T \to I \qquad (E)+ \to T+T+$$

to prevent incorrect manipulation of $I_3$.

Because '*' has the highest precedence of (arithmetic) operators present in the expression we can invoke the balancing of multiplicative trees without reference to '+' and hence we use

$$(T) \to T*T$$

Indeed, when an operator of highest precedence is used, no checks on the types of adjacent operators are required except in the case when the operator in question is not associative. In parsing terms the delimited expression

$$\$I_1+I_2+I_3*I_4*I_5\$$$

can now be reduced to $\quad \$(E_2)+(T_2)*I_5\$$

and then to $\quad \$(E_2)+(T_2)*T_1\$$

The (incomplete) multiplicative tree must now be reduced. This can be done in several ways. Following the strategy used in the additive grammar, $G_5$, we can enforce left to right balancing by removing the right-hand bracket from '$(T_2)$' and allowing the replacement bracket to be created at the extreme right of the expression. In consequence we have the productions

$$*T \to )*T \qquad \text{and} \qquad )\$ \to \$$$

However, this gives rise to the abortive reduction sequence

(1) $\$(E_2)+(T_2)*T_1\$$ $\qquad$ (4) $\$(E_2+((T))\$$

(2) $\$(E_2)+(T_2*T_1\$$ $\qquad$ (5) $\$(E_2+(T))\$$

(3) $\$(E_2)+(T_2*T_1)\$$ $\qquad$ (6) $\$(E_2+E))\$$

Reference to the desired admisible tree for this expression (Figure 12) reveals the requirement for the right subtree to be higher than the left subtree. Dealing with this phenomenan as before, by using the production and completely destroys the left-to-right balancing of additive trees and hence an alternative method must be found.

Such a method, based on the strict use of brackets to preserve tree height information and hence requiring no bracket inbalance at any stage, is described in four stages.

(i) First, we return to the (single operator) additive grammar and generate

$$L(X) = \{T(+T)^n : n > 0\} \text{ by the CS productions}$$

(1 $X \to \$S\$$, $\quad$ (2) $S \to \{S\}$, $\quad$ (3) $S \to E$, $\quad$ (4) $+E\} \to \}+E$,
(5) $+ \to \}+\{$, $\quad$ (6) $\{E\} \to E+E$, $\quad$ (7) $E \to T$ $\quad$ (Grammar 7)

Now any reduction sequence associated with grammar 7 has equal numbers of open and close brackets at every stage and before any application of rule 2, the number of balanced bracket pairs indicates the height of the structure tree. However, rule 4 is too general for our purposes, it allows any combination of trees $E_i$ and $E_j$ (in that order) where $h(E_i)>h(E_j)$. In particular it gives rise to the following reduction of $E_7$.

(1) $\$T+T+T+T+T+T+T\$$ $\qquad$ (6) $\$\{\{E+E\}\}+E\$$

(2) $\$E+E+E+E+E+E+E\$$ $\qquad$ (7) $\$\{\{\{E\}\}\}+E\$$

(3) $\$\{E\}+\{E\}+\{E\}+E\$$ $\qquad$ (8) $\$\{\{\{E+E\}\}\}\$$

(4) $\$\{E+E\}+\{E\}+E\$$ $\qquad$ (9) $\$\{\{\{\{E\}\}\}\}\$$

(5) $\$\{\{E\}+E\}+E\$$

This implies a tree of height 4 and relates to the tree in Figure 13 corresponding to the analysis $E_7=(E_4+E_2)+E_1$ instead of $E_7=E_4+(E_2+E_1)$. Both are possible analyses from grammar 7.

So there is a requirement for some indicator to stimulate the accepting of incomplete trees from right to left. This is easily achieved by a simple modification given as grammar 8 in which γ and δ are used as markers; each γ permitting a possible imbalance at each level and the δs preventing such an imbalance from occurring to the left of the central '+' at the corresponding level of the right sub-tree.

```
(1) X→$S$,  (2) S→{S}γ,  (3) S→E,  (4){E}→E+δE,
(5) +→}+{,  (6) E→T,     (7) γ→Λ,  (8) δ→Λ,
(9) +δE}γ→}+δE                      (Grammar 8)
```

(Notice that grammar 8 is not context-sensitive. However, its form enables the balancing methodolgy to be clearly seen and can be modified later to meet CS criteria.) The skeletal derivation of $E_7$ from grammar 8 is as follows: the underlying semantic tree being indicated by the arrowed progression of '+' symbols.

```
              X
 *
 =>  -  ${{{E}γ}γ}γ$
 *
 =>  =  ${{E+δEγ}γ}γ$
                ↓
 *
 => ${{E}  +  {E}γ}γ$
        ↓   ↓   ↓
 *
 => ${E+δE + E +δEγ}γ$
        ↓   ↓   ↓
 *
 => ${E+ E + E +δE}E}γ$
        ↓   ↓   ↓
 *
 =>${E}+{E}+{E}+δE$
     ↓ ↓ ↓ ↓    ↓
 *
 =>$E+E+E+E+E+E+E$
```

A context-senstivive equivalent of grammar 8 is given by the productions

```
(1) X→$S$,   (2) S→{S},   (3) S→{SΓ, (4) S→E,
(5) {E}→E+E, (6) {E}→E+F, (7) +→}+{, (8) E→T,
(9) +FΓ→}+E, (10) +FΓ→}+F           (Grammar 9)
```

(ii) The second stage in our grammar modifications is to introduce different kinds of brackets at different levels of the syntax thus enabling the balancing of multiplicative subtrees to be performed without regard to, and chronologically before, manipulation of any surrounding additive structure. This could be done syntactically but use of a distinct bracketing system allows processing of the entire multiplicative substructure to be analysed and reduced to an atomic additive term (of a suitable height) which can then not be dissected, by subsequent additive manipulation. In particular it can be included at the left- or right-hand side of a higher tree at will without creating an inadmissible tree or a tree which is higher than necessary.

Proceeding in this direction we can take the terminal symbol T of grammar 9, reclassify it as a non-terminal, and define it so as to generate multiplicative subexpressions, balanced from left to right. Accordingly we require the production.

```
(1) T→[T],      (2) T→[TΠ,      (3) T→P,
(4) [P]→P*P,    (5) [P]→P*P,    (6) *→]*[,
(7) *RΠ→]*P,    (8) *RΠ→]*R,    (9) P→I,
                                (Productions 9a)
```

Using the sets of productions 9 and 9a together to generate $\$I_1+I_2+I_3*I_4*I_5\$$ we obtain

```
      X         |   => ${{S}Γ$   |  => ${E}+E$
 => $S$         |   => ${{E}Γ$   |  => $E+E+T$
 => ${SΓ$       |   => ${E+FΓ$   |     etc
```

This reduction implies that h(T)=0 ie the term is atomic whereas the true position would be indicated by [[T]], say, having height 2 and corresponding (additively) to an expression such as $E_4$. Using the same productions, the required information is availble (at stage *) in the subsequent derivation, namely

```
      T            |  =>  [[P]Π   |  =>  *P*P*P
 => [TΠ            |  =>  [P*RΠ   |  =>  I*I*I
 => [[T]Π     (*)  |  =>  [P]*P   |
```

Utilization of this information is dealt with in the next two stages of the balancing process for the class of expressions in question.

(iii)-(iv) We now need to convert multiplicative brackets to additive ones and also allow the expression rather than the grammar to dictate left or right associativity of the resulting subexpression within the surrounding expression. Consequently additive brackets created by this process behave in more general ways than those occurring elsewhere and hence there is a requirement to deal with both of these processes together.

Explicitly, recall that indication of the height of the multiplicative subtree in $\$I_1+I_2+I_3*I_4*I_5\$$ is 2 and could be given by replacing [[T]Π by {{E}}. If done directly this yields the intermediate form $\$\{E\}+\{\{E\}\}\$$ which fails because it balances to the right and not to the left. In order to be able to accept such a form we need to know that the right subexpression is derived from multiplication.

We return to the form: $E}+[[T]Π$
To allow such a composition we need to achieve the progression

```
 =>${E}+[[T]Π$  |  => ${{E+T}}$  |  => ${{{E}}}$
 =>${E+[T]}$    |  => ${{E+E}}$  |
```

- indicating a tree of height 3.

This is done by incorporating the replacement of the leftmost '[' by '{' with the absorption of '}+{' into '+' and with the conversion of the corresponding close bracket, here 'Π', to '}'. To perform the required transformation we use α as a marker in the following productions.

```
(1) +α→}+[,     (2) [α→α[,      (3) Tα→αT,
(4) ]α→α],      (5) Πα→αΠ,      (6) }}→Πα},
(7) }$→Πα$      (8) }}→]α},     (9) }$→]α$,
```

Next, we must migrate any subsequent '[' to the left and convert that bracket and its corresponding ']' into curly brackets. We use $\alpha$ thus

$$\{E+\alpha\rightarrow E+[\quad,\qquad T\alpha\rightarrow\alpha T\quad,\qquad ]\alpha\rightarrow\alpha]$$
$$\Pi\alpha\rightarrow\alpha\Pi \qquad \text{etc. as before.}$$

(This sequence of productions again includes a non context-sensitive rule. At the risk of introducing parsing difficulties, the offending rule could be replaced by

$$Y+\alpha\rightarrow E+[$$

with corresponding changes, such as

$$+E\rightarrow\}+Y\ ,\qquad S\rightarrow Y\}\ ,\qquad S\rightarrow Y\Gamma$$

elsewhere in the grammar.)

The manipulation of high multiplacative subtrees to the left of an addition operator can be dealt with by straight forward bracket conversion and the additive balancing processing provided that extra conversion initiation rules are included, namely

$$\$\{\alpha\rightarrow\$[,\qquad \{\{\alpha\rightarrow\{[$$

and corresponding conversion rules

$$\{+\rightarrow]\alpha+,\qquad \{+\rightarrow\Pi\alpha$$

Yet again the modification would introduce non-context senstivive rules. However, their removal necessitates the inclusion of more markers hence the rules will be left in their present form. Justification for this decision will be given in section 6 of the paper.

We are now in a position to expand the sets of rules 9 and 9a into a full grammar. The only significant change being the omission of the first two rules in 9a, thus ensuring that multiplicative brackets are only obtained by conversion from additive ones.

The productions of the Grammar $G_{10}$, are displayed in two columns denoting the rules used in CBBTs and (additionally) in BBTs respectively.

$$G_{10} = (\{X,S,E,'\{','\}',T,P,'[',']',\ \alpha,\Gamma,F,R,\Pi\},\ \{I,+,*,\$\},P_{10},X)$$

| | | | | | |
|---|---|---|---|---|---|
| where $P_{10}$ = | | | | where | |
| 1) | $\{\{X\rightarrow\$S\$$ | | | | |
| 2) | $S\rightarrow\{S\}$ | $S\rightarrow\{S\Gamma$ | 10) | $P\rightarrow I$ | |
| 3) | $S\rightarrow E$ | | | | |
| 4) | $\{E\}\rightarrow E+E$ | $\{E\}\rightarrow E+F$ | | | $+\alpha\rightarrow\}+[$ |
| 5) | $+\rightarrow\}+\{$ | | 11) | $[\alpha\rightarrow\alpha[$ | |
| | | | 12) | $T\alpha\rightarrow\alpha T$ | |
| 6) | $E\rightarrow T$ | | 13) | $]\alpha\rightarrow\alpha]$ | |
| | | $+F\Gamma\rightarrow\}+E$ | | | $\Pi\alpha\rightarrow\alpha\Pi$ |
| | | $+F\Gamma\rightarrow\}+F$ | 14) | $\}\}\rightarrow]\alpha\}$ | $\}\}\rightarrow\Pi\alpha\}$ |
| 7) | $T\rightarrow P$ | | 15) | $\}\$\rightarrow]\alpha\$$ | $\}\$\rightarrow\Pi\alpha\$$ |
| 8) | $[P]\rightarrow P*P$ | $[P]\rightarrow P*R$ | 16) | $\}+\rightarrow]\alpha+$ | $\}\ \rightarrow\Pi\alpha+$ |
| 9) | $*\rightarrow]*[$ | | | | $\{E+\alpha\rightarrow E+[$ |
| | | $*R\Pi\rightarrow]*P$ | 17) | $\$\{\alpha\rightarrow\$[$ | |
| | | $*R\Pi\rightarrow]*R$ | 18) | $\{\{\alpha\rightarrow\}[\ \}$ | |

We conclude this section with outline derivations of three non-trivial expressions using $G_{10}$.

Example 1: $\$I_1+I_2*I_3+I_4*I_5\$$

(for structure see Figure 14)

| | | |
|---|---|---|
| $\overset{*}{\Rightarrow}\ \$\{\{\{E\}\Gamma\}\$$ | $\Rightarrow\ \$\{\{E\}\}+\{E\}\$$ | $\Rightarrow\ \$E+[T]+[T]\$$ |
| $\Rightarrow\ \$\{\{E+F\Gamma\}\$$ | $\overset{*}{\Rightarrow}\ \$\{E+E\}+[T]\$$ | $\overset{*}{\Rightarrow}\ \$I+I*I+I*I\$$ |
| $\Rightarrow\ \$\{\{E\}+\{E\}\$$ | $\overset{*}{\Rightarrow}\ \$\{E+\alpha T]+[T]\$$ | |

($\Gamma$ indicates RH subtree of 1 unit lower than LH subtree)

Example 2: $\$I+I+I*I*I\$$ (Figure 15)

## Further Extensions to The Grammar

So far we have dealt only with expressions constructed from simple identifiers, I, and the arithmetic operators '+' and '*'. Extending the language to handle more complex arithmetic atoms (such as numeric constants) and, without regard to their semantic properties, the operator symbols '-' and '/', is trivial. Similar methods applied to Boolean expressions are also obviously possible. Moreover, because our grammatical structure now incorporates information about the height of the respective semantic tree, the inclusion of the usual parentheses, '(' and ')', causes no difficulty; although introduction of the markers required to invoke the conversion of matching brackets, '{' and '}', and '[' and ']'; over the syntactic brackets necessitate many more productions.

Extension of these techniques to larger portions of programming languages may not seem feasible. However, recall that our basic construction eminates from the introduction of ambiguities to a suitable operator-precedence grammar. Such a grammar for an Algol-like language already exists, Floyd [9].

From the more pragmatic and practical standpoint we need to investigate implications of 'live-dead' variable analysis, Sheafer [10] etc. If this information could be detected and manipulated by syntactic means it would allow (i) for the inclusion of function calls within expressions and hence (ii) for the handling of statements as expressions with side-effects.

Nevertheless, even without these further semantic constraints, what we have so far is a system that enforces the necessary structure on the evaluation of a language fragment but, because

## Parsing Considerations

All the grammars presented in this paper are, or can be, written to conform to Context-Sensitive requirements. This is apparently the narrowest general classification that is satisfied by our grammars and hence before these grammars can be put to work we need to have a suitable parsing machine. In Abdollazadeh [1] various published algorithms are described and compared. Also included are details of several other parsing strategies applicable to certain of the grammars contained therein. However, most of these algorithms are more powerful than necessary since they can be used to analyse sentences of languages which are not context-free.

This 'sledge-hammer to crack a nut' situation has been studied before by Baker [5] and Aggarwal [2]. Indeed Aggarwal defines the set of so-called SVMT-bounded grammars which are CS but generate CFL's. This class of grammars extend previous classifications guaranteed to generate CFLs but does not include all the CS grammars developed here and in Abdollazadeh [1].

Because of the special form of our grammars and the possibility that the most manageable forms (from the parsing standpoint) may not be context-sensitive but even more general, we need to investigate, inter-dependently, parsing methodology and grammar modification. From our initial investigations it would appear that the most important need is to lessen the non-determinism provided that this is conversant with the retention of sufficient structural information.

## Conclusion

We have demonstrated that it is possible to balance simple arithmetic trees syntactically and indicated how the method can be extended to deal with more complicated program fragments. The balancing technique not only determines the minimal height of the expression tree, (subject to certain semantic constraints) but also allows for potential overlap of adjoining trees. Figures 17 and 18 depict a general and a specific situation.

As is seen from the latter figure, the diagonal length •• indicative of idealised execution time - is related to tree height and additionally, the diagonal width is related to the number of independent processors that could be usefully employed in the evaluation. This visualization is also capable of indicating store access operations and inter-machine transfers.

Our work is now to stretch (semantically motivated) syntactic methods as far as is practical and then introduce the minimal semantic structure (such as left-to-right attributes, Bochmann [60]) so as to move the less complex aspects of a language into the earlier phases of compilation and to facilitate more efficient code generation for however many processors are available at run-time.

## Abstract

A pipelined solution method for tridiagonal systems of linear equations is proposed which introduces parallelism in a way that may be effectively exploited by static data flow computers. It eliminates the substantial data rearrangement overhead incurred by many existing parallel algorithms, and sustains a relatively constant parallelism during various phases of program execution. Using the new method, we outline a pipepined code mapping scheme. The principle outlined in this paper may be extended to other suitable parallel machine architecture.

## 1. Introduction

Tridiagonal systems of linear equations form a very important class of linear algebraic equations. For example, the heart of finite difference solutions of partial differential equations may consist of tridiagonal systems of equations. A tridiagonal system of linear equations can be solved on a conventional computer using the classical *Gaussian elimination algorithm*. However, such solution method is sequential in nature and hence unsuitable for parallel computers without drastic alteration.

In the past decade, new techniques have appeared for solving tridiagonal systems of equations with parallel computers [11, 15]. The best known parallel algorithm is based on the cyclic reduction technique, first proposed by Golub and Hockney and applied by Buzbee et al, for solving tridiagonal system of equations efficiently [2]. One approach is using such parallel technique to solve the recurrences established by the LU-decomposition method of Gaussian elimination algorithm. One such algorithm, known as recursive doubling suggested by Stone and originally designed for Illiac IV, was later modified for other vector computers [16]. Another approach has resulted from considering the needs of parallel processing in the first place and trying to design fundamentally new algorithms which are inherently more parallel. The *odd-even cyclic reduction* algorithm is base on such a principle [2]. A major difficulty with the algorithms based on cyclic reduction technique is the overhead of data rearrangement between computation steps and the considerable variations of degree of parallelism between computation steps.

In this paper, a new method for solving tridiagonal systems of equations is proposed which introduces parallelism in a way that may be effectively exploited by data flow computers. The algorithm is based on the maximally pipelined solution of linear recurrences presented in a companion paper [8]. It performs a program transformation of the recurrences generated in the Gaussian elimination method to produce machine code which can be executed in a maximally pipelined fashion. The new method eliminates the substantial data rearrangement overhead incurred by many existing parallel algorithms and it sustains a relatively constant parallelism during various phases of program execution. Based on this scheme, the code structure of a maximally pipelined tridiagonal equation solver is outlined for a static data flow supercomputer. The principle outlined in the paper may be extended to other data flow computers.

## 2. Background and Related Work

In this section we state briefly the problem of tridiagonal system of linear equations and review the directed methods for solving them — such as the Gaussian elimination algorithm, in particular the linear recurrences established by the LU-decomposition technique. We also survey the related work of parallel tridiagonal solution methods, such as the well-known cyclic reduction technique.

### 2.1 Statement of The Problem

We consider the solution to the following tridiagonal set of linear equations:

$$\begin{pmatrix} b_1 & c_1 & 0 & \cdots & & 0 \\ a_2 & b_2 & c_2 & & & \vdots \\ 0 & a_3 & b_3 & & & \\ \vdots & & & \ddots & & 0 \\ & & & a_{n-1} & b_{n-1} & c_{n-1} \\ 0 & \cdots & 0 & & a_n & b_n \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{pmatrix} = \begin{pmatrix} k_1 \\ k_2 \\ \cdot \\ \cdot \\ \cdot \\ k_n \end{pmatrix}, \qquad (2.1)$$

or expressed in matrix-vector notation

$$Ax = k \qquad (2.2)$$

In this paper, our major concern will be the case where the coefficient matrix A is positive definite or at least pivoting is not required.

### 2.2 LU-Decompusition

There are a number of serial methods for solving the tridiagonal system as expressed in (2.1). The maximally pipelined solution method to be developed in this paper is based on the well-known *LU-decomposition* technique [5]. The Stone's recursive doubling algorithm to be discussed later is also based upon such technique. In this method, we find two matrices, L and U, such that

(1) LU = A;

(2) L is a lower bidiagonal matrix;

(3) U is an upper bidiagonal matrix with 1s on its principal diagonal.

When A is non-simpler, its LU decomposition is unique. In fact, it is shown that

$$L = \begin{pmatrix} e_1^{-1} & 0 & \cdots & & 0 \\ a_2 & e_2^{-1} & & & \vdots \\ 0 & a_3 & e_3^{-1} & & \\ \vdots & & & \ddots & 0 \\ 0 & \cdots & 0 & a_n & e_n^{-1} \end{pmatrix}$$

and

$$U = \begin{pmatrix} 1 & u_1 & 0 & \cdots & 0 \\ 0 & 1 & u_2 & & \vdots \\ \vdots & & 1 & \ddots & 0 \\ & & & \ddots & u_{n-1} \\ 0 & \cdots & & 0 & 1 \end{pmatrix}$$

where

$$\begin{aligned} u_1 &= c_1/b_1 \\ u_i &= c_i/(b_i - a_i u_{i-1}) \qquad i = 2,3 \ldots n-1 \qquad (2.3) \\ e_i &= u_i/c_i \end{aligned}$$

After computing L and U, it is relatively straightforward to solve the system of equations by a two-step process. First, letting Y = Ux, we have

$$Ly = K \qquad (2.5)$$

$$Ux = y \qquad (2.6)$$

and together, we have Ax = LUx = Ly = k.

The equation Ly = k can easily be solved for y as follow.

$$\begin{aligned} y_1 &= k_1/b_1 \\ y_i &= (k_i - a_i y_{i-1})/(b_i - a_i u_{i-1}) \qquad i = 2,3 \ldots n \qquad (2.7) \end{aligned}$$

Note that in the solution process, as indicated by (2.7), there is no need to compute $e_i$ explicitly unless the matrix L is needed in other places. Next, we solve Ux = y for x by noting that

$$\begin{aligned} x_n &= y_n \\ x_i &= y_i - u_i x_{i+1} \qquad i = n-1, n-2 \ldots 1 \qquad (2.8) \end{aligned}$$

The two steps of (2.7) and (2.8) are often called *forward-elimination* and *backward-substitution*. The recurrences (2.3), (2.7) and (2.8) constitute a complete solution for Ax = k. and a sequential algorithm to perform such a solution is the so-called *Gaussian elimination algorithm*.

### 2.3 Cyclic Reduction Technique

In this paper, we make no attempt to survey all parallel algorithms for tridiagonal linear equation solvers, but review only two well-known methods which are based on the cyclic reduction. This discussion will motivate the pipeined solution presented in this paper.

#### 2.3.1 Recursive Doubling Algorithm

The recursive doubling algorithm proposed by Stone [16] began with the observation that the formula required by LU factorization, such as (2.7) and (2.8), are first-order linear recurrences (FLR). The equation (2.3) appears not to be a linear recurrence. However, if we introduce a new variable $q_i$ such that $u_i = -q_i/q_{i+1}$, then (2.3) can be transformed into the following second-order linear recurrence (SLR):

$$a_i q_{i-1} + b_i q_i + c_i q_{i+1} = 0 \qquad i = 2,3,\ldots,n-1 \qquad (2.9)$$

where $q_1 = 1$, $q_2 = -b_1/c_1$.

Stone pointed out that (2.9) can be transformed into a first-order linear recurrence except that the sequence is now a set of vectors instead of scalar values. The recursive doubling algorithm uses standard cyclic reduction method for handling linear recurrences to solve them.

It is helpful to review the cyclic reduction technique for solving linear recurrences before we outline its disadvantages. For instance, we consider the evaluation of the sequence of $x_i$ from the following first-order linear recurrence relation.

$$x_i = a_i x_{i-1} + b_i \qquad \text{for } i = 2 \ldots n \qquad (2.11)$$

where $x_1, a_1, \ldots, a_n$ and $b_1, \ldots, b_n$ are known values. The basic idea of standard cyclic reduction technique is to back up the recurrence in (2.11) such that a new recurrence can be obtained which relates every other term, every fourth term, every eighth term, etc.

For example, from (2.11) we have

$$\begin{aligned} x_i &= a_i a_{i-1} x_{i-2} + a_i b_{i-1} + b_i \\ &= a_i^{(1)} x_{i-2} + b_i^{(1)} \qquad (2.12) \end{aligned}$$

where $a_i^{(1)} = a_i a_{i-1}$, $b_i^{(1)} = a_i b_{i-1} + b_i$. The superscript (1) denotes the fact that this is a first level backup. Such a backup process can be repeated (in a cyclic fashion) and we obtain a set of equations as follow.

$$x_i = a_i^{(l)} x_{i-2^l} + b_i^{(l)} \qquad (2.13)$$

where

$$a_i^{(l)} = a_i^{(l-1)} a_{i-2^{l-1}}^{(l-1)} \qquad (2.14)$$
$$b_i^{(l)} = a_i^{(l-1)} b_{i-2^{l-1}}^{(l-1)} + b_i^{(l-1)} \qquad (2.15)$$

with $l = 0, 1 \ldots \log_2 n$, $i = 2, 3 \ldots n$. An important observation is that if any of $a_i$, $b_i$ or $x_i$ is outside the defined range, its value can be taken as zero. Therefore, when $l = \log_2 n$, all $x_i$ are solved by

$$x_n = b_n^{(\log_2 n)}$$

We can have the following observation:

(1) high parallelism exists at certain phases (steps) of the algorithm, i.e., at a fix level l, (2.14) and (2.15) can be evaluated for all i in parallel;

(2) the parallelism grows roughly linearly with the size of the vectors — i.e. n in this case;

(3) the useful parallelism decreases as the computation progressing through different phases.

The amount of parallelism varies between phases of computation. This will increase the difficulty of fully utilize the parallelism of the machine.

### 2.3.2 Odd-even Reduction Algorithm

The *odd-even cyclic reduction algorithm* is perhaps the most successful cyclic reduction algorithm applied to solve tridiagonal systems [2]. It starts directly from the system of equations defined by (2.1), i.e.,

$$a_i x_{i-1} + b_i x_i + c_i x_{i+1} = k_i \qquad i = 1, 2 \ldots n^*$$

The algorithm first eliminates the odd numbered variables in the even numbered equations by performing elementary row operations. In each level, we cut down the total number of equations by 1/2, hence, in $\log_2 n$ levels, the middle element $x_{n/2}$ can be computed directly from the coefficients. The remaining unknowns can be found by a refilling procedure. This algorithm also involves the recursive calculation of coefficients for equations at each level. One important advantage of the odd-even reduction over the recursive doubling algorithm is that it reduces the number of operations considerably at each level, and the total number of operations is on the order of O(n).

One major difficulty with odd-even reduction is the data rearrangement of variable and coefficient vectors between phases of computation. For example, on the Cyber 205 one cannot apply vector operations directly to every other elements of the vector. Thus extra operations must be employed to reformat those elements into a new vector [14]. On the Cray it is possible to access elements of a vector at a fixed increment, but this may result in a performance degradation [12]. Because of the overhead of data rearrangement, the cyclic reduction algorithm may run slower than a serial algorithm for sufficiently small n [15].

Another problem is the degree of variation of parallelism between different phases of computation. Because the parallelism decreases very rapidly, this problem becomes more serious than that for the recursive doubling algorithm. A parallel version of odd-even reduction algorithm has been proposed to keep a high parallelism throughout the computation. However, it increases the number of operations significantly to O(nlogn) [11].

## 3. A Pipepined Solution Scheme for Linear Recurrences

### 3.1 Overview of the Pipelined Solution Scheme

In cyclic reduction scheme, the goal is to increase the speed through fully exploiting the parallelism in the original problem. High concurrency is obtained by replicating the

* In the remaining discussion of this section, we assume n is a power of 2, but this is not an essential assumption.

operations as much as necessary to compute all elements in the result vector in parallel. In contrast, we propose a new solution method which can explore and organize the parallelism in a way that best matches a suitable computer architecture, i.e. the static data flow architecture. It is based on a maximally pipelined code mapping scheme developed in our previous work [3,6].

Two forms of parallelism exist in a data flow machine level program, as shown in Figure 1, which consists of seven actors

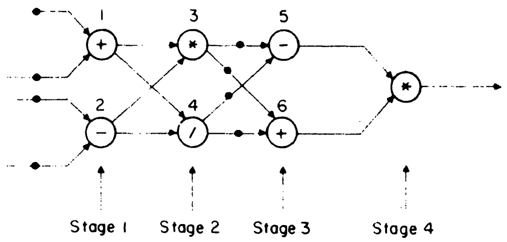

FIG. 1. Pipelining of data flow programs.

divided into four stages. In Figure 1 (a), actors 1 and 2 are enabled by the presence of tokens on their input arcs, and thus can be executed in parallel.* This is called *spatial* parallelism. Spatial parallelism also exists between actors 3 and 4, and between actors 5 and 6. The second form of parallelism is *pipelining*. In static data flow architecture, this means arranging the machine code such that successive computations can follow each other through one copy of the code. If we present a sequence of values to the inputs of the data flow graph, these values can flow through the program in a *maximally pipelined* fashion — i.e. input/output values are consumed/produced at maximum rate allowed by the machine architecture. In the configuration of Figure 1 (b), two set of tokens are pipelined through the graph, and the actors in stage 1 and 3 are enabled and can be executed concurrently. Thus, the two forms of parallelism are fully exploited in the graph.

The power of pipelined computation in a data flow computer can be derived from machine-level programs that form a large pipeline in which many actors in various stages are executed concurrently. Each actors in the pipe are activated in a totally data-driven manner, and no explicit sequential control is needed. With data values continuously flow through the pipe, a sustained parallelism can be efficiently supported by the data flow architecture.

### 3.2 Maximally Pipelined Mapping of Linear Recurrences

An attractive way to implement recurrence on data flow computers is to introduce feedback paths in the data flow graph. This, however, presents particular problems when maximum pipelining of the program is desired. A direct translation of the first order recurrence is shown in Fig. 2. The value $x_i$ depends on the value of $x_{i-1}$, therefore, a *feedback path*, such as the one marked in the graph, is generated. The key is to understand the role of the merge operator (denoted by M in Fig. 2): (1) under the *merge control* input values (<FT...T>), the initial output value of the loop is taken from the second input of the merge, i.e., $x_1$. (2) the upper output of M is routed under the *feedback control* values, i.e. <T...TF>, therefore all but the last element of the array will be fed back; and (3) the lower output of the merge is forwarded as the output of the loop unconditionally. Due to the existence of cycles, the data flow graph produced by such a scheme, in general, cannot be fully pipelined. More specifically, the feedback link between the output of cell 3 and the input of cell 1 prevents the whole graph from being fully pipelined.

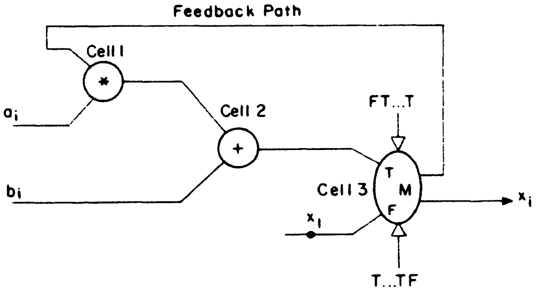

FIG. 2. The pipelined mapping of a first-order linear recurrence.

The problem of the above example and its solution have been studied by the author in [3, 6]. The problem is essentially a mismatch between the *dependence delay*— the dependence inherent in the recurrence (i.e., $x_i$ depends on $x_{i-1}$, therefore a two-stage feedback delay is required) and the *computational delay*—the actual length of the loop in the data flow graph generated by the direct translation scheme (3 stages in this example). In [8], the author described a solution for such a problem on a static data flow computer, based on the concept of *companion functions* [3,13]. It is essentially a way to remove the dependence of $x_i$ on $x_{i-1}$, thus, easing the feedback constraints in order to match the computational delay of the data flow graph. For the above example, we have:

$$x_1 = b_1$$
$$x_2 = a_2b_1 + b_2$$
$$x_i = a_ia_{i-1}x_{i-2} + a_ib_{i-1} + b_i \quad \text{where } i \geq 3 \quad (3.1)$$

* A solid disk on an arc represents the presence of a token.

This transformation is interesting to us because $x_i$ now depends on $x_{i-2}$ instead of $x_{i-1}$. Therefore, we can map our example, now expressed as in (3.1), into a data flow graph as shown in Fig. 3. Note that we have introduced two additional pipelines $a_i'$ and $b_i'$ as denoted by the dotted lined box C, where

$$a_i^{(1)} = a_i a_{i-1}$$
$$b_i^{(1)} = a_i b_{i-1} + b_i \qquad \text{where } i \geq 3.$$

This added pipeline is named the *companion pipeline* in [3], and its structure is shown in Fig. 4. To understand how the scheme works we first examine the loop in Fig. 3. The role of the merge operator is as before except that two initial values are presented to the second input of the merge, i.e. $x_1 = b_1$, $x_2 = a_2 b_1 + b_2$. The ID cell plays the role of a FIFO of size 1, and is inserted to tune the computational delay in the feedback path to match exactly the dependence delay. The two boxes in Fig. 4 are also FIFOs, and they can introduce proper skew needed in the pipelining of array operations [6]. The rest of the graph is self-explanatory and the reader should be convinced that the graph is maximally pipelined.

The transformation shown in the above example is equivalent to dividing the first-order linear recurrence into two equivalent classes of computation. In fact, since $x_i$ now depends on $x_{i-2}$, we may split the sequence of results into two subsequences:

$$X' = \langle x_1, x_3, x_5 \ldots x_{2i-1} \ldots \rangle$$
$$X'' = \langle x_2, x_4, x_6 \ldots x_{2i} \ldots \rangle.$$

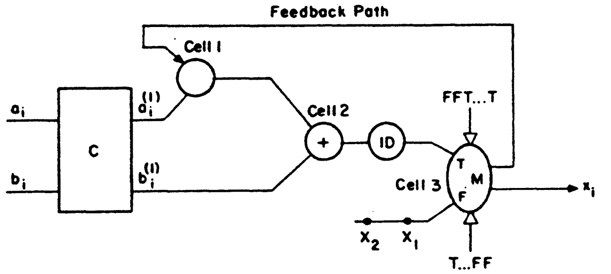

**FIG. 3. Maximally pipelined mapping of first-order linear recurrences.**

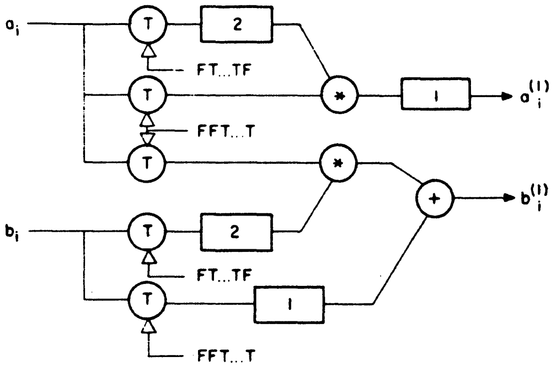

**FIG. 4. The companion pipeline of example (3.1).**

Either sequence can be computed independently by sharing the same loop, and the companion pipeline provides the appropriate input coefficients.

The advantage of this scheme is obvious. First, it does not require data rearrangement during the computation. In fact, it even eliminates the requirement that the input vectors be completely filled before the computation starts. If the input coefficient vectors themselves are generated by some preceding code block in a pipelined fashion, the producer-consumer type of interface technique (as described in [6]) can be applied to save considerable storage space for the intermediate values. Moreover, we observe that the degree of parallelism remains constant (5 floating point arithmetic operations and several other operations) in the computation.* The high throughput is achieved by the maximally pipelined execution of each actor in the data flow program, hence, the storage usage by the machine code is very efficient. Finally, there are no essential limitation on the length of the vectors which can be computed.

## 4. A Maximally Pipelined Method

Starting from LU-decomposition, we can observe that the major equations, such as (2.7) and (2.8), are first-order linear recurrences. Therefore, the pipelined method as described in the last section can be applied directly. Now consider (2.9) which can be transformed into the following second-order linear recurrence:

$$q_i = \alpha_i q_{i-1} + \beta_i q_{i-2} \qquad i = 3,4 \ldots n \qquad (4.1)$$

where $q_1 = 1$, $q_2 = -b_1/c_1$ and

$$\alpha_i = -b_{i-1}/c_{i-1}$$
$$\beta_i = -a_{i-1}/c_{i-1}$$

Performing one level backup we obtain

$$q_i = \alpha_i^{(1)} q_{i-2} + \beta_i^{(1)} q_{i-3} \qquad i=4,5 \ldots n \qquad (4.2)$$

where $q_1 = 1$, $q_2 = -b_1/c_1$, $q_3 = b_2 b_1/c_1 c_2 - a_2/c_2$, and

$$\alpha_i^{(1)} = \alpha_i \alpha_{i-1} + \beta_i$$
$$\beta_i^{(1)} = \alpha_i \beta_{i-1} \qquad i = 4,5 \ldots n$$

Fig. 5 shows a maximally pipelined data flow machine level program for mapping (4.2). The loop in the middle of Fig. 5 can easily be understood by noting its similarity with the loops in Fig. 3. The code in the dotted lined box is the companion pipeline generating values for $\alpha_i^{(1)}$ and $\beta_i^{(1)}$. The node labeled N performs a negation of its input. The boolean value sequences C0 - C5 can be found in Fig. 7. The boxes denote the FIFO buffers which are introduced for balancing the graph [4,6] to achieve maximum pipelining, and the number written inside the box is the number of stages in that buffer. It is easy to check that Fig. 5 correctly computes (2.9) and it is maximally pipelined.

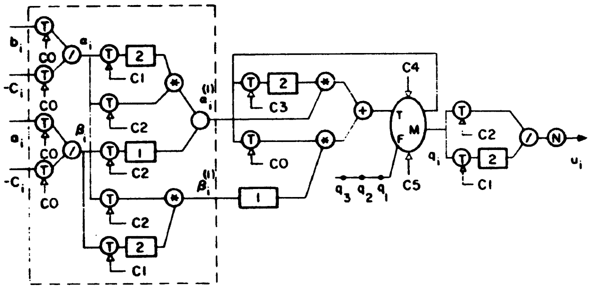

FIG. 5. Pipelined tridiagonal linear equation solver—Part 1.

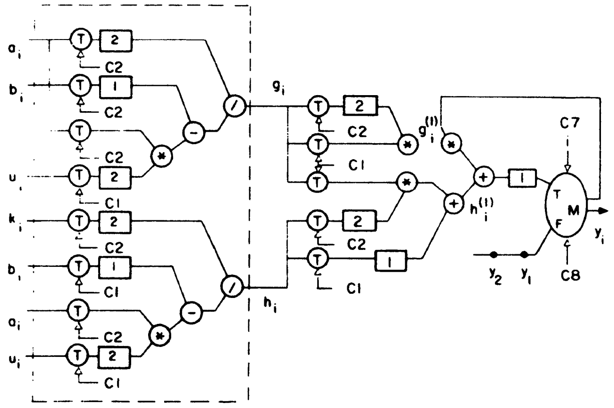

FIG. 6. Pipelined tridiagonal linear equation solver—Part 2.

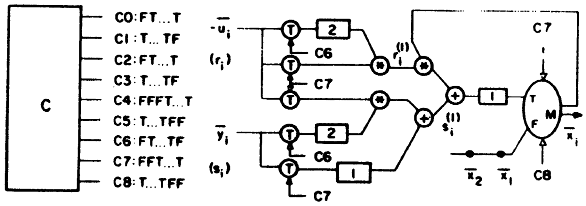

FIG. 7. Pipelined tridiagonal linear equation solver—Part 3.

We rewrite the first-order linear recurrence in (2.7) as

$$y_i = g_iy_{i-1} + h_i \qquad i=2,3...n \qquad (4.3)$$

where $y_1 = k_1/b_1$, $g_i = -a_i/(b_i-a_iu_{i-1})$, $h_i = k_i/(b_i - a_iu_{i-1})$. Performing one level backup we obtain

$$y_i = g_i^{(1)}y_{i-2} + h_i^{(1)} \qquad i = 3,4...n \qquad (4.4)$$

where $y_1 = k_1/b_1$, $y_2 = (-a_2k_1+b_1k_2)/(b_2 - a_2u_1)b_1$,

and

$$g_i^{(1)} = g_ig_{i-1}$$
$$h_i^{(1)} = g_ih_{i-1} + h_i.$$

Fig. 6 shows a maximally pipelined mapping of (4.4). The dotted lined box is the companion pipeline and the boolean sequences C1,C2,C7,C8 can be found in Fig. 7.

Finally, (2.8) can be conveniently treated as a first-order linear recurrence by introducing new variables $\bar{x}_i$, $\bar{y}_i$, $\bar{u}_i$ such that $\bar{x}_i = x_{n-i+1}$, $\bar{y}_i = y_{n-i+1}$, $\bar{u}_i = u_{n-i+1}$. Hence, (2.8) can be rewritten as

$$\bar{x}_i = r_i\bar{x}_{i-1} + s_i \qquad i = 2,3...n \qquad (4.5)$$

where $\bar{x}_i = \bar{y}_i$, $r_i = -\bar{u}_i$ and $s_i = \bar{y}_i$. We can note that (4.5) is a standard first-order linear recurrence, hence we can solve it by one level backup:

$$\bar{x}_i = r_i^{(1)}\bar{x}_{i-2} + s_i^{(1)} \qquad i = 3,4...n \qquad (4.6)$$

where $\bar{x}_1 = \bar{y}_1, \bar{x}_2 = \bar{u}_2\bar{y}_1 + \bar{y}_2$ and

$$r_i^{(1)} = r_ir_{i-1}$$
$$s_i^{(1)} = r_is_{i-1} + s_i$$

Fig. 7 shows a maximally pipelined mapping of (4.6).

Now we have constructed a complete pipelined machine code strucure for a maximally pipelined tridiagonal solver as shown by Fig. 5 - Fig. 7. Fig. 5 and Fig. 6 can be combined into one maximally pipelined data flow graph by observing that the sequence of values of $u_i$ produced by Fig. 5 can be directly fed into Fig. 6. The interface between the outputs of Fig. 5 and

* Here the variation of the parallelism during the start and finish time of the computation is not considered

Fig. 6 and the inputs of Fig. 7 cannot be connected directly. The main reason is that the order in which the elements $y_i$ and $u_i$ are generated by Fig. 5 and Fig. 6 is opposite to the order in which they are used for the maximum pipelining of Fig. 7. Hence, we should first store the values of $u_i$, $y_i$ into memory. Then, Fig. 7 will access the arrays in a reverse order. The code in Fig. 5 and Fig. 6 will sustain a constant parallelism such that there are 20 floating point operations and a number of other operations are concurrently in pipelined operation. When only the code of Fig. 7 is in execution, the parallelism will be reduced to a constant of 5. Although there is such a change of degree of parallelism between the forward elimination and backward substitution phases of the computation, the parallelism remain entirely stable during each phase, hence are easily to be handled by the processors. Furthermore, In Fig. 5 - Fig. 7, the pattern of runtime data routing is regular, thus eliminating the data rearrangement problem for cyclic reduction. Moreover, it essentially can work for tridiagonal systems regardless of their size, hence, has more flexibility and generality than the cyclic reduction scheme.

The reader may wonder if the 5 to 20 folds of parallelism available in the pipelined algorithm may not meet the appetite of a supercomputer. We argue that the major concern should be how the parallelism in the algorithm can be most effectively used by a suitable architecture. First, the new scheme maintains a relatively constant amount of parallelism and relatively simple data routing pattern. Thus, the resource management and allocation problems are more easy to handle, thereby providing better opportunity of parallel processing when the machine has extra power. Second, one is often faced with solving a set of m independent tridiagonal systems (say, m=64), as frequently occurs in the solution of PDE's [11]. In this case, the new scheme can be best used by generating m independent pipelines for each system to obtain 20xm folds of parallelism (more than 1000 if m=64 !). Finally, the new scheme is flexible enough to be extended to obtain more parallelism when such a requirement does occur [9].

## 5. Sumary and Discussions

In developing new parallel algorithms, high importance attached not only to the speed of the greatest computation rate, but to the numerical stability problems as well. The stability aspect of the pipelined tridiagonal solver has been studied by the author in a second companion paper [10].

The entire code for the pipelined tridiagonal linear equation solver has been translated into the machine code of a proposed static data flow supercomputer, and preliminary simulation results indicate that the projected maximally pipelined throughput can be sustained for each of the three loops.

The pipelined solution scheme has several important advantages over other existing parallel algorithms. Although, the primary target machine used in this paper is a static data flow computer, we expect that the principle can also be applied to other data flow computers, such as the dynamic data flow machine [1], although a different perspective of pipelining may be required [7]. It is my belief that the basic ideas may also be useful for a conventional parallel machine architecture. A compiler which can perform the automatic program transformation to implement the pipepined solution scheme is an interesting challenge to the compiler construction for such computers.

## 6. Acknowledgements

The author is indebted to the constant encouragement and direction from Prof. Jack Dennis at MIT. Dr. Bill Ackerman and Kevin Theobald have read the draft and made interesting comments. Natalie Tarbet has provided valuable helps in the improvements of the English for this paper. Finally, the author is grateful to Gao Ping, for her typing of the entire manuscripts and preparation of the figures.

**CR categories and Subject Descriptors:**
G.1.3 [**Numerical Linear Algebra**]: Matrix inversion, Sparse and very large matrices; E.1 [**Data Structures**]: Trees; C.1.2 [**Multiple Data Stream Architectures (Multiprocessors)**]: Array and vector processors, Parallel processors; D.1.1 [**Applicative (Functional) Programming Techniques**].
**General Term:** Algorithms.
**Additional Key Words and Phrases:** Quadtrees, quaternary trees, Gaussian elimination, Pivot Step.

## Abstract

The quadtree representation of matrices is explored, particularly as it admits a parallel matrix inversion algorithm. A version of Gaussian Elimination (full matrix pivoting) is described as an applicative program which minimizes process dispatch by folding the pivot search into the preceding pivot operation. The tree structure incorporates incremental decomposition (for arbitrary, but small, numbers of processors), aids in load balancing, and provides a uniform representation for both scalars and sparse matrices that eliminates all compatibility/bounds checking within the important algorithms. Like other algorithms particularly suited to larger problems (where parallelism pays off), it may be used at the higher level in a hybrid strategy, for example, over pipelined vector-processing on smaller, conventionally represented submatrices.

## Section 1. Introduction

Consider a scenario of parallel or multi- processing with realistic constraints. A machine with $p$ processors is available to implement a matrix algebra package for sparse matrices of size, say, $n \times n$. Restrictions are that $7 < p \ll n$ and that the cost to dispatch/recover a processor is significantly greater than the cost to perform simple arithmetic.

Those restrictions [12] preclude some popular solutions wherein processes are dispatched whenever a processor might be (wished) available and often on processes that are so simple as to be trivial. For an algorithm to be useful under these restrictions, it must admit isolation of *substantial* subprocesses, sufficiently high in the computation tree (of the the chosen algorithm) in order to assure that the $p$ processors can be loaded using as few process dispatches as possible while balancing the load and avoiding duplication of effort. To do that requires identification of independent, arbitrarily large processes as high in that tree as possible—particularly for the cases where $p$ is indeed very small.

What is really needed first is an algorithm, presenting such a tree with the suggested decomposition properties. This paper presents such an algorithm, matrix inversion via classic Gaussian elimination, over a new data structure—the quadtree representation for matrices—in a purely applicative style [3, 5]. This formulation lends itself to satisfying the restrictions set forth above, regardless of the particular values of $n$ and $p$.

Applicative programs are necessarily presented as expressions without assignment statements or control statements except for (pure) function application. Such programs implicitly solve the problem of decomposition into independent processes [4] because each subexpression within the program is necessarily independent; therefore, the syntax tree may be strongly associated with the tree for process decomposition. Intermediate binding still allows intermediate results to be shared—rather than recomputed. While these matrix results are interesting and useful as they stand, an implicit goal of this paper is to encourage further study of algorithms for parallel computation through the philosophy enforced by applicative (or functional) programming style.

Gaussian elimination is hardly new, so what can be said that is really novel? Certainly, no improvement to well-studied asymptotic behavior will be offered. Three results, however, are offered that, together, promise a thoroughly practical algorithm under the envisioned constraints, whether or not their ultimate realization follows the discipline of applicative programming.

First, the relatively new idea of quadtrees for representing matrices [10, 11] is developed further, in a way that unifies our approach both to matrix/scalar algebra and to sparse/dense matrix manipulation. All scalars, $x$, also represent diagonal matrices, blurring the distinction between scalar and matrix, between sparse representation and dense representation. We shall see that one family of algorithms handles all pathologies.

Second is a version of matrix-inversion via Gaussian Elimination, through Pivot Step [6] with the pivot element selected as the largest candidate (in magnitude) from the entire matrix before each pivoting. Known to be most stable, this algorithm is also shown to present a pattern of parallelism. Each pivot step naturally decomposes by quadrants which, most interestingly, is a pattern suitable for the search tree for identifying the next (largest in magnitude) pivot candidate. There is, therefore, no question whether a *search* for the next pivot element should be implemented using parallelism or on a cheaply-dispatched uniprocessor.

0190-3918/86/0000/0092 $01.00 © 1986 IEEE

While such a search surely could use parallel processing, eliminating the explicit search phase by folding it into each (sparse) pivot saves search time, and better amortizes the overhead to dispatch each pivoting process.

Finally, an interesting relationship between padding and processor allocation is proposed to balance the load across independent processes. The quadtree matrix representation appears to be suited only to representation of $2^m \times 2^m$ matrices. When the size of a matrix is not a power of two, some padding is necessary which only wastes space proportional to $m$. What is interesting is that, having embedded an $n \times n$ matrix in (the lower right of) a $2^m \times 2^m$ one, processor allocation can make profitable use of the value of $(2^m - n)$ in partitioning the $p$ processors among subproblems. The argument is cast in terms of familiar matrix operations.

The remainder of this paper is in four parts. The quadtree representation is introduced first, including discussions of its restriction to vectors and generalizations to higher dimensions. The second section explores a Gaussian elimination algorithm under the new parallelism, as outlined above. The third offers a strategy for allocation of processor resources to discount the padding that might be necessary to fill out the quadtree representation. The final section offers some conclusions and hopes for further work.

### Section 2. Matrices

Let any $d$-dimensional array be represented as a $2^d$-ary tree. Here we consider only matrices and vectors, where $d = 2$ suggests quadtrees, and $d = 1$ suggests binary trees.

Matrix algorithms will be arranged so that we may (without loss) perceive any scalar, $x$, as a diagonal matrix of arbitrary size, entirely of zeroes except for $x$'s on the main diagonal; that is, $x = [x\delta_{i,j}]$. Thus, a domain is postulated that coalesces scalars and matrices, with every scalar-like object conforming also as a matrix of any size. Of particular interest are 0 and 1, which are at once the *unique* additive and multiplicative identities, respectively, for scalar/matrix arithmetic. Similarly, the scalar $x$ as a binary tree is interpreted as a vector of arbitrary length, each of whose components is $x$ (much like Daisy's [7] notation $\langle x^* \rangle$.) Inferring the conventional meaning from such a matrix now requires additional information (*viz.* its size), but we can proceed quite far without size information; it only becomes critical upon Input or Output.

Lest it appear that this coalescing of hitherto disjoint types hides too much, it is useful to draw an analogy from ordinary computation on floating-point numbers (FPNs), where details of internal representation are also suppressed. The point is that the way that quadtree-matrices (and FPNs) are commonly represented outside the machine has little to do with their internal representation. There are, in fact, conventional styles for writing matrices on paper—in row-major order (and for writing FPNs in scientific notation), but these may differ wildly from the way that they (and FPNs) are to be represented within the machine. Although the algorithms for translating between such representations are elegant, they are so complicated that they are surely not the first thing that should be shown to those unfamiliar with the nature of these internal representations. Thus, an unfortunate barrier rises in the path before those who would tinker on them: one must first write the I/O translators, which are among the least comprehensible, least efficient, and least exercised programs over the structure.

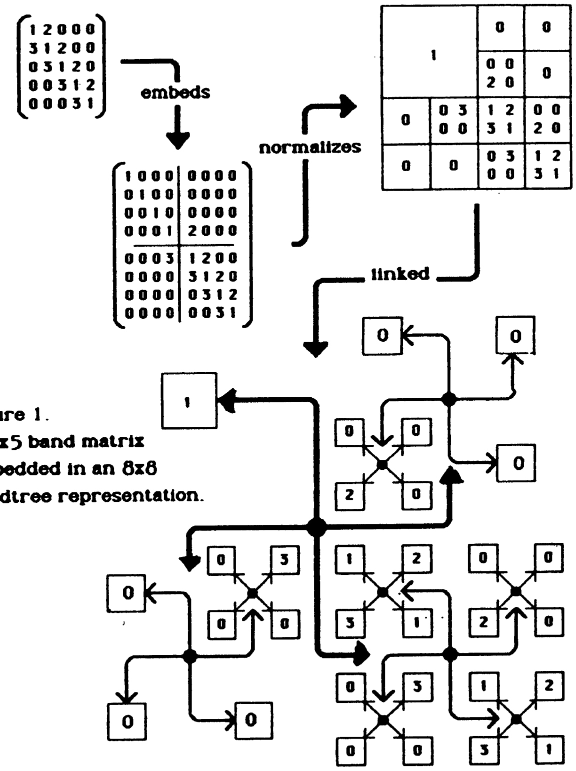

Figure 1. A 5x5 band matrix embedded in an 8x8 quadtree representation.

A matrix (of otherwise-known size) is either a vague 'scalar' or it is a quadruple of four equally-sized submatrices. So that this recursive cleaving works smoothly, we embed a matrix of size $n \times n$ in a $2^{\lceil \lg n \rceil} \times 2^{\lceil \lg n \rceil}$ matrix, justified at the lower, right (southeast) corner with zero padding to the north and west, except for nonzeroes—preferably ones—padded along the northwest diagonal (to avoid introducing an unnecessary singularity; see Figure 1.) The matrix is justified to the southeast, rather than the northwest, so that its eliminant [2] is properly defined.

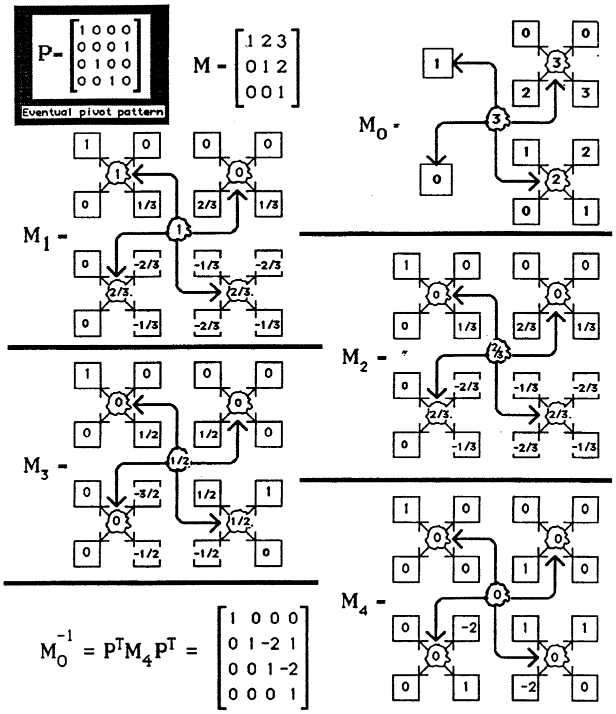
There is also a *normal form* convention. Under this quad representation, no submatrix will ever be composed of four 'scalar' quadrants, of whom the northeast and southwest are zero, and whose northwest and southeast coincide. Such a matrix would be represented, instead, by the latter 'scalar,' standing alone. Thus, the two important identity/annihilator matrices are represented *uniquely* by 1 and 0. If we require that the northwest padding, as in the previous paragraph, is necessarily one, then a *canonical form* results.

Elsewhere [10] I observed how algorithms for matrix addition, transpose, and multiplication follow the desirable pattern of decomposition, generally into $4^m$ or $8^m$ independent processes that can be dispatched high in the computation tree, up to the capacity of the execution environment. Of note is the role of 1 and, especially, of 0 as a constituent quadrant to such an operation. When any addend's quadrant is 0, the effort for matrix addition immediately simplifies by 25% because it is, therefore, unnecessary to descend and to traverse the corresponding quadrant of the other addend; all we need is a borrowed reference to it as one quadrant of the result. A factor's quad of 1 reduces Strassen's decomposition [9] of Gaussian multiplication from eight recursive multiplications to six; not only does a 0 quad similarly annihilate two recursive multiplications, but also it avoids two of the four subsequent additions, as well.

These properties are particularly valuable for matrices with regular patterns of non-zero entries, especially those that are sparse or in diagonal form. No special code is necessary to accelerate conventional operations on them (but one can wish for hardware that accelerates specialized tests like the ubiquitous tests for 0 submatrices.) It is, however, necessary to maintain the normal form so that, like rational numbers being always "reduced to lowest terms", matrices are reduced to their corresponding scalars whenever zero southwest\northeast quadrants and coincident northwest/southeast quadrants permit.

Another advantage shows up upon deeper study of several matrix manipulation programs over quadtrees: algorithms written to accept canonical-form operands need not be sensitive to the usual compatibility requirements. That is, ordinary quadtree algorithms for various operations will work regardless of the depth of their tree/operands; when operands are of different depth, the shorter paths—ending at a scalar—will be interpreted as all-conforming, diagonal matrices. Although their meaning may be questionable, the algorithms will run to completion instead of crashing with array-bounds-violations. In terms of domain theory, we have raised these operations to a higher point in their respective function-domain (given them more meaning by defining results where others fail because of incompatibility), while simplifying the code (by eliminating all the incompatibility tests and signaling thereof).

A "header" above each matrix quadtree might usefully contain two values needed for output translation: the length of the diagonal padding, and the exponent, $m$, for a $2^m \times 2^m$ matrix. The value of $m$ also suffices for runtime compatibility checking. Another bit there indicates whether the quadtree is to be interpreted as transposed, recursively interchanging southwest\northeast quadrants upon any access. Thus, not only does quadtree representation allow us to transpose an entire matrix in constant time—at the cost of building a new header—but also it allows row and column traversal at equally high efficiency, at the cost of symmetric-order traversal [6] of the appropriately projected binary tree.



P = [1 0 0 0; 0 0 0 1; 0 1 0 0; 0 0 1 0]

Figure 2. Knuth's Problem 2.2.6-18 [6, p. 556], worked.

### Section 3. Pivot Step and Inversion

This section describes an algorithm for matrix inversion, extended from Knuth's [6] for an entirely different data structure (also sparse). His terminology is used because it is readily available. Figure 2 outlines this algorithm applied to his problem, and should be compared against the solution that he provides. The algorithm is Gaussian elimination with full pivoting (although Knuth only selects pivots rowwise.) Much of the description applies to a single Pivot Step, but its most interesting property relates one such step to the next. It is easily simplified to one that only finds the root of the linear equation, $Ax = y$, for Matrix $A$ and Vector $y$.

Let a non-singular matrix, $M$, be represented with a quadtree as described in the previous section. Each nonterminal node, however, is to be decorated with additional information: the magnitude of the largest element in that quadrant, and its local horizontal and vertical coordinates. (It will be necessary to qualify the decoration further to exclude any element in an already-pivoted row or column from decorations. At this point, however, assume that no pivoting has yet occurred.) These coordinates need not be traditional indices—though it is easy to think of them that way. A cheaper implementation is just a pair of bits at each node selecting one subtree; the catenation of these subtrees identifies a path through each quadtree to the appropriately largest scalar.

Let us consider an algorithm to invert $M$, a matrix represented as a canonical-form quadtree, padded along its northwest diagonal as described in the previous section. The first step in computing the inverse of $M$, therefore, is to traverse its tree representation in postorder, installing these decorations at all internal nodes. (Sibling subtrees, of course, may be traversed in parallel.) Call the decorated matrix $M_0$. Decorations appear in florets in Figure 2; to save space, however, only the local maxima (no local coordinates) are shown.

Also needed are two trivial binary trees, each initially the scalar 0 indicating a boolean vector of all zeroes, and one trivial quadtree, $P_0$, also initially 0, similarly. For each $i$, Quadtree $P_i$, indicates the exact position of the first $i$ pivot elements—none so far; it will be filled in to become a permutation matrix, $P_{2^m}$, by the time the fully pivoted matrix, $M_{2^m}$, is computed. The boolean vectors indicate which rows/columns have already been pivoted; they will be filled with 1's until they both indicate that all rows/columns have been eliminated. The two vectors, therefore, are merely row (column) projections from the corresponding $P_i$, but in a format useful for directing subsequent decorations.

Having established the initial values of $M_i$ and $P_i$, for the next of $2^m$ pivot steps, we discover that the decoration at the root of this tree identifies the next pivot element. We presume here that $M_i$ is not a scalar. If it were (and thereby identified as the pivot scalar), then its reciprocal is the pivoted matrix.

Otherwise, the $M_i$ may be decomposed into quadrants, each distinguished by the decoration. One is *pivotquad,* distinguished because the pivot element lies within. Another is *rowquad,* named because it lies horizontally from *pivotquad.* The third is *columnquad,* because it lies above or below *pivotquad.* The last is *offquad,* so called because it does not coordinate on *pivotquad,* but lies diagonally from it.

The description that follows discusses the transformations on the four quadrants in reverse order from that just above. It turns out that *offquad*'s transformation is simplest, but it does depend on intermediate results derived from processing the other three quadrants. So many additional results are needed from handling *pivotquad,* moreover, that its description will be considerably eased by working backwards in order to justify them.

An important property of functions is that one invocation may return several results of differing types. This feature has been lost in many programming languages (perhaps because their designs presume that a computer has but one accumulator,) but it is critical to applicative style and allows one function invocation to return all these intermediate results.

Knuth's transformation of the matrix,

$$\begin{pmatrix} & \vdots & & \vdots & \\ \cdots & a & \cdots & b & \cdots \\ & \vdots & & \vdots & \\ \cdots & c & \cdots & d & \cdots \\ & \vdots & & \vdots & \end{pmatrix}$$

where $a$ is the pivot element, $b$ is any element in the pivot row, $c$ is any element in the pivot column, and $d$ is any off pivot element coordinating on $b$ and $c$, is

$$\begin{pmatrix} & \vdots & & \vdots & \\ \cdots & \frac{1}{a} & \cdots & \frac{b}{a} & \cdots \\ & \vdots & & \vdots & \\ \cdots & \frac{-c}{a} & \cdots & d-\frac{bc}{a} & \cdots \\ & \vdots & & \vdots & \end{pmatrix}$$

respectively. This is the transformation to be made, though it is to be done here recursively and (likely) in parallel.

The transformation of *offquad* requires the values of $d$ contained therein, and two vectors of values $b/a$ and $c$ coordinating on each $d$, occurring in the pivot row and column, respectively. Since these two vectors, represented as binary trees in normal form, occur in *rowquad* and *columnquad* they will have been extracted as intermediate results while processing those quadrants. If either of these vectors is zero, however, then the transformation collapses to the identity function; all values of $bc/a = 0$ and not even the internal decorations in *offquad* change, as neither the newly eliminated pivot row nor pivot column cross it. (This is *the* savings of sparse representation for Pivot Step.)

When *offquad* is a scalar, $d$—even if it is a normalized representation of a larger matrix (notably if $d = 0$) and $b/a$ and $c$ are vectors—then the correct transformation is the decorated form of $d$'s difference with their outer product, $d - bc/a$. In order to decorate the difference, the appropriate halves of the boolean vectors identifying rows and columns eliminated from $M_i$ are necessary parameters. (If $d$ is scalar and these vectors are non-trivial, then $d$ must be expanded into $\begin{pmatrix} d & 0 \\ 0 & d \end{pmatrix}$ and decomposed, as below.) When $d - bc/a$ is a scalar, either zero or its absolute value becomes its decoration, depending on whether it lies in an already pivoted row/column, or not.

When *offquad* is decomposed into four quadrants, then each of these is treated as an *offquad,* with the vector parameters cleaved in half to provide the four sets of vector arguments, and the four results decorated and normalized into the transformed quadtree.

The treatment of *rowquad* and *culumnquad* are similar, so only that of the former is presented here; the latter's is nearly dual to what follows. The treatment of *rowquad* requires the inverse of the pivot element, $a$, and a vector that is the portion of the pivot column that lies in *pivotquad*, but for the pivot element, itself. It is sufficient to represent both as a copy of the pivot-column vector with $1/a$ in place of the pivot element (which will have been extracted during the treatment of *pivotquad*). Also needed are a relative index locating the pivot row and halves from the boolean vectors indicating which rows/columns crossing *rowquad* have already been eliminated.

Results are the transformed *rowquad* and half of the pivot row (as a binary tree) extracted from *rowquad* for use in handling *offquad*. That vector is also needed for handling most of *rowquad*, itself because, unless *rowquad* is trivial, it must be decomposed into two sub*rowquad*s and two sub*offquad*s, the latter of which coordinates on that half of the pivot row.

Thus, the transformation of *rowquad* focuses first on the pivot row. When the row index indicates that *rowquad*–call it $b$— is entirely within the pivot row, then the residue column vector is just $1/a$, and the needed results (matrix and row-vector) are each the product, $b/a$. Decorated as a matrix, the local maximum is 0 because this row is being eliminated.

If *rowquad* is to be decomposed into submatrices, then the local index will indicate whether the pivot row crosses the upper or lower half. Accordingly, the pivot column and boolean vectors (identifying already eliminated rows/columns) are split, and those two containing the pivot row are treated (as *rowquads*) first. The pieces of the pivot row, extracted thereby, are joined at a binary node to become the vector-result of treating *rowquad, and* are passed as arguments with the other two quadrants for treatment as *offquad*s. Then these four quadrants are assembled and decorated into the matrix-result of this treatment.

Finally, we consider the treatment of *pivotquad*, upon which all the other three quadrants' treatments depend; it must occur first and yield as a partial result the transformed, decorated version of *pivotquad*; and as intermediate results: the row and column indices of the pivot element, and vector copies of the pivot column (with $1/a$ in place of the pivot element) and pivot row (with $-1/a$ in place of the pivot element). Moreover, while locating the pivot element, updated versions for $P_i$, the permutation matrix (which will only change in the quadrant corresponding to *pivotquad*), and for its projections, the two boolean vectors of eliminated rows/columns should be constructed. That's eight results, four of which are intermediate—not to be included directly in an answer, but to be used in treating sibling quadrants.

Three observations complete this description. First, the treatment of *pivotquad* is the same as the treatment of the whole matrix, $M_i$; the only difference is the unneeded, extra four results, beyond $M_{i+1}$, $P_{i+1}$, and the two boolean vectors projected therefrom. Secondly, the arguments to each Pivot Step (and pivoting successive *pivotquads*) are $M_i$, $P_i$, and the two boolean projections from $P_i$ (and the corresponding quadrants/halves therefrom.) The last three arguments are used as seeds for updated results, and the last two also help to place 0 decorations.

Finally, if $M_i$ (correspondingly, *pivotquad*) is a scalar, $a$, then all eight results are trivial: $M_{i+1} = 1/a$ and is decorated as 0 (now that both it's row and column have been eliminated); $P_{i+1} = 1$ and both its projections are 1, also; the pivot column is $1/a$, and the pivot row is $-1/a$; and both relative indices are 1.

When $M_i$ is not scalar, it decomposes into four quadrants, one of each type considered above. Algorithms for three of them (*rowquad, columnquad, offquad*) have been discussed above, and the fourth (*pivotquad*) is to be treated recursive as a Pivot Step, with basis stated the preceding paragraph.

The **parallelism** in this algorithm manifests itself in the interdependence of these recursive decompositions. For instance, treatment of successive candidates for *pivotquad* must precede transformation of all other quadrants; the depth of this recursion is at most $m$. After each is completed, its associated *rowquad* and *columnquad* may be dispatched simultaneously, and, of these, half must be transformed before the other half. Again, the depth of recursion is at most $m$. Thereafter, however, all *offquads* at all levels of the quadtree may be treated *simultaneously*. They generate most of the effort in a Pivot Step, but and thier transformations are mutually independent.

It should be clear that a pivot step can change lots of decorations from those in $M_i$; is there, then, sufficient information to restore them? Yes, because decorations will only change where scalar values have changed, or because a local maximum is disqualified because it resides in either the current pivot row or current pivot column. Such decorations have already been visited by this algorithm! (This point is most important when inverting sparse matrices, where little traversal is necessary.) We need only arrange that, as each interior node in the quadtree (that becomes the pivoted matrix) is reassembled, it must be redecorated with the appropriate maximum and local coordinates. Therefore, the position of each scalar encountered is resolved against the boolean vector indicating already-eliminated rows and columns; if it is to be excluded, treat its magnitude as zero *for the purposes of finding the maximum local magnitude.* If all four local maxima are zero, then the subtree is decorated with zero (and the local coordinates may be left undefined.)

As the four new quadrants are reassembled, it is necessary to find the maximum of their decorations and its two-bit coordinates, according to which of the four quadrants it came from. Internal zero decorations do not propagate, because some decoration must be positive if the original matrix was non-singular.

That completes the description of a single pivot step, $M_i \mapsto M_{i+1}$. It only remains to observe that the results of one step, including the pivoted, decorated matrix, the two vectors (binary trees) of eliminated rows and columns, and the building permutation matrix are passed from one step directly along to the next. *There is no need to search for the next pivot element,* because it has already been located. Moreover, it has been located by parallel processes already dispatched for the pivot step, itself, in parallel. Thus, there is no dispatch/recovery overhead for the parallel search!

Finally, observe that the desired inverse, $M^{-1}$ is readily available after permutations:

$$M^{-1} = P_{2^m}^T \times M_{2^m} \times P_{2^m}^T. \cdot$$

In fact, the code in the appendix builds up $P_i^T$, rather than $P_i$, anticipating this transpose..

This entire algorithm proceeds on non-singular matrices without any counters; even the outer control over of $2^m$ successive pivot steps may be set up as a loop until decoration becomes zero. In some sense, then, it is more abstract, and more useful, than algorithms that depend heavily on size declarations and bounds tests.

### Section 4. Subprocess Balancing

Suppose an $n \times n$ matrix is embedded in a $2^m \times 2^m$ matrix, where $k = 2^m - n$ and $0 \leq k < 2^{m-1}$ as in Figure 3. Section 2 suggested that the values of $k$ and $m$ might need to be available to the system at run-time, even though they remain unnecessary to (in particular) the abstract multiplicative operators. This section proposes another use for this same information: load balancing among the processors.

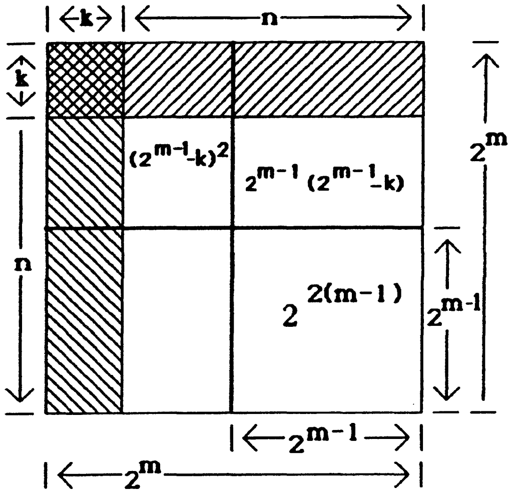

Figure 3. Areas within quadrants, excluding padding of k rows/columns.

The following discussion does not depend on denseness or sparseness of matrices. It does presume that the distribution of non-zero entries is uniform; if more patterns are known, then further inferences might be possible. The values of $m$ and $k$ indicate the size of a matrix and what proportion of it is trivial. From them we can determine what portion of each of the four quadrants is serious, *i.e.* likely to cause serious effort for the processors, and we can use this information to distribute the $p$ processors among the four quadrants.

Consider matrix addition, for instance. The quad recursion pattern is simple; each quadrant requires addition effort in proportion to its "serious" area (Figure 3). The serious area of such a matrix is $(2^m - k)^2$. It is divided up among its four quadrants in the following proportions:

| Quadrant | Relative share of area |
|---|---|
| Northwest | $\frac{2^{m-1} - k)^2}{(2^m - k)^2}$ |
| Northeast | $\frac{2^{m-1}(2^{m-1} - k)}{(2^m - k)^2}$ |
| Southwest | $\frac{2^{m-1}(2^{m-1} - k)^2}{(2^m - k)^2}$ |
| Southeast | $\frac{2^{2(m-1)}}{(2^m - k)^2}.$ |

It is unlikely that these proportions have integer products with $p$. If only a fraction of a processor is available to a quadrant, a good solution is to combine quadrants on shared processors in a way that the individual requests for a processor sum to an integer. A likely grouping is to set the northwest, northeast, and southwest sums (the partial quadrants) on one processor, and to set the southeast sum alone on another.

Therefore, if one had $p$ processors to add such matrices, one could use this information to distribute them to four quadrant process in these proportions in a top-down pattern. As mentioned in the introduction, it is important that processor allocation be done as high in the data structure/computation tree as possible, so that the overhead of process dispatch/recovery not be paid repeatedly.

In this way it is likely that larger quadrants (southeast) gets more processors. When a quadrant receives but one processor to compute its result, it operates as a uniprocessor; if it receives more than one, it can apply the same idea to divide up its processor resource once again, and so forth. The first three quadrants make the most interesting further processor allocations; the southeast quadrant is presumed to be uniform and so its share will just be divided in even fourths.

These same proportions could apply to the Pivot Step algorithm above. Unlike addition, however, we saw that there was some serial behavior to Pivot Step. Thus, (using terminology from before) *rowquad* and *columnquad* may be dispatched together, but they are only two of four quadrants. Nevertheless, their computational effort may also be approximated by the relative size of two areas (diagonal from each other), in the table above. Although we may not know which processors until run time, we may select the proper proportion then and split the processor resources in that manner.

Gaussian matrix multiplication (under Strassen's formulation [9]) easily decomposes into eight products, which are pairwise summed to form a four-quadrant answer. Excluding the effect of scalars (*i.e.* a quadrant of 1 or 0 avoids a quadrant multiplication) and asserting that the $O(n^3)$ algorithm does require a processor resource proportional to $(2^m - k)^3$, we determine the proportion of this resource that each of the eight products needs. This was done by setting two matrices, as in Figure 3, as multipliers and extrapolating the effort to multiply each of eight sub-products from the areas of the sub-multipliers (quadrants.)

The eight ratios are best described by combining them pairwise, as their associated products are to be added, to yield the proportion of effort invested in building each of the four sums that become the matrix product. The four ratios coincide with those already derived above! Furthermore, proportions associated with each of the eight products may be obtained by multiplying each of these four ratios by $2^{m-1}/(2^m - k)$ and by $(2^{m-1} - k)/(2^m - k)$, respectively. Thus, the four-quadrant ratios are exactly as before, and the eight-quadrant ratios are uniform extensions from these.

Such process allocation could be determined statically at compile time [8] when the language requires matrices to be of declared, constant size and uniform sparseness. The algorithms proposed here do not require bounds declarations, but if they were available, it would be possible to avoid much communication with, and system saturation of, a dynamic scheduler.

## Section 5. Conclusions

Because we assumed that the number of processors, $p$, is small compared to the size of the matrix, $n$, we need to cleave matrix manipulations into a *few* subprocesses of *balanced* size, so that the resource $p$ can be allocated deliberately. If one cleaving does not consume all the processes, the pieces may be further split. Avoiding repeated dispatch and recovery, these algorithms have the virtue of splitting at the base of the quadtree—at the root of the problem.

Although these algorithms are described as if only scalars could be leaves of the quadtree, that arrangement is not necessary. It is perfectly possible that sizable matrices dwell at the leaves, matrices that might be represented in traditional row-major order, and manipulated using traditional iterative and pipelining algorithms, programmed in FORTRAN *et fils*. (Pipelines would need an extra input stream of bits, identifying candidates for updated local maximum, and each could then compute updated vector decorations during a vector update.) The size of such leaf matrices should be chosen to balance the efficiencies of existing style and existing machinery against the obvious need for multiprocessing techniques to accelerate large matrix computation.

Derived from a purely applicative approach, they better suit a computing environment with many processors, with memory banked at varying distances from the different processors, and with contention for access to shared resources as a real constraint on efficiency. The quadtree approach shows us how to represent matrices so that useful pieces may be localized where some processor can make computational headway on the problem without excessive interference from all its brethren. It has long been known [4] that applicative style solves the problem of decomposing an extant algorithm; the problem addressed here is the discovery of good algorithms that cleave into usefully sized pieces.

One last issue raised by this work relates to all sparse matrix techniques. I have seen only vague definitions of a what makes matrices *sparse*, possibly because sparse representations are so different from one–another, and maybe because sparseness has been purely an operational concept. Quadtrees, as we have seen, offer a reasonable representation for sparse matrices that is consistent with what we would use for dense matrices; based on that observation, *alone*, I suggest a **measure of sparseness** for matrices: the ratio between its average path length in its quadtree representation (from root to leaf) and the logarithm of its size. Ratios closer to zero indicate sparser matrices..

· Quadtree representation of matrices was motivated by studies in applicative programming and as part of an effort to study its impact on Matrix Algebra for MIMD multiprocessors. The results of the effort are more than satisfactory: not only does the technique apply to a well-worked problem, but also it yields new insight (through a distribution of searching across Pivot Step) on optimal hardware/software solutions. Thus, there we have more support for using applicative programming (and its algebra) for programming parallel architectures and a suggestion that those architectures provide a multi-banked heap.

There is already interest using quadtrees as *the* uniform representation for matrices in a large computer algebra system [1], a sophisticated piece of software running on fairly conventional hardware. They also have an important role to play within conventional languages used on very sophisticated hardware, an experiment that remains to be done.

### Appendix

The following examples, all of which evaluate to 1, are useful as an introduction to the Daisy [7] code that follows. They exemplify a new style of applicative programming that depends on functional combination and *data recursion* [5] to specify multiple and interdependent results without cognizance of a necessary sequence of evaluation. All primitives used here, however, have been in Daisy from its birth. The forms

```
let:[  identifierStruc  binding  result]
rec:[  identifierStruc  binding  result]
```

return *result* computed in an environment enhanced with *identifierStruc* bound to *binding*. Evaluation is lazy, and the list structure of *binding* must match the structure of *identifierStruc*, wherein bound identifiers become bound according to their position within that list. Functional combination [4] is indicated by a list structure as a function, to the left of the colon, the "apply" operation. In the layout below, one may perceive that the constituent components of that combination is applied vertically to the (transposed) argument matrix. Thus, the intermediate results of all the functional combinations below is that of ⟨10⟨3 1⟩⟩.

```
let:[   [sum    [quotient          remainder]]
         <add    <div               rem      >>:<
         <6      <        10        *        >>
         <4      <        3         *        >> >
    remainder]

divide = ^λ[a b].<div:<a b> rem:<a b>>
let:[   [sum    [quotient          remainder]]
         <add              divide            >:<
         <6                10                >
         <4                3                 > >
    remainder]

rec:[   [sum    [quotient          remainder]]
         <add              divide            >:<
         <6                sum               >
         <4                3                 > >
    remainder]
```

The skeleton of the Daisy code for Pivot Step follows. It presumes that quadtree-matrix arguments/results are decorated at non-terminal nodes. This code has been cut back to remove all provision for normalized (sparse matrix) representation and for permuting the quadrants. Normalized matrices may require expansion of scalar arguments into a quadruple (two of which are zero; two of which are the scalar) upon function entry. and collapse of such quadruple patterns to the scalar upon exit. Without provision for permuting, this code will pivot only on the northwest-most (upper left) scalar entry; the expanded code tests two bits of "decoration" (*ibit* and *jbit*), and provides permutations on arguments and results to translate to/from this northwest orientation.

Notice that the instances of functional combination in *PIVOT*, *ROW*, *COLUMN*, and *OFF* are

$$[PIVOT\ ROW\ COLUMN\ OFF],$$

$$[ROW\ OFF\ ROW\ OFF],$$

$$[COLUMN\ OFF\ COLUMN\ OFF],$$

$$[OFF\ OFF\ OFF\ OFF],$$

respectively, reflecting the recursive decomposition of each kind of quadrant. It is also important that *OFF* immediately tests whether either vector argument (the projection from the pivot row or pivot column) is zero, and acts as an identity function in that instance. Also, this code builds the transpose of the permutation matrix ($P_i^T$ from the paper) directly.

# SK-Banyans: A Unified Class of Banyan Networks

Julio de Melo
Roy M. Jenevein
Department of Electrical and Computer Engineering
University of Texas at Austin
Austin, Texas 78712

## Abstract

A unified class of banyan networks is proposed which presents better distance properties than SW-banyans. This new class is called SK-banyans for the *SK*ewing scheme that is adopted for the connections between nodes at different levels. Its definition is given along with the characteristic properties relative to SW-banyans. A consideration is given for the virtue of symetric connection schemes in relation to their distance properties. Examples of different Characteristic Connection Patterns (CCP's) for SK-banyans are presented. A general construction scheme is proposed and a comparison of distance properties of SK- and SW-banyans is presented. Optimality criteria have been developed to determine whether a given CCP provides the best distance properties.

## 1 Introduction

Interconnection networks have become an important component of parallel or distributed computer systems, and as such have stimulated much interest in recent years [16]. Topics such as topologies, routing, data manipulation, fault-tolerance and VLSI design, to name but a few, have by themselves spawned new research areas where so much is yet to be done.

On the issue of topologies, the topic to which this paper is related, new structures have been proposed recently [6,10,16], as well as old structures have been subject of renewed studies [11].

Banyan networks [5,14] constitute one such class of the many proposed topologies, and reports on their fault- tolerance properties, resource allocation algorithms and performance evaluation can be found in the literature [3,4,7,8,12,15].

It was with much hesitation that we considered putting forward a paper on "yet another network topology". The reason, however, for doing so is twofold. First, the SK-banyan represents a unification and not a fragmentation of the networks issue, because the SW-banyan (and all of its isomorphic counterparts) is a member of the class of SK-banyans. Second, significant understanding of the issue of network connectivity and distance properties have been attained by the study of SK-banyans.

Our research focuses on the evaluation of the distance properties of a specific class of banyans, motivated by results reported in [13] regarding the distance properties of KYKLOS multiple-tree networks. These results showed that, by changing the connections of the second tree in an appropriate and regular way, the distance properties of this so modified double-tree were shown to be better than for the conventional double-tree. This represented a break from traditional symetric interconnection schemes of the past which have lead to symetric redundancy. The connections, while a break from the past trends, are regular and predictable from stage to stage. As the banyan networks have an embedded tree structure, they might also show some improvement by using this modified connection scheme. It must also be pointed out that the modified connection still provide a tree topology between the apex and base of the structure.

The emphasis on the study of the distance properties of this new banyan network is justified by the fact that the delay observed in the transmission of messages across an interconnection network is closely related to their distance properties [1]. Since the apex-distance is always $log_2 N$, the distance referred to here is from any node to any other node. This is particularly useful when studying single-sided networks, because base-to-base distance becomes quite important. Also, the fault-tolerance properties of the ICN may show some improvements as well, due to the existence of alternative routes. This is true for both KYKLOS and SK-banyans where better distance properties are obtained by avoiding redundant connections between sets of nodes at different levels.

## 2 Banyan Networks

A *banyan* network is defined in terms of a directed graph representation, which is a Hasse diagram of partial ordering with a unique path between every base and apex. A *base* is defined as a node of out- degree 0 and an *apex* is defined as a node with in-degree 0. In this paper, we assume the convention that levels are enumerated from apex to base, with level 0 corresponding to the apex. Two examples of banyan networks are shown in figure 1. The left network is irregular and is restricted to special applications, such as mapping an algorithm into a network. The right network, being regular, is very appropriate for use in interconnection networks, both because data routing algorithms can be easily specified, and because of its good properties for data manipulation, due to its embedded tree structure. A regular banyan is characterized by the fact that all of its nodes (with the exceptions mentioned above) have the same in-degree (called *spread* in banyan terminology) and the same out-degree (called *fanout*). These parameters are represented by the letters $s$ and $f$, respectively.

Regular banyans can be further classified into different networks, according to the connection scheme applied to the nodes. Two of them have been reported in the literature, the SW-banyan and the CC-banyan. The former is defined as a recursive expansion of a crossbar structure (which itself can be thought of as a one-level SW-banyan), by interconnecting $s^{l-1}$ such crossbars and $f$ identical $l-1$ SW structures, all with the same fanout and spread.[1]

SW-banyans can also be further divided into *rectangular* and *non-rectangular* SW-banyans, the only difference being that for the former the spread and fanout are the same. SW-banyans are described by a set of numbers in the format $(s,f,l)$ for non-rectangular banyans, and by $(s,l)$ or $(f,l)$ for rectangular banyans. This latter class of SW- banyans has been shown to be topologically equivalent to a number of other proposed topologies [16], and as such the results presented here could also be applied to these isomorphic topologies.

[1] $l$ is the number of levels in the SW-banyan.

## 3 Skewed Banyan Topology

### 3.1 Basic principle

One property of (s,f,l)SW-banyans is that $s$ nodes at level $i$ have each one of their links connected to the same $f$ nodes at level $i+1$. In other words, we can say that $f$ nodes at level $i+1$ are connected to the same $s$ nodes at level $i$. This property is illustrated in figure 2 for a (2,3,2) SW-banyan.

With this connection scheme we can notice that $f$ edge-disjoint paths of length 2 exist between the $s$ nodes of every set at level $i$. Although the redundant paths improve the reliability of connections between $s$ nodes, and only between these, they represent a bottleneck if we consider their distance to other nodes at the same level or to nodes at different levels(the numbers at each node in figure 2 represent their distance to the node marked '0'). If the connections in the original network are rearranged in a way such that two nodes at level $i$ have no more than a single node in common at level $i+1$, the remaining $f-1$ links for each node at level $i$ might be connected to nodes at level $i+1$ that connect to different nodes at level $i$, rather than back to the original two nodes. The basic idea then is to reduce the distance between nodes at the same level by avoiding redundant connections between them through nodes at level $i+1$. For the original network of figure 2, the connections can be rearranged as shown in figure 3. Comparing the distance properties between these two connection schemes, we can observe some improvement caused by the use of a skewing scheme (the numbers represent distances to node '0' as in figure 2).

That these improvements are scalable to larger size networks or to networks with different fanouts and spreads can be easily verified, and examples in a later section will show this.

### 3.2 Definition of SK-banyans

As an SK-banyan is closely related to an SW-banyan, we will define the former in relation to the latter.

**Definition 1:** An (s,f,l) SK-banyan is a banyan network for which the following conditions hold :

1. it is regular;
2. it has the same number of nodes per level as an (s,f,l) SW-banyan;
3. it has the same number of links between levels as an (s,f,l) SW-banyan.

We continue by defining an important property of SK-banyans, namely, the existence of two characteristic levels.

**Definition 2:** The characteristic levels of an (s,f,l) SK-banyan are the two levels that correspond, on an (s,f,l) SW-banyan, to the levels whose respective connected subgraphs have the following property :

$$n_i = \begin{cases} s \times f & \text{if } s \leq f \\ s \times s & \text{if } s > f \end{cases}$$

$$n_{i+1} = \begin{cases} f \times f & \text{if } s \leq f \\ f \times s & \text{if } s > f \end{cases}$$

where :

$n_i$ - number of nodes at level i
$n_{i+1}$ - number of nodes at level i+1
s - spread
f - fanout

Another related definition is presented as follows.

**Definition 3:** The Characteristic Connection Pattern **(CCP)** of an (s,f,l) SK-banyan is an undirected graph formed by the characteristic levels and the connection pattern between them.

In figure 4, a (2,3,3) SW-banyan is shown. For this case, $s < f$ and then $n_i = s * f = 6$ and $n_{i+1} = f * f = 9$. Of all the connected subgraphs in this particular banyan, the only ones that satisfy definition 2 are those marked. They will correspond then to the characteristic levels on a (2,3,3) SK-banyan. If the connections between these levels are rearranged, the particular connection pattern chosen will constitute the Characteristic Connection Pattern (CCP) of the SK-banyan, as defined. Two of the many possible choices for the CCP for a (2,3,l) SK- banyan are shown in figure 5.

The importance of defining the characteristic levels and the characteristic connection pattern will become clear after the following definition.

**Definition 4:** A uniform (s,f,l) SK-banyan is an (s,f,l) SK-banyan for which the connection patterns between levels are reproductions of the Characteristic Connection Pattern, taken on a group-wise basis.

In figure 6, a (2,3,3) SK-banyan is shown, for which the CCP is that shown in figure 5(a), and the nodes at levels 1 and 2 constitute the characteristic levels. If we look at a group of connections between levels 2 and 3, each group with three links, we can recognize the same pattern as the CCP. This is what is meant by "group-wise" in the above definition. Between levels where $n_i > s * f$ and $n_{i+1} > f * f$ (for $s <= f$), a group of connections, rather than individual connections, will follow the CCP, no matter how large the group.

Since the CCP completely defines a uniform SK-banyan, once it is chosen we are able to construct the whole network and to define a routing algorithm. Although not proved here, it may also be anticipated that non-uniform SK-banyans, where the connection patterns between levels are not necessarily reproductions of the characteristic connection pattern, may be more difficult to construct and as complex as irregular banyans for data routing, thus will not be considered here. Also, by Definition 1, SW-banyans can be considered a case of SK-banyans, for which a specific CCP is used.

For simplicity, we will assume in the following discussion only the case for $s <= f$. The case for $s > f$ obeys the same principles.

We now introduce a matricial representation of the CCP, in order to facilitate its analysis and classification. The CCP is a bipartite graph, where one set has $s * f$ nodes and the second set has $f * f$ nodes, as given by Definition 2. The CCP can be further divided into $s * f$ bipartite subgraphs, each one with $f$ nodes in each of its two sets. The number of different subgraphs is equal to $f!$, and as there are $s * f$ of these subgraphs in a CCP, the total number of different CCP's for a given $s$ and $f$ is equal to $(f!)^{s*f}$. Table 1 shows these values for different spreads and fanouts.

The natural partition of the CCP into bipartite subgraphs of a larger bipartite graph leads to the following definitions.

**Definition 5:** The Connection Matrix (**CM**) of a bipartite subgraph of a CCP, is an $f \times f$ binary matrix $CM = [x_{ij}]$ such that :

$$x_{ij} = \begin{cases} 1 \text{ if node } i \text{ is connected to node } j \\ 0 \text{ if they are not connected} \end{cases}$$

**Definition 6:** A Primitive Connection Matrix (**PCM**) is one element of the set that is composed of all the $f!$ possible Connection Matrices.

**Definition 7:** The Characteristic Connection Matrix (**CCM**) of a CCP is an $s \times f$ matrix whose elements are Connection Matrices taken from the set of Primitive Connection Matrices.

Given the CCP of figure 5 (a), we can partition it into six bipartite subgraphs as shown in figure 7, where the respective CM's are also shown. The CCM will be formed by these CM's, as shown in figure 8. The set of PCM's for this case ($s = 2; f = 3$) is shown in figure 9, along with the respective graphs. Numbering each of the PCM's from *0* to $[(f!) - 1]$, the CCM can be represented as an $s \times f$ matrix whose elements represent the number of the PCM that corresponds to each CM in the CCM. For the CCM of figure 8, this notation would lead to the matrix shown in figure 10. This notation is more compact and as complete as the CCM itself.

### 3.3 Optimality criteria

It is clear, by looking at table 1, that an algorithm or criteria should be proposed in order to determine which of the large range of CCP's provides the best distance properties. Given the size of the problem, and the fact that in order to gather meaningful results we must deal with reasonably large networks, an analytical approach seems unfeasible. Instead, we performed a computation of the distance properties of a subset of all the possible (2,3,4) SK-banyans. From these results, we were able to derive two criteria that can determine, based on the CCM, if the resulting (2,3,l) SK-banyan is optimal in terms of distance properties.

The first criterion is related to the connectivity of the nodes of the upper level of the CCP. As pointed out in section 3.1, the connections of these nodes should be made in a way such that they linked the maximum number of nodes in the lower level. This spreading of connections is represented by a matrix, called Spread Connectivity Matrix, defined as follows.

**Definition 8:** The *k-th* Spread Connectivity Matrix (**SCM**) SCM$^k$ of a CCP is an $f \times f$ matrix whose elements are given by the *k-th*-row-summation of the Connection Matrices of the corresponding Characteristic Connection Matrix, or :

$$SCM^k_{ij} = \sum_{l=0}^{f-1} CCM^l_{ij}$$

$$\text{for } 0 \leq i,j \leq f-1$$
$$0 \leq k \leq s-1$$

As the CCM is an $s \times f$ matrix, there will be $s$ SCM's. We can now state the first optimality criterion.

**Definition 9:** Connectivity Criterion : a (2,3,l) SK-banyan presents optimal distance properties if all the elements of every SCM are equal to 1, or :

$$SCM^k_{ij} = 1$$

$$\text{for } 0 \leq i,j \leq f-1$$
$$0 \leq k \leq s-1$$

This criterion was established by verifying that from the set of PCM's, $f$ of them can always be selected such that their summation, as defined above, leads to a matrix with all the elements equal to 1. This corresponds to the optimal case.

The second criterion is related to the redundancy in connections between two nodes of the upper level of the CCP. As also pointed out in section 3.1, nodes at the upper level should have only one node in common at the lower level. This redundancy is represented by a matrix, called Redundancy Matrix, defined as follows.

**Definition 10:** The Redundancy Matrix (**RM**) of a CCP is an $f \times f$ matrix whose elements represent the number of ocurrences of the indices $i,j$ of the nodes of the upper level of the CCP to which each of the nodes of the lower level are connected.

The nodes at the upper level are numbered as shown in figure 11. The numbers at each node of the lower level indicate the indices of the nodes of the upper level to which they are connected. In this case, each ordered pair occurs only once, and so the Redundancy Matrix will have all of its elements equal to 1. We state the second criterion as follows.

**Definition 11:** Redundancy Criterion : a (2,3,l) SK-banyan presents optimal distance properties if all the elements of the Redundancy Matrix are equal to 1, or :

$$RM_{ij} = 1$$

$$\text{for } 0 \leq i,j \leq f-1$$

This criterion was established by noticing that any redundant connection results in an entry in the Redundancy Matrix equal to 2, whereas the absence of a connection results in an entry equal to 0. The only case where there is no redundancy is when all the entries in the Redundancy Matrix is equal to 1, which means that there are no redundancy or absence of connections between the nodes.

As an example of the application of these criteria, figure 12 shows three cases of different CCP's with their respective CCM's and the Connectivity and Redundancy matrices. Figure 12 (a) refers to a (2,3,l) SW-banyan, (b) refers to a non-optimal CCP, and (c) to an optimal CCP. As can be seen, only in the last case the two optimality criteria are satisfied.

Using these criteria to compute the Spread Connectivity and the Redundancy matrices of all the (2,3,4) SK-banyans takes less than 1/1000 of the processor time needed to compute their distance matrices and average distances. By selecting the PCM's such that the connectivity criterion is satisfied, the range of CCM's to be searched for optimal cases can be significantly reduced. A procedure to perform these selections systematically is being investigated.

### 3.4 Construction Scheme

Given the definitions from the previous section, we now present a construction scheme for (s,f,l) SK-banyans, based on the CM's. One reason for using these matrices is that, once $s$ and $f$ are selected, the PCM's are defined and any CCM can be constructed by assigning to each of its CM's the corresponding PCM.

```
for i = 0 to (number of levels - 1) do

  $gs_i = s * f^i$
  $bs_i = f^i$

  for k = 0 to (number of nodes
              at level i) - 1 do

    offset = k / $gs_i$
    $gn_{k,i}$ = k mod $gs_i$
    $bn_{k,i}$ = (k mod $gs_i$) / $bs_i$

    for l = 0 to (f - 1) do

      skew = skew_factor [ pcm [ cm_num, l]]

      and connect

        node(k,i) to
          node(offset + l * $bs_i$ + skew, i+1)

    where :

      $gs_i$ - group size at level i
      $bs_i$ - block size at level i

      k, i - node number (number, level)

      offset - lowest node number of the group
      gn - group number of the node
      bn - block number of the node

      cm_num - CM number (0 <= CM <= ($s*f$)-1)
      pcm - PCM number (0 <= PCM <= f-1)
```

This algorithm has been implemented in Pascal, and was used to generate all of the examples used in this paper.

# 4 Distance Properties

The distance properties of some examples of SW- and SK-banyans will now be presented, and two metrics will be used. One measures the percentile of nodes that are within a given distance from a particular set of nodes. We will call this measure the *reach factor*. The second measures the average distance between sets of nodes.

## 4.1 (2,5) SW- and SK-banyans

It is also necessary to consider rectangular banyans, hence table 2 shows the distance properties of both banyans, in terms of reach factor. It can be seen that SK-banyans provide better distance properties than SW-banyans. This table also shows a very important property, namely, that the improvement obtained for some levels is not at the expense of others. As can be seen, level 0 in both banyans present the same distance properties, but starting at level 1, the SK-banyan provides improved distance at every level. Figure 13 shows the same results in a graphical form, for levels 0 and 4.

## 4.2 (2,3,4) SW- and SK-banyans

Table 3 shows the distance properties for (2,3,4) SW- and SK- banyans. Again, the SK-banyan shows an improvement over SW-banyans, this time higher than in the previous case. Figure 14 compares the reach factor for the two types of banyans. As before, the improvements obtained for any level is not at the expense of the distance properties of any other level.

## 4.3 (2,3,4) SK-banyans with different CCP's

As mentioned in the previous section , different CCP's may provide different distance properties. Computing the distance matrices for the CCP's of figure 5, we obtain the results shown in table 4. It is important to realize that not only are some improvements achieved by using SK- over SW-banyans, but also by choosing one CCP over another. Figure 15 shows how different CCP's compare to each other and to the respective (2,3,4) SW-banyan.

## 4.4 Average distances

For a specific subset of (2,3,4) SK-banyans (which included the sub-class of SW-banyans), we computed the average distances between sets of nodes at each level. Three results are shown in table 5, respectively for the SK-banyans whose CCM's are those shown in figure 12. As shown, the improvement in average distance varies with the level. For a better visualization figure 16 shows the variation of the average distance with the CCP type, for this particular subset of SK-banyans.

# 5 Conclusions

A new class of banyan networks has been presented which has been shown to have better distance properties than SW-banyans. Although these improvements have been demonstrated only in relation to distance properties, it should be expected that similar improvements would occur for other properties, especially traffic and fault-tolerance. Justification for this reasoning is provided by way of analogy with KYKLOS and many other topologies, which have shown the connection between distance and traffic [9].

Improvements in the distance properties are essential for minimizing communication overhead. An example of this is the architecture proposed for database applications [2]. In this architecture, a set of host computers at the apex of an ICN processes the queries and send requests to a set of I/O nodes at the base of the same ICN. The storage allocation scheme proposed assumes heavy traffic between these I/O nodes, both to decrease the effects of "hot spots" and to reallocate the database as it changes. It is desirable in this case that the distance between these nodes be as low as possible, without aggravating the distance properties of the apex nodes.

The matricial representation of CCP's allowed the construction and classification of SK-banyans, as well as the proposal of criteria for determining the optimality of a CCP. Although results here were provided only for the case where $s = 2; f = 3$, the formulations and definitions are general in nature.

Because SW-banyans are a case of just one CCP, the concept of SK-banyans represent a generalization of the topology , and allow a more unified view of the properties resulting from interconnection variation. The symetry applied to conventional networks, while providing simple routing, has lead to redundant connections. Minimization of this redundancy results in networks with a richer set of properties such as distance and traffic.

ABSTRACT -- This paper extends the modeling and analysis of packet switched multistage cube interconnection networks to include the use of multiple-packet message formats. A multiple-packet message format is needed within an interconnection network when the message to be transmitted exceeds the network's packet size. The packet offset time is introduced and used to gauge the transmission rate differential between the network interchange boxes and the system PEs. Based on assumed network and system operating characteristics, optimum network performance offset values are given. A methodology for evaluating the relative performance of circuit and packet switching transmission modes is developed. For an assumed set of network and system parameters, results indicate that, in contrast to inter-computer networks, the performance of packet switching networks is better than that of circuit switching networks for long message lengths.

## 1. INTRODUCTION

An integral part of any parallel processing system is its interconnection network, used to link the processors and, possibly, memory modules together. One class of networks suitable for use in a parallel processing system is the multistage cube networks [24]. This class includes topologically equivalent networks such as the baseline [26], the indirect binary n-cube [18], the generalized cube [22], the omega [14], the flip [1], and the SW-banyan (S=F=2) [11]. Multistage cube networks have been used in the STARAN [1] and BBN Butterfly [4] and have been proposed for use in many future systems such as: the IBM RP3 [19], PASM [23], Ultracomputer [10], and database machines [7].

Multistage cube networks can be designed to function using circuit or packet switching methodologies for data transmission within the networks. A general framework is developed in this paper that quantizes system and network parameters and thereby facilitates the comparison of circuit and packet switched networks. A specific set of network and system parameters are used to demonstrate the utility of the framework. The general framework can be used by network designers to select which network switching methodology best meets their system requirements. Networks can also be designed that incorporate both circuit and packet switching modes [20]. In networks where both modes are available, this analysis framework can be used to identify which transmission mode should be used for a given set of operating conditions.

In a packet switched network, when the amount of data to be transmitted exceeds the network's packet size, multiple data packets must be generated by the network source and then be transmitted to the appropriate destination. The performance analysis of networks operating in a multiple-packet environment is considered in this paper. Packet switching network models are extended, through the use of simulations, to include the transmission of multiple-packet messages. A tradeoff analysis, based on assumed network and system operating characteristics, is made to compare the performance of this format to that of circuit switching. This research has been motivated by the design of the PASM parallel processing system system at Purdue University [23, 16].

Section 2 defines the system and network operating environments. The performance analysis of multiple-packet message transmissions is then presented in Section 3. Performance comparisons between circuit and packet switching network operations is discussed in Section 4. Conclusions are presented in Section 5.

## 2. NETWORK MODEL AND SYSTEM OPERATION

In this paper, the generalized cube network will be used as a model of all of the networks within the multistage cube class. The network model will be the same as the models developed in previous analyses for omega networks [2, 3] and baseline networks [15]. Assume the network has N inputs (sources) and N outputs (destinations), where $N = 2^n$. The network consists of n stages with each stage being composed of N/2 2-by-2 interchange boxes. Interchange boxes in stage *i* pair I/O lines with labels that differ only in the *i-th* bit position. The same labeling is used for both the input and the output lines connected to an interchange box. A generalized cube network is shown in Figure 1, with N=8. The network's sources and destinations are assumed to be *processing elements (PEs)*, processor-memory pairs; i.e., PE i is connected to network input port i and network output port i, $0 \leq i < N$. This configuration is generally referred to as a *PE-to-PE* system architecture. Distributed routing control is assumed, with the settings of the individual interchange boxes (straight or exchange -- broadcasting will not be considered in the model) determined by routing information contained within the routing tag of each message [14, 22]. Prior to the transmission of data between a source-destination pair in a circuit switched network implementation, a complete path linking the pair must be established and then held until the completion of the data transfer. Using packet switching, a message consists of one or more data packets. Each packet makes its way from stage to stage releasing links and interchange boxes immediately after using them.

The network is assumed to be operating under the following assumptions [8]. Each source PE generates its messages independently from all other sources. Each source generates messages for each destination PE with equal probability. Messages will be generated based on a predetermined, fixed loading factor. The destination PE can receive data from the network faster than the network can transmit the data (this simplification implies that an output device will not act to bottleneck the operation of the network itself). Finally, a message, or a message packet, consists of two parts -- the routing tag and one or more data words.

This research was supported by the Rome Air Development Center, under contract number F30602-83-K-0119.

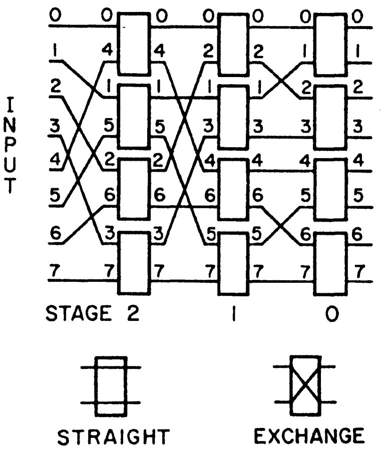

Figure 1. The generalized cube network for N=8.

In an interchange box, if two different message requests (routing tags) attempt to reserve the same output link, or (in the case of circuit switching) if a request is blocked by an already established message path, a conflict is said to have occurred. A conflict resolution algorithm must be invoked to resolve the conflict. In packet switching networks, the algorithm selects one of the requests and permits it to pass through the interchange box. The other request is held in an input buffer and will attempt to traverse the box at a later time. In circuit switching networks, the message that is blocked at the switch is either dropped and then resubmitted to the network (the drop algorithm) or is held in the box until the blockage is removed (the hold algorithm). These two circuit switched algorithms have been investigated in, for example, [15, 6].

## 3. MULTIPLE-PACKET NETWORK OPERATION

In this section, the effects of multiple-packet messages on the operation of a packet switching generalized cube network are investigated. The system is assumed to be operating in the MIMD mode. The message to be transmitted will consist of a routing tag and one or more data words. If, however, the message size exceeds the size of the network transmission packet, multiple dependent packets must be generated. Each packet will contain the same routing tag and a portion of the data to be transferred. The packets are processed sequentially by the network since only one network path exists between any source-destination pair.

Operational dependencies exist between multiple-packet messages that do not exist when single-packet message formats are used. These dependencies center on the sequential generation of packets (within any given message) all being routed to the same network output port (recall that in single-packet messages, the routing of all of the packets is assumed to be a strictly independent process [8]). As an example, consider two multiple-packet messages, where the packets of one message are being held in one input buffer of an interchange box and the second message's packets are held in the other input buffer. Any conflict (or lack of a conflict) that occurs when the first packets in the two buffers are processed will also occur when the succeeding packets are processed.

The dependencies that exist between packets in multiple-packet message transmissions cause network performance analysis using "standard" Markov chain modeling techniques, as in [8, 3], to be extremely complex. Interconnection network simulators such as PUGS [5] can, however, be used to accurately predict the performance of multiple-packet messages. PUGS is capable of simulating both single- and multiple-packet message formats. When using the multiple-packet format, performance statistics for both individual packets and complete messages (composed of dependent packets) can be obtained. The accuracy of PUGS output data has been validated through comparisons with other researchers' published network simulation and Markov chain performance data, such as [6, 3, 15, 8]. To increase the accuracy of the statistics, the length of the simulation runs was adjusted so as to insure the simulated network had reached a "steady-state" operating condition. This occurred after the first 250-300 simulated packet cycles. The actual simulation lengths were then set to approximately ten times this value -- 2000 simulation cycles. Statistics gathered before steady-state was reached were discarded. Lastly, for each combination of network variables that were evaluated, each simulation was repeated ten time and the results averaged so as to further reduce the statistical variations. Data and statistics obtained from PUGS will be used throughout this paper.

Assume that the data to be transferred is stored in the memory of the source PE. As a result of the slow memory access time within the PE (due to memory device speed limitations and long inter-IC and inter-circuit board transmission delays) and the comparatively fast interchange box logic (small, fast packet buffers and straightforward control logic), the time required by a PE to construct a data packet will be much longer than the time required by an interchange box to process the same size packet. This operational speed differential between the PE and the network (i.e., the interchange boxes) requires that packets be held in a PE's output buffer and not released to the network until the packet is completely formed.

In analyzing multiple-packet message performance, the *packet cycle time*, defined as the time delay incurred by a packet in traversing a network interchange box, will be used as the basic unit of system/network timing. This delay is the amount of time required to move a packet from the front of one of an interchange box's input buffers to the input buffer of an interchange box in the next stage. As discussed above, this time delay will be much shorter than the time delay associated with the generation of a packet within a PE. A *packet offset time*, the time (in packet cycles) between packet generations of a multiple-packet message, can be used to quantize the speed differential between the network and the system PEs. If the time to generate a packet equals the time to process a packet in an interchange box, the packet offset would be one. If a message consisted of w packets and the first packet was generated and then submitted to the network at time t, then, in general, a y-cycle packet offset would cause packets to be submitted at times t, t+y, t+2y, $\cdots$ t+y·(w−1). The total message transmission delay is the time difference between the beginning of the generation of the first packet of the message and the completed transmission time of the last packet of the message. Note that the time from the generation of the first packet to its submission to the network is y. This delay will be y·(w) + (the transmission delay of the last packet), where the first term is the delay incurred by the message before the last packet is available for transmission. Recall that, because of pipeline effects, the delays of the other packets in the message will be reflected in the transmission delay of the last packet.

In [13], Kruskal and Snir have presented an alternate, more constrained, discussion of multiple-packet network operation. They assumed that all of the message packets were generated simultaneously (this corresponds to a packet offset of zero) and that the packets moved through the network as a single "group." Additionally, the inclusion of the packet generation time in the overall transmission time has not been incorporated into previous analyses. In [8], for example, timing delay calculations start when a packet is accepted by a network input port. Time devoted to generating a packet and any time lost waiting for the availability of an network input port is not included in their analysis.

Representative performance analysis results of multiple-packets messages, obtained using PUGS, are shown in Table 1. Results in this table are for a 5-stage network (N=32) and multiple-packet messages consisting of 2, 4, and 8 packets. The packet offset ranges from 1 to 15 packet cycles and the loading factor is 100% in each case. The loading factor is the probability in a given time cycle of a network source generating a new message, given that it is not currently transmitting a message. Buffers at the inputs to each interchange box, capable of holding four packets, are assumed to be in use (buffer size is based on analysis results in [8]). The packet and message delay times can be used to gauge the effects of the packet offset on network performance. Ideally, a packet would require k packet cycles to traverse a k-stage network. An m-packet message would, in turn, require k+(m−1) packet cycles to completely traverse the network (this time value assumes the packets are transmitted through the network in a pipeline fashion). The normalized packet and message delays can therefore be computed by dividing the packet and message delay times by k and k+(m−1), respectfully.

| Number of packets per message | Packet offset | Delay | | Normalized delay | |
|---|---|---|---|---|---|
| | | Packet | Message | Packet | Message |
| 2 | 1 | 17.90 | 20.94 | 3.58 | 3.49 |
| | 2 | 16.35 | 20.91 | 3.27 | 3.49 |
| | 5 | 6.75 | 16.60 | 1.35 | 2.77 |
| | 10 | 6.57 | 26.36 | 1.31 | 4.39 |
| | 15 | 6.56 | 36.35 | 1.31 | 6.06 |
| 4 | 1 | 21.24 | 28.18 | 4.24 | 3.52 |
| | 2 | 17.66 | 27.19 | 3.54 | 3.40 |
| | 5 | 6.40 | 26.29 | 1.28 | 3.29 |
| | 10 | 6.30 | 46.51 | 1.26 | 5.81 |
| | 15 | 6.28 | 66.21 | 1.26 | 8.28 |
| 8 | 1 | 26.40 | 40.89 | 5.28 | 3.41 |
| | 2 | 21.53 | 40.83 | 4.30 | 3.40 |
| | 5 | 6.29 | 46.36 | 1.26 | 3.86 |
| | 10 | 6.18 | 86.53 | 1.24 | 7.21 |
| | 15 | 6.16 | 126.20 | 1.23 | 10.52 |

Table 1. Performance results for multiple-packet message transmissions (5-stage network (N=32) and 100% network load).

From Table 1, it can be seen that, for any given message size, as the packet offset is increased, the delay experienced by a packet in the network decreases and approaches the minimum traversal delay (normalized delay of 1). This is to be expected since the *apparent* network loading decreases as the packet offset is increased, thus reducing the network conflict delays that a packet will experience. The overall delay experienced by the entire message is also seen to decrease as the packet offset begins to increase from its initial value of 1, again a result of decreased network conflicts. However, as the packet offset continues to increase, the message delay time is seen to drop to a minimum level and then begin to increase. The increase is due to the longer delays between packet submissions that unnecessarily increase the message transmission delay. Packet offsets that lead to minimized overall message delays are in the range of 2 to 5. For example, message delays for two and four packet messages are minimized with a packet offset of 5, while an offset of 2 produces minimum delays in an eight-packet message. PUGS was also used to collect statistics for many different combinations of network operating parameters, such as: network size, number of packets per message, network loading, and packet offset values. In all cases, packet offsets in the area of 2-5 have been seen to produce the minimum message delays through the network.

In a typical system development process, the speed of the PEs is determined by the selection of a target microprocessor chip/chip set. The packet offset will then be fixed by the specification of the network interchange boxes and their packet cycle times. The analysis discussed above allows the most cost-effective tradeoff point for the network's hardware design to be predicted. The network's estimated performance over a range of cycle times can be used as a guide in determining the required hardware sophistication of the network design. The most desirable design, in terms of the cost-performance tradeoff, would be the slowest and typically the least expensive network that did not act as a bottleneck to the anticipated inter-PE message flow.

## 4. PACKET vs. CIRCUIT SWITCHED OPERATIONS

In inter-computer networks, the classic tradeoff between circuit and packet switching is one of message length. Long message formats are best supported by circuit switching whereas short, ''bursty" formats are ideally suited for packet switching. The design of these networks tends to neglect propagation delays through the switch points in the network and instead concentrates on the transmission channel (link) delays [21, 25]. The differences in the two switching methods are not as clear-cut in intra-computer networks found in parallel processing systems. Because the processors are generally ''close" physically, the interchange box delays dominate over the transmission link delays. System characteristics such as the operational mode (e.g., SIMD or MIMD), the architecture supporting the network, as well as the anticipated message format and system loading, greatly influence the selection of the switching method.

Systems that utilize the network solely for inter-PE data transfers (e.g., the PE-to-PE system architecture) can be characterized by lightly loaded, low message conflict networks. In this case, circuit switched networks can give very acceptable performances using circuitry that is much less complex than a comparable packet switched network (e.g., message queues and their control logic are not needed in the interchange boxes). Implementation of a circuit switched network is particularly advantageous in SIMD systems performing data permutations with no network conflicts where, once the path connecting the source-destination PE pair is established, the interchange boxes contribute only minimal gate delays to the transmission time.

In systems where the network is used to connect processors to memory modules (e.g., the processor-to-memory system architecture), inter-processor communication *and* instruction fetch operations utilize the network. The network loading would be expected to be high due to the preponderance of instruction and data fetch operations that must be supported. Packet switched networks have been proposed for this environment [8, 9]. Note that, through the use of cacheing techniques, the network loading can be substantially reduced and, in effect, giving a network performance similar to the PE-to-PE architecture's. PE-to-PE architectures will be assumed in this paper.

When packet switching is used for inter-PE transfers, if the message exceeds the packet length, multiple packets must be sent through the network. The processors must absorb the added overhead of message packetization (at the source PE) and packet recombination (at the destination PE). Each packet must independently perform its own routing/path establishment. These delays, coupled with the queueing delays at each switch, can increase the overall message transmission time in a packet switching network.

In this section, performance tradeoffs between packet and circuit switched interconnection networks will be explored. The analysis will be done using the same external system conditions in both switching modes. SIMD and MIMD operations will be considered separately.

### 4.1 SIMD operations

SIMD system operations that utilize interconnection network transfers generally employ data permutations, where data is transferred from a set of network sources to a set of network destinations using a particular transfer scheme. Cube-type networks have been found to perform most useful SIMD permutations in one pass through the network, with no conflicts [14, 18]. Permutations that cannot be performed without conflicts in a single pass can be performed in multiple, conflict free, passes through the network. As a result, the analysis for SIMD operations will assume that data transfers through the network will take place without network conflicts.

To enable direct comparisons of the performance of circuit and packet switched networks, a number of assumptions must be made concerning the operation of the computer system external to the interconnection network. These assumptions are listed below:

1. Data that is to be transferred through the network will originate from the same point within the source PEs (i.e., data for circuit switched transfers will not be in a PE's memory while the data for packet switched transfers is in the PE's registers). This ensures that the time overhead required by the source PEs to fetch the data will be the same for both switching modes.
2. The message transmission time will start when the first word of the message is generated by the source PE.
3. The overhead of computing the routing tag is not included in the message transmission time. In the case of multiple packet messages, the routing tag is computed only once (at the beginning of the message) and is stored for later use in subsequent packets.
4. Processing of data at the destination PEs will not degrade the performance of the network or impede the message generation process of the source PEs.
5. Packets must be fully formed at the source PE before they can be submitted to the network.

In the following discussions, assumptions are made about values for various network parameters to demonstrate the methodology developed. The framework established here can, of course, also be used to evaluate different systems by modifying the values of these parameters. The values used below are estimates developed from our design of the PASM system prototype [16].

Using circuit switching, the message transmission process can be decomposed into two phases -- set-up (or path establishment) and the actual data transfer. During the set-up phase, the message request (routing tag) must propagate through interchange boxes in each stage of the network and establish the desired data path. Let the time to establish a path through an interchange box be $(T_{cu} + T_{ib} + T_t)$. $T_{cu}$ is the time required by the box's control unit to check the routing tag and establish the needed box setting and $T_{ib}$ is the propagation delay through the interchange box's switching logic. $T_t$ is the link transmission time between interchange boxes in adjacent stages as well as between the PEs and the network input and output stages. From this, the path set-up time, $T_{setup}$, can be calculated and will require

$$n(T_{cu} + T_{ib} + T_t) + T_t + n(T_{ib} + T_t) + T_t \qquad (1)$$

time units to establish a path through an n-stage network. Note that the first two terms represent the total time required by the message request to traverse the network from the source to the destination. The second two terms represent the time required by a message grant signal to be returned from the destination to the source.

Once the path through the network has been established, the actual data transfer can begin. The delay experienced by a data word in traversing an n-stage network is

$$T_{delay} = 2(n{+}1)T_t + 2(n)T_{ib} \, . \qquad (2)$$

The factors of 2 represent the time to transmit the data word itself to the destination plus a returned data acknowledge signal generated by the destination PE. Let L be the total message length, excluding the routing information. Additionally, let $T_{generation}$ be the time required by a PE to fetch a data word from memory and send it to the network input port. The actual data transmission time, $T_{xmit}$, will be

$$T_{xmit} = \begin{cases} T_{generation} + L{\cdot}T_{delay}, & T_{delay} > T_{generation} \\ L{\cdot}T_{generation} + T_{delay}, & T_{delay} \le T_{generation} \end{cases} \qquad (3)$$

If the generation time of a word is less than the transmission delay of a word, the total delay will be the generation time of the first word plus L transmission delays. Under these conditions, the performance of a circuit-switched network could possibly be improved through the use of data pipelining (with data buffers placed between the network stages) or the use of a message-switched network design [12]. If, on the other hand, the generation time is greater than the transmission delay, the total time will be L generation delays plus the transmission delay of the last data word. In other words, if the transmission delay of the network is small with respect to time required by the source PEs to generate the data words, the overall data transmission time of a message will be determined by the speed of the PEs -- not the speed of the network. In these instances, circuit-switched network performance enhancements such as data pipelining will not improve the overall message transmission time. Hybrid techniques such as pipelining and message-switching will not be considered in this paper.

For example, the Motorola MC68010 microprocessor, operating at a clock frequency of 10 Mhz, is capable of performing one memory-to-memory data transfer in, at best, 800 ns (the network source and destination ports are considered to be memory addresses by the PE) [17]. If the 2-by-2 switching logic of the interchange boxes is implemented using multiplexers or by two levels of tri-state buffers, $T_{ib}$ can be expected to be approximately 20 ns (worst-case, TTL logic). $T_t$ can be assumed to be no more than 5 ns. A reasonable value for $T_{cu}$ is 100 ns. The total delay experienced by a data word would then be (from Equation 2)

$$\begin{aligned} \text{Network delay} &= 10(n{+}1) + 40n \qquad (4) \\ &= 50n + 10 \, . \end{aligned}$$

Clearly, for system and network sizes that are currently implementable, the speed of the PE will be the determining factor in the data transmission time. Using the representative timing values, listed above, the set-up time (from Equation 1) and the data transmission times can be combined into the overall message transmission time, $T_{message}$:

$$\begin{aligned} T_{message} &= T_{setup} + T_{xmit} \\ &= (150n + 10) \\ &\quad + L{\cdot}(\text{PE word generation rate}) \, . \qquad (5) \end{aligned}$$

Next, consider the operation of a packet switched network. Note that, because there are no conflicts within the network, there will be no queueing delays within the network. The size of the interchange box buffers will not effect the overall network operation. With the exception of the logic to form and control the interchange box buffers, the architecture and speed of a packet switched interchange box will be the same as that of the circuit switched box, discussed above. The values for $T_{cu}$, $T_{ib}$, and $T_t$ will be the same. Let $T_q$ be the time needed to access a buffer in an interchange box. Because the buffer will be physically close to the rest of the circuitry for the box, if not on the same VLSI chip, $T_q$ will be substantially less than the time required to perform a PE memory access. Assume that buffer reads and writes can be overlapped. The delay, $T_{packet}$, that a data packet would experience in traversing a packet switched box would be

$$T_{packet} = T_{cu} + (T_q + T_{ib} + T_t)(P{+}1) \, . \qquad (6)$$

The factor (P+1) is the *actual* packet size including the routing tag (P data words plus one routing word). Time required for handshaking between adjacent interchange boxes can be overlapped with the other phases of $T_{packet}$.

Using dual-ported memories for the packet buffers, $T_q$ would be at least 100 ns. Substituting this and the previously assumed values, Equation 6 then reduces to

$$T_{packet} = 125(P+1) + 100 \text{ ns} . \qquad (7)$$

The time required by a PE to generate a packet would be (P+1)(PE word generation time). Continuing with the MC68010 example, this would be, at best, 800(P+1) ns. The ratio of the packet generation time and $T_{packet}$, the packet offset, will be approximately 6. This leads to an alternate view of the packet offset time for SIMD operations.

When more than one packet is generated per message, if the number of stages in the network is less than or equal to the packet offset, a packet will completely traverse the network before the next packet in the message can be formed by the source PE and submitted to the network. The pipelining of message packets will not occur -- effectively eliminating one of the general advantages of packet switched networks. An L-word message, divided into $\lceil L/P \rceil$ data packets will have a transmission time of

$$T_{message} = \lceil L/P \rceil(\text{Packet generation time}) + n \cdot T_{packet} . \qquad (8)$$

The first term represents the delay between the generation of the first word in the message (contained in the first packet) and the time the last packet is submitted to the network. The second term is the time required by the last packet to traverse the network.

Table 2 lists the message transmission times for various sized messages using both packet and circuit switching modes. The message transfer times were calculated using the representative timing values for the interchange box components and PEs, discussed above. It is clear that, for SIMD operations, the circuit switched mode provides lower message transmission delays since the transmission of individual data words can be overlapped with the PEs' generation of the next data words to be transmitted. The overlap or pipeline performance normally associated with packet switched operations is precluded by the processing speed differential between the PEs and the packet switched network. From Table 2, it is also observed that packet sizes of two or four words yielded generally lower message transmission times than the other packet sizes. Small packet sizes incur an additional generation overhead of having to write the routing tag to many different packets (e.g., for a 4-word message, four 1-word packets with routing tags must be generated compared to only two 2-word packets and one 4-word packet). As the packet size increases, the packet delay time through an interchange box, $T_{packet}$, increases, as does the packet generation time. The combination of these two effects causes an increase in the total transmission delay through the network of each packet and negates the relative advantage of having to transmit fewer total packets for a given message size. The performance of the 2- and 4-word packets were a compromise between the two extremes.

## 4.2 MIMD operations

The performance analysis and comparison of circuit and packet switched networks presented in the last subsection was based on the assumption that network transfers would take place without conflicts. In MIMD operations, this assumption is not valid. Here, the performance of a network will be affected by conflicts within the network and the associated queueing delays.

For MIMD networks, the circuit switched message transmission process can still be decomposed into the set-up and the data transfer phases, as before. The conflict and blocking effects on the network's MIMD performance can be predicted using the Markov analysis of [15] or by simulation. The analysis of packet switched networks must also include the effects of queueing delays within the buffers associated with each interchange box. The simulation methodology described in Section 3 for multiple-packet messages can also be used here.

Any attempt to directly compare the performance of circuit and packet switched networks must use the same operational environment for both networks. External (to the network) factors such as the system size, processing speed of the PEs, and the network loading factor must be the same for both networks. Additionally, the fundamental design of the two networks must also be the same (e.g., data path width, the technology used in the interchange box implementations, and the PE-network interface methodology). When these internal and external factors are fixed, a comparison between the two switching methods can be made.

| Network size | Switching mode | Packet size | Data transfer size | | | | |
|---|---|---|---|---|---|---|---|
| | | | 1 | 2 | 4 | 8 | 16 |
| 4 stages | circuit | - | 1.41 | 2.21 | 3.81 | 7.01 | 13.41 |
| | packet | 1 | 3.00 | 4.60 | 7.80 | 14.20 | 27.00 |
| | | 2 | 4.30 | 4.30 | 6.70 | 11.50 | 21.10 |
| | | 4 | 6.90 | 6.90 | 6.90 | 10.90 | 18.90 |
| | | 8 | 12.10 | 12.10 | 12.10 | 12.10 | 19.30 |
| | | 16 | 22.50 | 22.50 | 22.50 | 22.50 | 22.50 |
| 5 stages | circuit | - | 1.56 | 2.36 | 3.96 | 7.16 | 13.56 |
| | packet | 1 | 3.35 | 4.95 | 8.15 | 14.55 | 27.35 |
| | | 2 | 4.78 | 4.78 | 7.18 | 11.98 | 21.56 |
| | | 4 | 7.63 | 7.63 | 7.63 | 11.63 | 20.53 |
| | | 8 | 13.33 | 13.33 | 13.33 | 13.33 | 20.53 |
| | | 16 | 24.73 | 24.73 | 24.73 | 24.73 | 24.73 |

Table 2. SIMD performance comparison of circuit and packet switched networks (times in microseconds, packet size does not include routing tag).

Assume the networks are constructed such that the timing values used in Section 4.1 remain valid. Specifically, $T_{cu} = 100\text{ns}$, $T_{ib} = 20\text{ns}$, $T_t = 5\text{ns}$, and $T_q = 100\text{ns}$. Furthermore, assume that the PEs are implemented using a clock frequency of 10 Mhz, as in an MC68010 microprocessor (the microprocessor requires 800ns to write one word from memory to the network). Under these assumed conditions, Tables 3 and 4 list simulation results for the message transmission times and throughput performances of circuit and packet switched networks for a range of loading values and message lengths. Comparing the data in these tables to that of Table 2, it can be seen that the MIMD performance of both network types approaches the SIMD performance values as the network loading is decreased (as would be expected). The performance relationship between the circuit switched conflict resolution algorithms is as predicted by [15] -- the drop algorithm provides generally lower transmission times and higher message throughputs than does the hold algorithm.

Over the range of message lengths considered in Tables 3 and 4, minimum message transmission times for a given data transfer size (message length) can be obtained in the packet switched network when the entire message is contained in only one or two packets. As in SIMD operations, the performance tradeoff is lighter network loading (number of packets) with larger packet sizes versus shorter packet transmission times of the individual packets with smaller packet sizes.

A representative plot of the message transmission times for both circuit and packet switched networks is shown in Figure 2. For each plot, the data used was taken from the conflict resolution algorithm (for circuit switching) or the packet size (for packet switching) that provided the lowest transmission times. The circuit switched network provided superior network performance for smaller message sizes while packet switching performed best with larger message sizes. This can be attributed to, in circuit switch-

| Switching mode | Packet size | Loading factor | Data transfer size | | | | |

ing, significantly higher conflict rates and blocking times that result when the network paths are held for periods of time corresponding to the transmission of "long" messages, as reported in [3, 15]. This does not occur in packet switched networks. In contrast, packet switched networks tend to perform better with longer messages, where the overhead of the packet generation (i.e., the routing tag) is proportionately smaller (when compared to the actual message transmission time) and the delays due to network conflicts do not increase as fast as in circuit switched networks. For small message transfers, the blocking delays within a circuit switched network will be reduced, thus producing good overall message delay characteristics. This, coupled with the relatively high overhead of packet generation and queueing delays experienced by packet switched messages (when compared to the transmission time), enables circuit switched networks to function better than packet switched networks for small message lengths.

## 5. CONCLUSIONS

This paper has centered on the modeling and analysis of multiple-packet message formats and their relative performance advantages when compared to circuit switched networks. A multiple-packet message format is needed within an interconnection network when the message to be transmitted exceeds the network's packet size. In order to quantize network performance, the operation of interchange boxes, networks, and external systems were expressed as time functions. General equations relating these time functions to the performance of a network were developed. By using these equations and the PUGS simulator, the effects of any set of internal and external environment assumptions could be evaluated and network performance -- either packet or circuit switched -- could be predicted.

During the analysis of packet switched networks, the effects of various packet sizes was examined. The packet offset figure of merit was introduced and used as a performance gauge of the transmission rate differential between the network and the PEs. It was observed that the optimum network performance (in terms of low transmission delays and reasonable network component costs) could be obtained with a packet offset in the range of 2 to 5.

Comparing the performance of circuit and packet switched networks for a specific set of time function values, circuit switching was shown to provide minimum transmission delays in all

SIMD operations and in short message transfers in MIMD operations. Packet switched networks functioned better than circuit switched networks as the message length increased. The dominant element of the network performance was seen to be the processing rate of the PEs themselves.

A general methodology has been developed that quantized system and network parameters, thus allowing the performance of a network design to be evaluated under a set of anticipated operating conditions. By adjusting the assumed values of these parameters, this methodology can be used by other researchers as an aid in the design of their own networks.

ABSTRACT: A reconfigurable multicomputer architecture based on rectangular CC-banyan multistage interconnection network is presented. A graph-theoretical approach is used to study this network's permuting and structural properties. It is shown that a CC-banyan has a modular structure and hence can be recursively defined. A method for evaluation of the total number of permutations in CC-banyans is presented. Using this method, we derive the analytical expressions for the number of permutations in CC-banyans with fanouts two and three.

## 1. INTRODUCTION

There is growing interest in multicomputer systems for increased performance and improved reliability. The operation of these systems is critically dependent on the interconnection network which connects system resources such as processors and memories (or computers). As a result of the rapid advances in LSI and VLSI technology, extensive research is being conducted on multicomputer systems. Many of these systems are based on multistage interconnection networks (MINs).

Various MINs implemented with 2x2 switching elements, such as baseline, modified data manipulator, flip, omega, indirect binary n-cube and regular rectangular SW-banyan (s=f=2) are known to be topologically equivalent to each other [1]. These equivalent networks possess a "buddy property," i.e., the outputs of two switching elements at stage i are connected as inputs to only two switching elements at the (i+1)th stage [2].

Banyans [3] represent a large class of interconnection networks. An SW-banyan with fanout two describes a class of equivalent MINs implemented with 2x2 switching elements. Also, many non-equivalent MINs [4] represent special cases of cylindrical crosshatch (CC) banyans [3]. It has been shown in [5] that the so-called 'non-equivalent' delta network [6] is isomorphic to a CC-banyan, and that the ADM network [7] can be viewed as two overlapping CC-banyans. Permuting and partitioning properties of SW-banyans and of equivalent MINs have been extensively studied elsewhere [2,3,8,9, 10,11]. In this paper we focus on non-equivalent networks. We analyze the recursive structure and evaluate the total number of permutations supported by a CC-banyan. Detailed derivations of results presented in this paper can be found in [12].

## 2. SYSTEM DESCRIPTION

The system model is composed of the resources and the interconnection network. In this paper we use the rectangular CC-banyan interconnection network to study system mapping properties.

In the following we give a brief description of CC-banyans. A banyan network [3] is a network with a unique path from each source to each sink vertex. A multistage interconnection network is a network in which vertices can be arranged in stages, with all the source vertices at stage (level) 0, and all the outputs at stage i connected to inputs at stage i + 1. An L-level banyan, or an L-stage MIN, is a network in which every path from any source (base) to any sink (apex) has length L. An (f,L) banyan is an L-level banyan in which the indegree (spread-s) of every intermediate vertex equals its outdegree (fanout-f).

(f,L) regular rectangular CC-banyan: An (f,L) banyan in which there is an edge from vertex i at vertex level k+1 to a vertex j at vertex level k whenever $j=(i+mf^k) \bmod f^L$ for m = 0, 1, 2,...,f-1, $0 \leq i, j \leq f^L-1$ and $0 \leq k \leq L-1$.

Examples of (3,2) and (2,3) regular rectangular CC-banyans are shown in Fig. 1 and 2, respectively. The vertex levels are numbered from bases (level 0) to apexes (level L). The interpretation of the network graph is the one commonly used with respect to banyan networks: a vertex represents a tie point and an edge represents a switch contact. According to this interpretation, connections through vertices in a banyan graph are mutually exclusive.

An example of a multicomputer system based on a rectangular CC-banyan network is shown in Fig. 2. In this system each computer (processor with local memory) is attached to both sides of an (f,L) CC-banyan. A similar approach utilizing a different network topology but similar connection of processing nodes to both sides of the MIN is used in the Star network [13]. The communication through the network is unidirectional and the control is based on the routing tag technique. The labeling and routing schemes for a system based on a CC-banyan are discussed in [14]. We just note here that the routing scheme in CC-banyan leads to relative addressing, based on the difference between destination and source address, in contrast to the systems based on SW-banyans which use absolute addressing.

## 3. RECURSIVE STRUCTURE OF CC-BANYAN

Whereas the original definition of CC-banyans is not recursive, it will be shown here that CC-banyans can be recursively defined. Conceptually, it is convenient to view an (f,L) rectangular CC-banyan as

This work was supported in part by the Graduate School, University of Minnesota.

a union of L stages, where each stage represents a bipartite graph [4]. For example, three bipartite graphs for (2,3) rectangular CC-banyan are shown in Fig. 3a.

Theorem 1: In an (f,L) rectangular CC-banyan a bipartite graph of stage k ($0 \le k \le L-1$) contains $f^k$ identical components (disjoint subgraphs).

Different components of a (2,3) CC-banyan are shown in Fig. 3b.

Corollary 1: In an (f,L) rectangular CC-banyan, the bipartite graphs of all L stages are not isomorphic (to each other).

Note that in the case of equivalent MINs (e.g., baseline, omega) the bipartite graphs of all stages are isomorphic, since these MINs have the "buddy property" [2].

Corollary 2: Each component of stage k ($0 \le k \le L-1$) has $2*f^{L-k}$ vertices.

Corollary 3: In an (f,L) rectangular CC-banyan the bipartite graph of stage-0 at the base side contains one component; and the bipartite graph of stage-(L-1) at the apex side contains $f^{L-1}$ components, which are (fxf) crossbar graphs.

Note that the recursive decomposition of a CC-banyan into networks of smaller size may be only possible from the base side (due to Corollary 3). In contrast to CC-banyans, SW-banyans and networks equivalent to them can be recursively decomposed from either side.

Theorem 2: An (f,L+1) CC-banyan can be recursively decomposed from the base side into f disjoint (f,L) CC-banyans.

Based on Theorem 2, we give the following recursive definition.

Definition: An (f,1) CC-banyan is simply an (fxf) crossbar graph. An (f,L+1) CC-banyan is constructed from f (f,L) CC-banyans by the following procedure:

1. Assign a number m (m=0,1,...f-1) to each (f,L) CC-banyan.
2. In the m-th (f,L) CC-banyan, label the vertices at every vertex level by the numbers
   $m+jf$ , where $j = 0,1,2,\dots,f^L$
   (see Fig. 4a).
3. Form stage-0 (base stage) of the composite (f,L+1) CC-banyan by connecting the bases numbered $i(i=0,1,\dots,f^{L+1}-1)$ to the bases of the component (f,L) CC-banyans numbered $(i+mf)\bmod f^{L+1}$ for all $m=0,1,\dots,f-1$ (see Fig. 4b).
4. Rearrange the vertices of the composite (f,L+1) CC-banyan in the order of increasing label numbers, thus resulting in the conventional representation (see Fig. 4c).

## 4. PERMUTING PROPERTIES

In this section we evaluate the number of various permutations performable by an (f,L) CC-banyan in one pass. We view an (f,L) rectangular CC-banyan as a permutation network that performs a one-to-one mapping (permutation) of a set of $N(N=f^L)$ apexes onto a set of N bases.

Since in a banyan network every input-output connection (base-apex path) is unique, the total number of permutations is equal to the product of all permutations performable by each stage:

$$P = \prod_{k=0}^{L-1} P_k \qquad (1)$$

where $P_k$ is the number of stage-k permutations.

In view of Theorem 1 and Corollary 3,

$$P = (f!)^{f^{L-1}} * \prod_{k=0}^{L-2} (C_{f,k})^{f^k} \qquad (2)$$

Here $C_{f,k}$ denotes the number of permutations performable by each of $f^k$ disjoint subgraphs of stage k. The indices indicate that this number, generally, depends on both fanout f and stage k. An exact analytical evaluation for $C_{f,k}$ does not seem feasible for arbitrary fanout f. However, we present a general approach which enables systematic enumeration of all permutations. Our analysis uses unconventional representation for a stage-k subgraph, in which the vertices of a bipartite subgraph are located on the two concentric circles corresponding to the vertex levels k and k+1. An example of such symmetric circular representation, or circular diagram, is shown in Fig. 5. Consider circular diagram of a stage-k subgraph. As follows from Corollary 2, this subgraph performs permutations on $f^{L-k}$ numbers. A permutation in this subgraph is a one-to-one mapping of its level-(k+1) vertices onto its level-k vertices.

A stage-k circular diagram may be divided into radial sectors of equal size (f-1) using radial cuts as shown in Fig. 5. The radial cuts and radial sectors are numbered clockwise from 0 to $(f^{L-k}-1)/(f-1)$, so that a radial sector m is formed by radial cuts m and m+1, $m = 0,1,\dots, (f^{L-k}-1)/(f-1)$. Then each of the sectors has (f-1) vertices, and the last sector has only one vertex. Consider a set of edges corresponding to a permutation in a circular diagram. An edge corresponding to a permutation is called a cross edge if it crosses a radial cut in a circular diagram. Now we can state an important invariant property of permutations in CC-banyans.

Theorem 3: For any stage-k subgraph permutation in a circular diagram, all radial cuts have the same number of cross edges i ($0 \le i \le f-1$).

An example of two different permutations and corresponding cross edges in a circular diagram is given in Fig. 5.

Theorem 4: In a circular diagram of stage-k subgraph, there exists only one permutation corresponding to 0 or (f-1) cross edges:

$$C^{0}_{f,k} = C^{f-1}_{f,k} = 1.$$

Specifically, the identity permutation has 0 cross edges, and the cyclic shift $i \rightarrow (i+f-1)\bmod f^{L-k}$ has f-1 cross edges (see Fig. 5). Theorem 4 also implies that in a CC-banyan with fanout f=2 all stage-k subgraphs can perform exactly 2 permutations, regardless of k.

Theorem 5: The total number of permutations performable by rectangular CC-banyan with fanout f=2 and number of stages L is:

$$P = 2^{2^L-1}$$

A systematic enumeration of all permutations in the case of arbitrary f uses a "divide-and-conquer" approach based on Theorems 1 and 3. Specifically, the number of permutations performable by a stage-k subgraph can be represented as

$$C_{f,k} = \sum_{i=0}^{f-1} C^{i}_{f,k}$$

where $C^{i}_{f,k}$ is the number of permutations which have exactly i cross edges.

In view of Theorem 4, the above expression is simplified to:

$$C_{f,k} = 2 + \sum_{i=1}^{f-2} C^{i}_{f,k} \qquad (3)$$

The value of $C^{i}_{f,k}$ $(1 < i < f - 2)$ can be found by enumeration of all permutations having the same number of cross edges i. A method for a systematic enumeration of such permutations is discussed below. Consider a set of permutations having the same number of cross edges $i(1 < i < f - 2)$. We may enumerate all permutations in a circular diagram by choosing, successively, i cross edges for every radial cut m, m=0, 1,2,..., $(f^{L-k}-1)/(f-1)$. Since i cross edges in a radial cut (m+1) can be chosen independently from i cross edges in a preceding cut m, we can construct a tree of all possible outcomes (decision tree) for a systematic enumeration of all permutations. We illustrate this method using an example of CC-banyan with fanout f=3. Only the case when the number of cross edges i=1 has to be considered, since $C^{0}_{3,k} = C^{2}_{3,k} = 1$. In this decision tree, a tree level corresponds to the radial cut number (see Fig. 6). Since every sector has f-1=2 vertices, a vertex incident to a cross edge can be chosen by 2 different ways, and the decision tree fanout is two. If the vertices in each sector are numbered from 0 to f-2, as shown in Fig. 5, then the vertex $m(0 < m < f-2)$ can be incident to f-1-m=2-m different cross edges. Therefore, two different cross edges can be chosen for vertex m=0, and only one cross edge can be chosen if m=1. Hence, we assign the weights 1 and 2 correspondingly to every "right" and "left" outgoing link in the decision tree. The total number of permutations can be found by adding the weights of all leaves where the weight of each leaf is a product of all link weights along the path from root to this leaf. Since we may choose outgoing links (with weights 1 or 2) independently at every tree level, the total weight represents a binomial sum:

$$\sum_{j=0}^{h} \binom{h}{j} 2^{j} * 1^{h-j} = 3^{h}$$

where h is the decision tree height, or the number of radial cuts, whose i cross edges can be chosen independently:

$$h = (f^{L-k}-1)/(f-1)$$

Therefore, the number of permutations having the number of cross edges i=1 in a stage-k subgraph of an (3,L) CC-banyan is:

$$C^{1}_{3,k} = 3^{(3^{L-k}-1)/2} \quad , \quad 0 < k < L-2 \qquad (4)$$

The total number of permutations in a (3,L) CC-banyan follows immediately from (2), (3) and (4).

Theorem 6: The number of permutations in an (f,L) CC-banyan with fanout f=3 is:

$$P = (3!)^{3^{L-1}} * \prod_{k=0}^{L-2} [2+3^{(3^{L-k}-1)/2}]^{3^{k}}$$

The method of decision trees can also be used for enumeration of all permutations in the case of general fanout f. However, the process of constructing decision trees becomes quite complex for the big values of f.

## 5. CONCLUSIONS

In this paper we presented a graph-theoretic approach to the analysis of rectangular CC-banyan net works with an arbitrary fanout f and an arbitrary number of stages L. It is shown that CC-banyans, like many other networks can be constructed recursively. This recursiveness enables the modular structure of CC-banyans and can be used in the analysis of its partitioning properties.

We presented a general approach to the analysis of permuting properties of CC-banyans. The analytical expressions for the number of permutations performable by CC-banyan with fanouts 2 and 3 are derived. In the case of general fanout f, we propose a method, based on decision tree analysis, for a systematic enumeration of all permutations.

## ABSTRACT

In this paper we prove the rearrangeability of a multistage shuffle/exchange network with 8 inputs and outputs consisting of five stages. A lower bound of $(2 \log_2 N - 1)$ stages for rearrangeability of a shuffle/exchange network with $N = 2^n$ inputs and outputs is known; we show its sufficiency for $N = 8$. We not only prove the rearrangeability, but also describe an algorithm for routing arbitrary permutations on the network and prove its correctness. In contrast to previous efforts to prove rearrangeability, which rely on topological equivalence to the Benes class of rearrangeable networks, our approach is based on first principles. We also show that two switches in the network are redundant. The results in this paper are useful for establishing an upper bound of $(3 \log_2 N - 4)$ stages for rearrangeability of a multistage shuffle/exchange network with $N \geq 8$, as demonstrated in [14].

## 1. INTRODUCTION

Shuffle/Exchange networks, initially proposed by Stone [13] have been the subject of extensive treatment by several researchers *(for a survey on shuffle/exchange networks, see* [3]). A shuffle/exchange network with $N = 2^n$ inputs and outputs consists of a perfect shuffle permutation [13] followed by an exchange stage with $N/2$ switches, each of size 2 x 2. A multistage shuffle/exchange network is constructed by cascading multiple shuffle/exchange stages in series. A multistage shuffle/exchange network for $N = 8$ with five stages is shown in Figure 1.

Interconnection networks with the capability of passing all the $N!$ permutations on $N$ elements in one pass through the network are known as *rearrangeable networks* [2]. The Omega network [5], which is a multistage shuffle/exchange network with $\log_2 N$ stages, can perform only a small fraction of the $N!$ permutations when $N$ is large. However, the permutation capability can be improved by adding more stages.

The universality of shuffle/exchange networks was studied by researchers in an attempt to determine how many stages are required to attain the capability of performing arbitrary permutations, *ie.,* rearrangeability [4, 7, 10, 11, 12, 14, 16]. An asymptotic lower bound of $(2 \log_2 N - 1)$ stages of 2 x 2 switching elements for rearrangeability has been known for long [15]; the validity of this lower bound for shuffle/exchange networks can be established for any $N = 2^n$ by showing the existence of permutations which cannot be performed with less than $(2 \log_2 N - 1)$ stages [14]. The sufficiency of this many stages for shuffle/exchange networks has neither been proved nor disproved. Stone observed that, by using an algorithm due to Batcher [1], sorting of arbitrary sequences of data can be performed by cycling through a single shuffle/exchange stage $(\log_2 N)^2$ times when the switching elements are replaced by 2-input, 2-output sorting elements [13]. This algorithm can be used to map arbitrary permutations on a multistage network with $(\log_2 N)^2$ shuffle/exchange stages. An algorithm for performing arbitrary permutations on a single-stage shuffle/exchange network in $2(\log_2 N)^2$ passes was also described by Siegel [10], and the number of passes was subsequently improved to $(3/2)(\log_2 N)^2 - (\log_2 N)/2$[11]. Parker improved this bound by showing that $3 \log_2 N$ stages are sufficient for rearrangeability [7], though he did not specify a control algorithm for finding the states of the switching elements for arbitrary permutations. Wu and Feng observed that $(3 \log_2 N - 1)$ stages are indeed sufficient for rearrangeability [16]; they also showed how to compute the switch settings for arbitrary permutations. Kothari *et al.* observed that $(3 \log_2 N - 3)$ stages are sufficient for $N = 16$ and 32 [4]. More recently, Varma and Raghavendra showed that, if the rearrangeability of $(2 \log_2 R - 1)$ stages can be proved for a shuffle/exchange network of size $R = 2^r$, then $3 \log_2 N - (r + 1)$ stages are indeed sufficient for rearrangeability of a network of size $N > R$ [14].

For networks of small size, it may be possible to use exhaustive techniques to prove or disprove rearrangeability. Notice that, for $N = 4$, a cascade of three shuffle/exchange stages is identical to the Benes binary network and hence rearrangeable. Parker showed, by exhaustive enumeration, that 5 stages of shuffle/exchange are sufficient for rearrangeability when $N = 8$ [8], thereby suggesting that the limit of $(2 \log_2 N - 1)$ may be reachable, at least for small networks. In this paper we provide a constructive proof for showing that the lower bound of $(2 \log_2 N - 1)$ stages for rearrangeability of a multistage shuffle/exchange network is also an upper bound for $N = 8$ by establishing the rearrangeability of the network in Figure 1. As opposed to previous efforts to prove rearrangeability, which relied on reduction of the network to the topology of the Benes rearrangeable network, our approach is based on first principles. It is possible, in fact, to show that the network in Figure 1 cannot be reduced to a topology equivalent to that of the Benes network. We also describe an algorithm for routing arbitrary permutations on the network and prove its correctness. When used in conjunction with the results in [14], this establishes an upper bound of $(3 \log_2 N - 4)$ stages for rearrangeability of a multistage shuffle/exchange network for all $N \geq 8$. Our analysis also shows that two switches in the net-

work are redundant and could be eliminated without affecting the rearrangeability (Note that the Benes binary network of size 8 has three such switches).

## 2. PARTITIONING OF PERMUTATIONS

The procedure for routing arbitrary permutations on the 5-stage network is based on partitioning the connections of the permutation into four connection sets, consisting of two connections each, and assigning each connection set to one of the switches in the middle stage of the network. This partitioning is done such that no conflicts arise in either the first two stages or the last two stages of the network.

*Definition* 1: Let $\pi$ be a permutation on the set of integers $\{0,1, \dots ,7\}$ . A connection set $C$ of $\pi$ is a collection of $k$ input–output pairs of $\pi$, $k \leq 8$, expressed as

$$C = \left\{ \binom{x^1}{\pi(x^1)}, \binom{x^2}{\pi(x^2)}, \dots, \binom{x^k}{\pi(x^k)} \right\}, \tag{1}$$

where $\{x^1,x^2, \dots ,x^k\} \subseteq \{0,1, \dots ,7\}$. If $k = 8$, then $C$ defines the whole permutation.

*Definition* 2: The set of input terminals of a connection set $C$ , denoted by $C^-$, is the set of all inputs $x$, $0 \leq x \leq 7$, such that the pair $\binom{x}{\pi(x)}$ belongs to $C$. Formally,

$$C^- = \left\{ x \mid \binom{x}{\pi(x)} \in C \right\} \tag{2}$$

Similarly, the set of output terminals of $C$, denoted by $C^+$, is the set of output terminals of the pairs in $C$.

$$C^+ = \{\pi(x) \mid x \in C^-\} \tag{3}$$

*Definition* 3: A valid partition of a permutation $\pi$ is a partition of $\pi$ into four disjoint connection sets $C_0$, $C_1$, $C_2$, $C_3$ , with two elements each, satisfying the following properties:

**Property 1:** Each $C_i^-$, $0 \leq i \leq 3$, contains exactly one element from each of the sets of input terminals $I_0$ and $I_1$ defined by

$$I_0 = \{0,2,4,6\}; I_1 = \{1,3,5,7\}. \tag{4}$$

**Property 2:** For every $0 \leq x \leq 7$ with $x = x_2x_1x_0$ (in binary), if $x$ is contained in the set $C_0^- \cup C_1^-$, then the element $x' = \bar{x}_2x_1x_0$ is in the set $C_2^- \cup C_3^-$ .

**Property 3:** The sets $C_0^+ \cup C_2^+$ and $C_1^+ \cup C_3^+$ each contain exactly one representative from each of the sets of output terminals $O_0$ , $O_1$, $O_2$, $O_3$, defined by

$$O_0 = \{0,1\}; \; O_1 = \{2,3\}; \; O_2 = \{4,5\}; \; O_3 = \{6,7\} \tag{5}$$

**Property 4:** Each $C_i^+$, $0 \leq i \leq 3$, contains exactly one element from each of the sets $O_0 \cup O_1$ and $O_2 \cup O_3$ .

Properties 1-4 have been selected so that, if Switch $i$ in the middle stage of the network carries the connections in the set $C_i$ , for $0 \leq i \leq 3$, no conflicts can arise in any of the switching stages of the network.

The following algorithm constructs a valid partition of the permutation $\pi$ :

**Algorithm 1**

**Step 1:** Partition the set of output terminals of $\pi$ into four sets $P_0$ , $P_1$, $P_2$, $P_3$, with two elements each, as defined below:

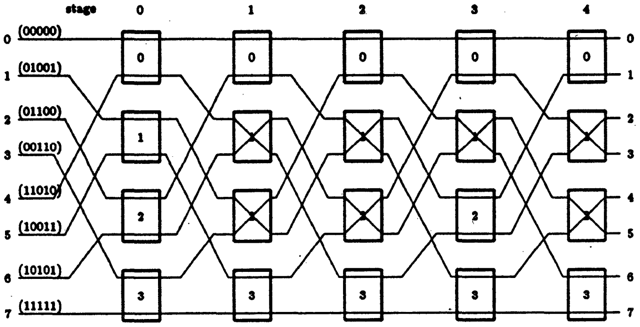

**Figure 1**

**A 5-Stage Shuffle/Exchange Network with $N = 8$**

$$P_0 = \{\pi(0), \pi(4)\}; \; P_1 = \{\pi(1), \pi(5)\}; \quad P_2 = \{\pi(2), \pi(6)\}; \; P_3 = \{\pi(3), \pi(7)\} \tag{6}$$

**Step 2:** Construct two sets $X_0$ and $X_1$, of four elements each, such that each contains exactly one representative from each $P_j$ and $O_j$, for $0 \leq j \leq 3$. That is,

$$|X_i \cap P_j| = |X_i \cap O_j| = 1, \tag{7}$$

for all $0 \leq j \leq 3$ and $i = 0,1$. The set $X_0$ can be constructed in a strictly sequential manner as follows: Start from one of the $P$'s, say $P_i$, and select an element arbitrarily for inclusion in $X_0$. Let this element be '$a$' and let $a \in O_j$ for some $0 \leq j \leq 3$. If '$b$' is the other element in $O_j$ and $b \in P_k$, for some $k$, then $b$ cannot be selected for inclusion in $X_0$ and the other element in $P_k$ has to be chosen. Thus the selection is performed by *looping* from $P_i$ to $O_j$ to $P_k$ and so on, until we reach a set $P_l$ from which an element has already been chosen, which indicates the completion of a cycle. At this point, a fresh cycle may be started by choosing any of the unvisited $P$'s, until all $P$'s are processed. This procedure is identical to the looping algorithm for control of the Benes network [6], and can be likened to the vertex-coloring of a bipartite graph.

Once $X_0$ is constructed, the remaining elements naturally fall into $X_1$ . That is, $X_1 = \{0,1, \dots ,7\} - X_0$.

**Step 3:** Construct sets $R_0$, $R_1$ , $R_2$, $R_3$ as

$$R_0 = X_0 \cap \pi(I_0); \; R_1 = X_0 \cap \pi(I_1); \quad R_2 = X_1 \cap \pi(I_0); \; R_3 = X_1 \cap \pi(I_1) \tag{8}$$

where $\pi(I_0) = \{\pi(x) \mid x \in I_0\}$ and $\pi(I_1) = \{\pi(x) \mid x \in I_1\}$.

**Step 4:** Construct two sets $Y_0$ and $Y_1$, of four elements each, such that each contains exactly one representative from each $R_j$ and $O_j$, for $0 \leq j \leq 3$. That is,

$$|Y_i \cap R_j| = |Y_i \cap O_j| = 1, \; \forall \, 0 \leq j \leq 3 \text{ and } i = 0,1. \tag{9}$$

This construction can be performed in an identical manner as the construction of $X_0$ and $X_1$ in Step 2.

**Step 5:** Construct two sets $X'_0$ and $X'_1$ from $R_0$, $R_1$, $R_2$, $R_3$ as follows:

*Case (i):* If $(X_0 \cap Y_0)$ has representatives from both $\{0,1,2,3\}$ and $\{4,5,6,7\}$ then $X'_0 = X_0$ and $X'_1 = X_1$ .

*Case (ii):* If $(X_0 \cap Y_0)$ has representatives from only one of the sets {0,1,2,3} and {4,5,6,7} then

$$X'_0 = R_0 \cap R_3;\ X'_1 = R_1 \cup R_2. \tag{10}$$

**Step 6:** The connection sets $C_0$, $C_1$, $C_2$, and $C_3$ are now obtained as $C_{2i+j} = \left\{ \begin{pmatrix} x \\ \pi(x) \end{pmatrix} \mid \pi(x) \in X'_i \cap Y_j \right\}, \quad 0 \le i, j \le 1.$ (11)

Before proceeding to prove that the algorithm produces a valid partition of the permutation $\pi$, we show an example to illustrate the idea.

*Example* 1: Consider the permutation

$$\pi = \begin{pmatrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ 0 & 1 & 4 & 6 & 2 & 3 & 5 & 7 \end{pmatrix}.$$

In this example, $\pi(I_0) = \{0, 4, 2, 5\}$ and $\pi(I_1) = \{1, 6, 3, 7\}$.

*Step 1:*

$$P_0 = \{0, 2\};\ P_1 = \{1, 3\};\ P_2 = \{4, 5\};\ P_3 = \{6, 7\};$$
$$O_0 = \{0, 1\};\ O_1 = \{2, 3\};\ O_2 = \{4, 5\};\ O_3 = \{6, 7\}.$$

*Step 2:*

$$X_0 = \{0, 3, 4, 7\}\ \ X_1 = \{2, 1, 5, 6\}.$$

The set $X_0$ was constructed by first choosing the element 0 from $P_0$; Since $0 \in O_0$, the element 1 cannot be included. As $1 \in P_1$, the element 3 from $P_1$ has to be selected; this completes a cycle. Since $P_2 = O_2$ and $P_3 = O_3$, the representatives from $P_2$ and $P_3$ can be chosen arbitrarily.

*Step 3:*

$$\begin{aligned} R_0 &= X_0 \cap \pi(I_0) = \{0,4\} \\ R_1 &= X_0 \cap \pi(I_1) = \{3,7\} \\ R_2 &= X_1 \cap \pi(I_0) = \{2,5\} \\ R_3 &= X_1 \cap \pi(I_1) = \{1,6\} \end{aligned}$$

*Step 4:*

$Y_0$ and $Y_1$ are constructed by choosing one element from each of $R_0$, $R_1$, $R_2$, $R_3$ so that they have one element in common with each of $O_0$, $O_1$, $O_2$, $O_3$. If we force $Y_0$ to contain the element 0, then

$$Y_0 = \{0, 6, 3, 5\};\ Y_1 = \{4, 1, 7, 2\}.$$

*Step 5:*

Since $X_0 \cap Y_0 = \{0, 3\} \subset \{0, 1, 2, 3\}$, case (ii) applies. Hence,

$$X'_0 = R_0 \cup R_3 = \{0, 1, 4, 6\};$$
$$X'_1 = R_1 \cup R_2 = \{2, 3, 5, 7\}.$$

*Step 6:*

$$X'_0 \cap Y_0 = \{0, 6\};\ X'_0 \cap Y_1 = \{1,4\};$$
$$X'_1 \cap Y_0 = \{3, 5\};\ X'_1 \cap Y_1 = \{2,7\}.$$

Therefore, the connection sets $C_0$ - $C_3$ are given by:

$$C_0 = \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 3 \\ 6 \end{pmatrix} \right\};\ C_1 = \left\{ \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \begin{pmatrix} 2 \\ 4 \end{pmatrix} \right\};$$

$$C_2 = \left\{ \begin{pmatrix} 5 \\ 3 \end{pmatrix}, \begin{pmatrix} 6 \\ 5 \end{pmatrix} \right\};\ C_3 = \left\{ \begin{pmatrix} 4 \\ 2 \end{pmatrix}, \begin{pmatrix} 7 \\ 7 \end{pmatrix} \right\}.$$

It may be verified that these sets satisfy Properties 1 through 4.

We now prove that Algorithm 1 produces a valid partition of the permutation $\pi$ as per Definition 3.

*Theorem 1:* The connection sets $C_0$, $C_1$, $C_2$, $C_3$ produced by Algorithm 1 satisfy Properties 1 through 4.

*Proof:* Since $X'_0 \cap X'_1 = Y_0 \cap Y_1 = \emptyset$ and $X'_0 \cup X'_1 = Y_0 \cup Y_1 = \{0,1, \ldots ,7\}$, the connection sets $C_0$, $C_1$, $C_2$, $C_3$ form a partition of $\pi$. We now show that they satisfy each of Properties 1-4.

*Property 1:*

$$C_0^+ \cap \pi(I_0) = (X'_0 \cap \pi(I_0)) \cap Y_0. \tag{12}$$

Assuming that case (i) holds in Step 5 of Algorithm 1,

$$\begin{aligned} C_0^+ \cap \pi(I_0) &= ((R_0 \cup R_1) \cap \pi(I_0)) \cap Y_0 \\ &= (R_0 \cap \pi(I_0)) \cap Y_0, \quad \text{since } R_1 \cap \pi(I_0) = \emptyset \\ &= R_0 \cap Y_0, \quad \text{since } R_0 \subset \pi(I_0). \end{aligned} \tag{13}$$

Now, if case (ii) holds,

$$\begin{aligned} C_0^+ \cap \pi(I_0) &= ((R_0 \cup R_3) \cap \pi(I_0)) \cap Y_0 \\ &= R_0 \cap Y_0, \quad \text{since } R_3 \cap \pi(I_0) = \emptyset \text{ and } R_0 \subset \pi(I_0). \end{aligned} \tag{14}$$

By construction, $|R_i \cap Y_j| = 1$, for $0 \le i \le 3$ and $0 \le j \le 1$. Hence $|C_0^+ \cap \pi(I_0)| = 1$. Similarly, it can be shown that $|C_i^+ \cap \pi(I_j)| = 1$ for all $0 \le i \le 3$ and $0 \le j \le 1$. Thus Property 1 is satisfied.

*Property 2:* If case (i) holds during Step 5, then $X_0 = C_0^+ \cup C_1^+$ and $X_1 = C_2^+ \cup C_3^+$. Hence, Property 2 is satisfied by construction of $X_0$ and $X_1$.

If case (ii) were true, then $X'_0 = C_0^+ \cup C_1^+ = R_0 \cup R_3$ and $X'_1 = C_2^+ \cup C_3^+ = R_1 \cup R_2$. Since $R_0 \subset X_0$ and $R_3 \subset X_1$, the elements in $R_0$ and $R_3$ independently satisfy Property 2. Also, since $R_0 \subset \pi(I_0)$ and $R_3 \subset \pi(I_1)$, $\pi(x_2x_1x_0) \in R_0$ implies $\pi(\bar{x}_2x_1x_0) \notin R_3$. Hence,

$$\pi(x_2x_1x_0) \in (R_0 \cup R_3) \Rightarrow \pi(\bar{x}_2x_1x_0) \notin (R_0 \cup R_3). \tag{15}$$

Similarly,

$$\pi(x_2x_1x_0) \in (R_1 \cup R_2) \Rightarrow \pi(\bar{x}_2x_1x_0) \notin (R_1 \cup R_2) \tag{16}$$

Thus, $X'_0$ and $X'_1$ satisfy Property 2.

*Property 3:*

$$\begin{aligned} C_0^+ \cup C_2^+ &= (X'_0 \cap Y_0) \cup (X'_1 \cap Y_0) \\ &= (X'_0 \cup X'_1) \cap Y_0 \\ &= Y_0 \end{aligned} \tag{17}$$

$$\text{and } C_1^+ \cup C_3^+ = Y_1. \tag{18}$$

By construction of $Y_0$, Property 3 is satisfied.

*Property 4:* $C_0^+ = X'_0 \cap Y_0$.
If case (i) holds during Step 5 of the construction procedure, then $X'_0 = X_0$ and $|(X_0 \cap Y_0) \cap \{0, 1, 2, 3\}| = |(X_0 \cap Y_0) \cap \{4,5,6,7\}| = 1$. This is true of $C_1$, $C_2$, $C_3$, also.

Hence Property 4 holds.

If case (ii) were true, then we have

$$\text{either } (X_0 \cap Y_0) \subset \{0,1,2,3\}, \qquad (19)$$
$$\text{or } (X_0 \cap Y_0) \subset \{4,5,6,7\}. \qquad (20)$$

Equation (19) implies

$$((R_0 \cup R_1) \cap Y_0) \subset \{0,1,2,3\}$$
$$\Rightarrow ((R_0 \cap Y_0) \cup (R_1 \cap Y_0)) \subset \{0,1,2,3\}$$
$$\Rightarrow (R_0 \cap Y_0) \subset \{0,1,2,3\}. \qquad (21)$$

Also, by construction, $|Y_0 \cap \{0,1,2,3\}| = |Y_0 \cap \{4,5,6,7\}| = 2$. Hence,

$$(X_1 \cap Y_0) \subset \{4,5,6,7\}$$
$$\Rightarrow ((R_2 \cup R_3) \cap Y_0) \subset \{4,5,6,7\}$$
$$\Rightarrow (R_3 \cap Y_0) \subset \{4,5,6,7\}. \qquad (22)$$

$$C_0^+ = X'_0 \cap Y_0 = (R_0 \cup R_3) \cap Y_0 = (R_0 \cap Y_0) \cup (R_3 \cap Y_0). \qquad (23)$$

By construction, $|R_0 \cap Y_0| = |R_3 \cap Y_0| = 1$. Hence by Equations (21) and (22), $C_0^+$ has exactly one representative from each of $\{0,1,2,3\}$ and $\{4,5,6,7\}$. Similarly Equation (20) can be shown to imply $(R_0 \cap Y_0) \subset \{4,5,6,7\}$ and $(R_3 \cap Y_0) \subset \{0,1,2,3\}$. Hence $C_0^+$ satisfies Property 4.

In a similar way, each $C_i^+$, $1 \leq i \leq 3$, can be shown to possess representatives from both $\{0,1,2,3\}$ and $\{4,5,6,7\}$. Thus Property 4 is satisfied.

## 3. ROUTING OF PERMUTATIONS IN THE NETWORK

Once a valid partition of the permutation $\pi$ satisfying Definition 3 is obtained, actual routing of the permutation on the network is accomplished as follows:

A 5-bit routing tag is assigned to each of the input–output connections of $\pi$. The routing tag for the connection from input terminal $s = s_2s_1s_0$ to output terminal $d = d_2d_1d_0$ has the form $c_1c_0d_2d_1d_0$, where the bits $c_1$ and $c_0$ are set depending on to which of the sets $C_0$, $C_1$, $C_2$, $C_3$, the connection belongs ($c_1c_0 = 00$ for $C_0$, 01 for $C_1$, 10 for $C_2$, and 11 for $C_3$). The switches in the network are set according to the individual bits of the routing tag — the top output is chosen if the bit is 0 and the bottom output if it is 1. The bit $c_1$ controls Stage 0, $c_0$ controls Stage 1, and $d_2$, $d_1$, $d_0$ control Stages 3, 4, 5, respectively.

*Theorem 2:* If $C_0$, $C_1$, $C_2$, $C_3$ form a valid partition of the permutation $\pi$, the routing described above produces no conflicts in any of the switching stages of the network.

*Proof:* Refer to [9].

Figure 1 shows the routing of the permutation in Example 1 on the 5-stage shuffle/exchange network. The 5-bit vectors shown in parenthesis on the input side are the routing tags for the corresponding connections. Notice that the connections in the set $C_i$ pass through Switch $i$ of the middle stage for all $0 \leq i \leq 3$.

## 4. REDUNDANCY IN THE NETWORK

Due to the flexibility in the construction of $X_0$ and $X_1$ in Step 2 of Algorithm 1, and in the construction of $Y_0$ and $Y_1$ in Step 4, it is possible to fix the state of one switch in each of the last two stages (or the first two stages) of the 5-stage shuffle/exchange network. For example, if we force $X_0$ and $Y_0$ to contain the element 0, then Switch 0 of the last two stages can be set permanently in the *straight* position. Similarly, if $X_0$ and $Y_0$ are forced to contain the element $\pi(0)$, Switch 0 of the first two stages can be set straight permanently. This shows that two switches in the network are redundant. Notice that a Benes binary network of the same size contains three redundant switches [6].

## 5. CONCLUDING REMARKS

In this paper we showed that the lower bound of $(2 \log_2 N - 1)$ stages for rearrangeability of a multistage shuffle/exchange network is also an upper bound for $N \leq 8$. An algorithm for routing arbitrary permutations on the network was also described. The results in this paper have been used in [14] for establishing an upper bound of $(3 \log_2 N - 4)$ stages for rearrangeability of a multistage shuffle/exchange network with $N \geq 8$.

## Abstract

The cube networks are equipped with very efficient local control algorithms: the bit control by the destination tags. In this paper we present an equally efficient local control algorithm called the **signed bit difference (SBD) tag control** for the ADM (IADM). The signed bit (0, 1, $\bar{1}$) control in place of the bit (0, 1) control is a natural consequence of the (3x3) switch size of the ADM (IADM).

We show that the $\Omega(\Omega^{-1})$-passable permutations are a subset of the ADM(IADM)-passable permutations under the SBD tag control. We also show that for the $\Omega(\Omega^{-1})$-passable permutations the SBD tag can be replaced by the destination tag together with a single bit information of a switch number yielding the **destination tag control** for the ADM (IADM).

A global control algorithm which realizes all the IADM-passable permutations is also given.

## 1. Introduction

In multiple processor systems an interconnection network provides communication paths for processor-processor or processor-memory information exchanges. The (NxN) augmented data manipulator (ADM) network [8] is an interconnection network, which consists of n switching stages each with $N = 2^n$ (3x3) switches plus one output stage. The inverse ADM (IADM) is identical to the ADM except that the direction from the input side to the output side is reversed. An (8x8) IADM is shown in Figure 1 together with its switching stage numbers and switch numbers of each stage. The properties of the ADM (IADM) have been studied actively [1, 11, 8, 13, 9, 10, 6, 4, 5].

The ADM control algorithm is based on the routing tag T which is a representation of (D-S), where D is the destination and S is the source:

$$T = t_{n-1} \ldots t_0 = D-S \pmod N),$$
$$-(N-1) \leq T \leq (N-1), \text{ where } t_i \text{ can be } 0,\ 1 \text{ or } \bar{1}.$$

For a given D and S there exist many different representations of (D-S) modulo N, and each different representation (or tag) corresponds to a possible path from S to D. To realize a permutation we have to choose N such tags without causing a conflict. Definitely some systematic generation of tags is required. One candidate is the **signed magnitude difference (SMD)** tag (called the natural tag in [11])

$$T = t_n t_{n-1} \ldots t_0 = D-S, \ -(N-1) \leq T \leq (N-1),$$

where $t_i$ is 0 or 1, and $t_n$ is the sign bit. Thus the value of T is

$$\text{value}(T) = (-1)^{t_n} \sum_{i=0}^{n-1} 2^i t_i$$

**Unfortunately it was shown in [3] that a very small subset of ADM-passable permutations can be realized with this type of tags. In Section 2, a new tag called the signed bit difference (SBD) tag is defined. It can be regarded as a natural extension** of the bit control of a cube network for the ADM(IADM), which is based on (3x3) switches. It was known that the ADM passes all the omega-passable permutations ($\Omega$) [8]. We show that the set of ADM-passable permutations under the SBD tag control contains $\Omega$. The 2n-bit full routing tag obtained by bitwise exclusive-oring of the source and the destination for the cube-passable permutations [12] is in essence identical to the SBD tag. Also in Section 2 we show that the destination tag together with a single bit information from a switch number can replace the SBD tag for $\Omega(\Omega^{-1})$.

In Section 3 a global control algorithm of the IADM is given, which realizes all the IADM-passable permutations. The conclusions are drawn in Section 4.

## 2. Local Control Algorithms

### *2.1.* The Signed Bit Difference Tag Control Algorithm

Let the source $S = s_{(n-1)} \dots s_1 s_0$, and the destination $D = d_{(n-1)} \dots d_1 d_0$, where $s_i, d_i \epsilon \{0,1\}$ for $0 \leq i < n$. Define the **signed bit difference (SBD) tag**

$$T = t_{(n-1)} \dots t_1 t_0,$$

where $t_i = 0$ if $d_i = s_i$,

$t_i = 1$ if $d_i = 1$ and $s_i = 0$,

$t_i = \bar{1}$ if $d_i = 0$ and $s_i = 1$.

In other words the bit $t_i$ of the SBD tag T is the bit difference $(d_i - s_i)$ represented in the fully redundant binary number system. The IADM can be controlled locally at each switch as follows.

### SBD Tag Control Algorithm of IADM (ADM)

**The switch j of the switching stage i is controlled using the SBD tag in the following way:**

if $t_j = 0$, choose the straight connection,

if $t_j = 1(\bar{1})$, choose $+2^i(-2^i)$ connection,

for $0 \leq j < N$, $0 \leq i < n$.

The SBD tag control of the ADM (IADM) is very natural, in that it covers each bit difference of the destination and the source at each corresponding switching stage, without generating any carry to or borrow from neighbor stages. It is a direct one-to-one mapping of the signed bit difference $(d_i - s_i)$ to the i-th switching stage of the ADM (IADM).

Let $\Omega(\Omega^{-1})$ denote the set of the omega (inverse omega) network passable permutations [2]. Similarly let $A(A^{-1})$ denote the set of the ADM (IADM) passable permutations. It has been known [8] that

$$\Omega \subset A.$$

Because of the symmetry this also implies that

$$\Omega^{-1} \subset A^{-1}.$$

In the following we show that the SBD tag is the control tag for $\Omega(\Omega^{-1})$ on the ADM(IADM).

**Theorem 1.**

The SBD tag control algorithm realizes $\Omega^{-1}$ on the IADM.

**Proof**

For all i, $0 \leq i < n$, the SBD tag has the property:

if $s_i = 0$ then $t_i = d_i = 0$ or $1$,
if $(s_i = 1$ and $d_i = 1)$ then $t_i = 0$
else if $(s_i = 1$ and $d_i = 0)$ then $t_i = \bar{1}$.

Consider two input sources $S_1 = s_{1,(n-1)} \dots s_{1,0}$ and $S_2 = s_{2,(n-1)} \dots s_{1,0}$, where $s_{1,i} = 0$, $S_2 = S_1 + 2^i$ for an i, $0 \leq i < n$. Let $D_1 = d_{1,(n-1)} \dots d_{1,0}$, $D_2 = d_{2,(n-1)} \dots d_{2,0}$, $T_1 = t_{1,(n-1)} \dots t_{1,0}$, $T_2 = t_{2,(n-1)} \dots t_{2,0}$ be the destinations of $S_1$, $S_2$, and the SBD tags of $S_1$, $S_2$, respectively. Then by the above property of the SBD tag:

$$(t_{1,i}, t_{2,i}) = \begin{matrix} (0,0) \\ (1,\bar{1}) \\ (0,\bar{1}) \\ (1,0) \end{matrix}$$

These four cases correspond to the four possible settings of a (2x2) switch in the inverse omega network: straight, cross, upper broadcast, lower broadcast. (Only the first two are relevant for the permutations.)

Q.E.D.

**Corollary 1.**

The SBD tag control algorithm realizes $\Omega$ on the ADM.

### *2.2.* The Destination Tag Control Algorithm

Next we show that $\Omega^{-1}$ can be realized on the IADM using a different tag -- the destination tag together with a single bit information of a switch number as well.

### Destination Tag Control Algorithm of IADM (ADM)

The switch number j of the switching stage i, $j_i = j_{i,(n-1)} \dots j_{i,0}$ is controlled by $d_i$ of the incoming destination tag $D = d_{(n-1)} \dots d_0$ and $j_{i,i}$ as follows, $0 \leq i < n$, $0 \leq j_i < N$:

if $(j_{i,i} = 0$ and $d_i = 0)$ or
  $(j_{i,i} = 1$ and $d_i = 1)$ then
  choose the straight connection,
if $(j_{i,i} = 0$ and $d_i = 1)$ then
  choose the $+2^i$ connection,
if $(j_{i,i} = 1$ and $d_i = 0)$ then
  choose the $-2^i$ connection.

Note that IADM(ADM) destination tag control is exactly like the cube destination control with the $(j_{i,i} = 0)$ condition substituted for the upper input port, and the $(j_{i,i} = 1)$ condition for the lower input port of a switch in a cube network.

**Theorem 2**

The IADM destination tag control algorithm realizes $\Omega^{-1}$ on the IADM.

**Proof**

The two cases of the SBD tag $(t_{1,i}, t_{2,i})$ being (0,0) or $(1,\bar{1})$ correspond to ($s_{1,i} = d_{1,i} = 0$, and $s_{2,i} = d_{2,i} = 1$) or ($s_{1,i} = 0$, $d_{1,i} = 1$, and $s_{2,i} = 1$, $d_{2,i} = 0$), respectively. The switch $j_i$ receives its destination from one of possible $2^i$ sources of stage 0. If $j_{i,i}$ is equal to the i-th bit of any possible source numbers, the IADM destination tag control algorithm is equivalent to the SBD tag control algorithm for $\Omega^{-1}$, thus realizing $\Omega^{-1}$ on the IADM.

Let $S_j = s_{j,(n-1)} \dots s_{j,0}$ for $0 \leq j < N$ denote the N sources at the stage 0. Then $j_0 = S_j$ for $0 \leq j < N$. At stage 1, by the destination tag control algorithm applied to the stage 0, the output from $j_0$ is the input to $j_1$ of the stage 1,

$$j_1 = s_{j,(n-1)} \cdots s_{j,1} \, d_{j,0}$$

In general at stage i, $0 \leq i < n$, by the destination tag control algorithm

$$j_i = s_{j,(n-1)} \cdots s_{j,i} \, d_{j,(i-1)} \cdots d_{j,0}$$

receives the input destination created by $j_0$ of stage 0. Thus

$$j_{i,i} = s_{j,i}$$

for $0 \leq j < N$, $0 \leq i < n$.

Q.E.D.

**Corollary 2**

The destination tag control algorithm of ADM realizes $\Omega$ on the ADM.

The SBD tag control, the destination tag control of the IADM and the destination tag control of the cube networks are shown in Figure 2.

## 3. A Global Control Algorithm

### *3.1.* Background

In the previous section we showed two local control algorithms which can realize $\Omega^{-1}$ on the IADM. The implication of the previous section is the fact that although the ADM is more powerful than a cube network, once a fixed local control algorithm is imposed upon, it is generally equal to a cube network. The power of the ADM is rather in the variety of control structures; many different types of local control tags with different permuting power can be generated, whereas only two control tags (the destination tag, and the tag obtained by bit exclusive-oring the destination and the source [11], which have the same permuting power) exist for a cube network. It seems to be the case that a global control algorithm is in order to achieve the full potential of the ADM. In this section we describe a global control algorithm which is simple, systematic, and can pass all the IADM-passable permutations. If a given permutation is not IADM-passable, it prints the fact.

Define a **control matrix** C(0:(N-1), 0:(n-1)) of which the element C(i,j) contains the switch setting information 0, 1, $\bar{1}$ for the i-th switch of the j-th stage. As before the straight path is chosen for the control signal 0, and $+2^j(-2^j)$ path is chosen for $1(\bar{1})$. At the beginning, C is initialized by setting C(i,j) = j-th bit of the SBD tag at source i. The column C(-,j) represents the switch settings of N switches of the switching stage j, called the **stage setting.** A stage setting creates a conflict if there is any pair C(i,j), C(k,j) choosing the paths leading to the same switch at the next switching stage (j+1).

A permutation is IADM-passable if all the stage settings are conflict free. In [3] a ring model is used to describe the IADM. Due to the $0, \pm 2^i$ connection patterns at stage i, all the switches of stage i are partitioned into $2^i$ equivalence classes modulo $2^{(n-i)}$ (see Figure 3). The stage setting of stage i consists of $2^i$ independent settings of $2^i$ partitions (called **partition setting**).

A stage setting is conflict free if all the $2^i$ partition settings are conflict free. A permutation is IADM-passable if every stage setting is conflict free. Each conflict free partition setting (called a **good string**) can be divided into two types [3]. In the following * ($^+$) denotes a repetition of zero or more (one or more) times, and the length of the string is equal to the cardinality of a partition.

(I) **Good string type 0.**
There is at least a pair of 0s, and can be represented as
$(0(1\bar{1})^*0 + 0^*)^*$

Each type 0 string creates a unique partition at the next stage.

(II) **Good string type 1.**
There is no 0 switch setting in a string. There are four type 1 strings, and all these strings create identical partitions at the next stage:
$(\bar{1})^*$, $(1\bar{1})^*$, $(1)^*$, $(\bar{1}1)^*$

The good string type 0 is based upon the fact that once a pair of switches in a partition are set straight, any switch between the pair should be set 1 followed by $\bar{1}$ repeatedly to avoid a conflict. The basis for the good string type 1 is that if there is no switch set straight, then the given four switch settings are the only conflict free switch settings. There are $(G_k\text{-}2)$ type 0 strings, where $G_k = G_{(k-1)} + G_{(k-2)}$, k(= string size) $\geq 3$, $G_2=3$, $G_1=1$. The relation of $G_N$ to the number of IADM-passable permutations $P_N$ is given as [3]

$$P_N = (G_N - 1)\ P^2_{N/2}$$

with all $(G_N\text{-}2)$ type 0 strings included in $(G_N\text{-}1)$ plus one coming from type 1 strings.

Thus the majority of the IADM-passable permutations have unique switch settings. The choice of switch settings can only be provided when a partition setting does not require any straight switch setting, and thus belong to type 1 good string. Although the four different type 1 strings, $(\bar{1})^+$, $(1\bar{1})^+$, $(1)^+$, $(\bar{1}1)^+$ create identical partitions, they create two different permutations: one by $(\bar{1})^+$ or $(1\bar{1})^+$, and the other by $(1)^+$, or $(\bar{1}1)^+$. Hence given an overall permutation for the IADM a partition can be set at most in two different ways.

### 3.2. IADM-Global-Control Algorithm

We are ready to introduce the IADM-global-control algorithm. First a very brief description of the general flow is given.

**General Flow of the IADM-global-control**

```
Start with the SBD control tags for
the IADM;
loop for all stages 0 to (n-1);
loop for all partitions of each stage;
```

If the partition setting has any 0, then there is a unique partition setting $(0(1\bar{1})^*0 + 0^*)^*$. Change the original partition setting into this form. If it can not be done, backtrack to the most recent stage with an alternative. If there is no such stage, the given permutation is not IADM-passable. Stop.

If the partition setting does not have any 0, change it into $(1)^+$ (an arbitrary choice between $(1)^+$ and $(\bar{1}1)^+$), mark it for backtracking as there is an alternative, $(\bar{1})^+$ (an arbitrary choice between $(\bar{1})^+$ and $(1\bar{1})^+$).

```
end loop
end loop

Conflict free control tags have been
obtained.

end IADM-global-control
```

Next we give the algorithm in detail. The procedures called by IADM-global-control are omitted due to space limitation.

**Procedure** IADM-global-control (D,C);

/* IADM-global-control generates control signals in C if the given permutation D is passable. It prints "not passable" if D is not passable. */

```
        bit array   D(0: N-1, 0: n-1);
         /* N n-bit destinations */
 signed bit array   C(0: N-1, 0: n-1);
          /* control bits 0, 1 or 1,
             for the entire IADM */

 signed bit array   STRING(0: N-1);
          /* control bits 0, 1, or 1,
             for a partition of a stage */

     integer array  BTR.STAGE(0: n-2),
                    BTR.PART(0: $2^{(n-2)}-1$);
          /* stacks for backtracking */

           integer  j, k, m, length,
                    btr-ptr;
           boolean  success;

initialize C with SBD tags;

for all stage j=0 to n-1;

for all partition k=0 to $2^{j}-1$;
    btr-ptr = 0; success = false;
    /* build a string for stage j,
       partition k */
    call build-string(STRING, j, k,
     length);

    if any 0 in the STRING
        then
        /* type 0 string : unique
           setting */
        call make-good-string(STRING,
         length, 0, success);
            if success = false
                then /* can we backtrack
                        to change (1)+ to
                        (1̄)+ in previous
                        stages? */
                if btr-ptr = 0
                    then
                    /* no backtracking
                       possible */
                       print ("not
                        passable
                        permutation");
                       return;
                fi;

                /* start backtracking */
                j = BTR.STAGE(btr-ptr);
                k = BTR.PART(btr-ptr);
                btr-ptr = btr-ptr - 1;
                call  build-string
                 (STRING, j, k, length);
                call  make-good-string
                 (STRING, j, k, length,
                    1, success);
           fi;

      else /* type 1 string:  two
                alternative ways of
                setting (1)$^+$ or ($\bar{1}$)$^+$ */
                /* (1)$^+$ tried first */
                call make-good-string
                (STRING, j, k, length,
                1, success);

                /* store in the back
                   track stacks */
                btr-ptr = btr-ptr + 1;
                BTR.STAGE (btr-ptr) = j;
                BTR.STAGE (btr-ptr) = k;
    fi
    simulate the switch setting by moving
    the rows of C according to the
    control signals for this partition
    (only stages j+1 through n-1).

end for partition;
end for stage;

/* C contains the complete, correct
   switch setting signals for the IADM */

endproc IADM-global-control;
```

### *3.3.* An Example

As an example consider the unshuffle permutation on an (8x8) IADM. We obtain the SBD tags C = $c_2c_1c_0$ by calculating the signed bit difference $d_i$-$s_i$ for $c_i$, $0 \leq i < 3$.

| D | | | S | | | C | | |
|---|---|---|---|---|---|---|---|---|
| $d_2$ | $d_1$ | $d_0$ | $s_2$ | $s_1$ | $s_0$ | $c_2$ | $c_1$ | $c_0$ |
| 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| 1 | 0 | 0 | 0 | 0 | 1 | 1 | 0 | $\bar{1}$ |
| 0 | 0 | 1 | 0 | 1 | 0 | 0 | $\bar{1}$ | 1 |
| 1 | 0 | 1 | 0 | 1 | 1 | 1 | $\bar{1}$ | 0 |
| 0 | 1 | 0 | 1 | 0 | 0 | $\bar{1}$ | 1 | 0 |
| 1 | 1 | 0 | 1 | 0 | 1 | 0 | 1 | $\bar{1}$ |
| 0 | 1 | 1 | 1 | 1 | 0 | $\bar{1}$ | 0 | 1 |
| 1 | 1 | 1 | 1 | 1 | 1 | 0 | 0 | 0 |

The unshuffle is not IADM-passable under the SBD tag control because at the very first stage (stage 0) we have the stage tag

$$0\ \bar{1}\ 1\ 0\ 0\ \bar{1}\ 1\ 0$$

which does not satisfy the condition of type 0 good string $(0\ (1\bar{1})^*\ 0 + 0^*)^*$ as it is. Figure 4 shows the actual conflicts caused by 0 followed by $\bar{1}$.

So by the IADM-global-control C(-,0) is changed to (Figure 5) a good type 0 string $(01\bar{1}0)^2$ or

$$0\ 1\ \bar{1}\ 0\ 0\ 1\ \bar{1}\ 0$$

resulting in new tags ($C_1$). When we simulate the effect of switch settings at stage 0, we obtain $C_2$. For stage 1, we have two independent partitions of switches (0, 2, 4, 6), (1, 3, 5, 7). Both partition tags are $(0\ \bar{1}\ 1\ 0)$ obtained by $c_1$. These should be changed to $(0\ 1\ \bar{1}\ 0)$ as shown in $C_3$. $C_4$ is obtained from $C_3$ by simulating switch settings of stage 1. The stage 2 has four independent partitions of switches (0, 4), (2,6), (1, 5), (3, 7). All the partition tags are (0 0) which is a good type 0 string. Thus $C_4$ contains a complete, conflict free switch setting for the unshuffle. The application of $C_4$ to IADM is given in Figure 6. This permutation did not require any backtracking, as all the partition settings were type 0 tags.

### *3.4.* ADM-global-control Algorithm

The ring model of ADM [3] defines two types of good strings. Based on these the IADM-global-control was developed. We can obviously develop an ADM-global-control in much the same way. The only difference is that the ADM-global-control works from stage n to stage 1 reversing the order. The reverse direction does complicate the conflict free tag calculation. When we start from the lowest order bit, value 0 in that position can not change thus rendering some degree of determinism. This fact is propagated to bit position 1, 2 .... (n-1). But this is not the case when we work from the reverse direction. Thus we might end up with a conflict stage setting for stage i, while producing conflict free stage settings for stages < i, requiring much more backtracking than is required for the IADM in general. Hence, the IADM can be controlled faster than the ADM for the realization of all the possible permutations. Instead of presenting another very similar procedure to the IADM-global-control, we simply show an example of the effect of such a procedure.

Consider a shuffle on the (8x8) ADM. We first calculate SBD tags C = $c_2c_1c_0$.

| D | | | S | | | C | | |
|---|---|---|---|---|---|---|---|---|
| $d_2$ | $d_1$ | $d_0$ | $s_2$ | $s_1$ | $s_0$ | $c_2$ | $c_1$ | $c_0$ |
| 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| 0 | 1 | 0 | 0 | 0 | 1 | 0 | 1 | $\bar{1}$ |
| 1 | 0 | 0 | 0 | 1 | 0 | 1 | $\bar{1}$ | 0 |
| 1 | 1 | 0 | 0 | 1 | 1 | 1 | 0 | $\bar{1}$ |
| 0 | 0 | 1 | 1 | 0 | 0 | $\bar{1}$ | 0 | 1 |

$$\begin{array}{ccc} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 1 \end{array} \qquad \begin{array}{ccc} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 1 & 1 & 1 \end{array} \qquad \begin{array}{ccc} \bar{1} & 1 & 0 \\ 0 & \bar{1} & 1 \\ 0 & 0 & 0 \end{array}$$

The stage 2 consists of four independent partitions of switches (0, 4), (2, 6), (1, 5), (3, 7) with partition settings $(0\ \bar{1})$, (1 0), $(0\ \bar{1})$, (1 0), respectively. These partition settings are not good type 0 strings, so we change all of them into (0 0) in $C_1$ (Figure 7). The stage 1 consists of two independent partitions of switches (0, 2, 4, 6) and (1, 3, 5, 7) with partition settings $(0\ 1\ \bar{1}\ \bar{1})$, $(1\ 1\ \bar{1}\ 0)$, respectively. We change both into $(0\ 1\ \bar{1}\ 0)$ in $C_2$. By simulating stage 1 stage settings $C_3$ is produced. The stage tag of stage 0 in $C_3$ is a good type 0 string, $(0\ 1\ \bar{1}\ 0\ 0\ 1\ \bar{1}\ 0)$. The switch setting of the (8x8) ADM for the shuffle by $C_3$ is shown in Figure 8.

## 4. Conclusions

The signed bit difference (SBD) tag was defined. Due to the three possible paths of each switch in the ADM a signed bit $(1, 0, \bar{1})$ is required to control each switch. The signed bit control algorithm for the ADM can be regarded as a natural extension of the bit control algorithm for a cube network. The SBD tag control algorithm is the signed bit control algorithm, which maps the bit difference in the destination and the source directly onto the corresponding switching stage. The $\Omega(\Omega)^{-1}$-passable permutations are shown to be a subset of ADM(IADM)-passable permutations under the SBD tag control.

We also showed that for the cube passable permutations the SBD tag can be replaced by the destination tag itself together with a single bit information from each switch (the i-th bit of the switch number in the i-th stage). Thus the destination tag control algorithm for the ADM was defined.

A global control algorithm which realizes all the IADM-passable permutations was presented.

Both local control algorithms are applicable to the gamma network [7]. A global control algorithm for the gamma network is being investigated.

## ABSTRACT

The Performance evaluation of concurrency control algorithms (CCA) has been extensively studied in both the centralized and decentralized environments (GARE79, HSIA81, SHMU82, CHES83, SHUM81, AGRA85, MITR84). However, differing performance models, assumptions and parameters studied have led to contradictory results [AGRA85,HELA86].

In this paper the behaviour and performance of two fundamentally different CCAs in single site databases has been investigated. These are the dynamic two-phase locking (2PL) and the commit-time validation (CTV). 2PL represents a pessimistic approach to concurrency control whereas CTV is an optimistic approach [KUNG81]. For each algorithm a performance model was constructed and the simulation technique was used to perform the study. Three parameters affecting data contention are studied in this paper. These parameters are: the degree of multiprogramming (the load effect), the read/write mix (ratio of query to update) and the database granularity. Unlike previous studies, in this paper we studied the three aforementioned parameters altogether; thus, providing insight into the composite effect of these parameters.

## Introduction

Although, the parallel processing of transactions enhances the system's performance, data misuse may result in the absence of concurrency control mechanisms. There are three generically different approaches that can be used to design concurrency control algorithms. These are: locking, timestamping, and the optimistic approach [BERN81]. In this paper we study and compare the performance of two of these three generically different approaches. These are the Dynamic Two-Phase Locking (Locking approach) [Mena78, Rose 78] and the Commit-Time Validation algorithms (Optimistic Approach) [Bada79, Baye80, Kung81].

Dynamic Two-phase Locking synchronizes reads and writes by explicitly detecting and preventing conflicts between concurrent operations. It regulates data access as follows. Before reading a data item X, a transaction must own a readlock on X. Before writing into X, it must own a writelock on X. The ownership of locks is governed by two rules: (1) A transaction may own a readlock on an item x as long as no other transaction owns a writelock on X, and a transaction may own a writelock on an item X if no other transaction owns a readlock or a writelock on the same item X. (2) Once a transaction surrenders ownership of a lock it may never obtain any additional locks. The 2PL controller may block a transaction by causing it to wait for unavailable locks. Due to this blocking, deadlocks may result. Deadlocks could either be prevented or detected and then resolved [ELMA85]. In this paper, 2PL uses a deadlock detection scheme.

In CTV (also called serial validation), the concurrency controller keeps track of the write-sets of recently commited transactions. Transactions run freely until commit time, at which point each transaction is submitted to a validity test to see if commiting it will leave the database in a consistent state. For a committing transaction $T_i$, the test considers all recently committed transactions $T_{rc}$, where a recently committed transaction is one that has committed since $T_i$ started running. The test results in $T_i$ being commited iff:

$$\text{Readset}(T_i) \cap \text{Writeset}(T_{rc}) = \phi$$

for all $T_{rc}$ and being restarted otherwise.

Two-phase commit, a recovery protocal normally used in distributed database systems, is utilized both by the 2PL and the CTV algorithms (in single site database) in order to preserve transaction atomicity and database consistency in presence of system failures. There is no logging, shadowing, nor differential files used in this work. In two-phase commit (2PC), transactions write their updates in the main memory. When a transaction ends, its updates are committed in two-phases. In the first phase, the updates in the main memory are copied to a secure storage. The second phase starts by copying each single update to its place in the stored database. If a failure occurs before the second phase starts, then the database is still consistent. If a failure occurs during the second phase, the database may become inconsistent but this inconsitency can be rectified using the secure storage.

In this study it is assumed that the transaction size is large. This gives worst case results for a system with transactions of mixed sizes. In the next two sections, the simulation performance model is explained for each of the 2PL and the CTV algorithms. Section 4 lists the

0190-3918/86/0000/0131 $01.00 © 1986 IEEE

unified model assumptions. Section 5 explains the experiments and the results. Finally, the concluding remarks are given in section 6.

## 2. Simulation of the Two-Phase Locking algorithm

A fixed number of transactions are continuously cycled around the model shown in figure 1. Initially, all transactions are put on the lock request queue. A transaction then goes through the following stages.

(1) A transaction requests the next needed lock from the lock manager which in turn tries to get this lock. If the lock manager succeeds, the transaction is granted the lock. If the lock granted was a read lock, the transaction is put on the low priority disk queue in order to read the item needed. When the read operation ends, the transaction is put back on the lock request queue to request the next needed lock when the lock manager is free. If the lock granted was a write lock, no disk write operation takes place (as the two-phase commit is employed, all writes take place at commit time) and again, the transaction is put back on the lock request queue to request the next needed lock when the lock manager is free.

(2) If the lock manager fails to get the lock on the item needed, because other transaction(s) hold(s) a lock on that item, the lock manager tries to let the requesting transaction wait for the unavailable lock until it is released. If this waiting would result in a deadlock, the lock manager then restarts the requesting transaction. Otherwise, the requesting transaction is put on one of the block queues (virtually, each database item has a block queue) in which case the transaction is said to be blocked.

(3) When the restarter restarts a transaction, it releases all locks held by that transaction. Consequently, some blocked transactions should become unblocked and they are put on the front of the lock request queue. The workspace of the restarted transaction is reset and it reexecutes from the beginning.

(4) When a transaction completes, it is put on the high priority disk queue and all its writes are committed following the two-phase commit protocol. When a transaction is committed, another transaction arrives instantaneously at the system.

The concurrency control is modeled by two servers: The lock manager and the restarter. The lock manager provides two kinds of services. The first is the "Try to lock" service for a requesting transaction. This service takes a time delay $\Delta_{ttl}$ to be completed. $\Delta_{ttl}$ is found by evaluating the size of actually executed code for this service. Size of code for this service is found to be around 100 instructions. Assuming one MIPS processor, this service takes about 0.0001 seconds to be completed. The second service provided by the lock manager is the "Try to block" service in which the lock manager performs several deadlock detection tests to see if blocking a transaction would result in a deadlock or not. This service takes a time delay $\Delta_{ttb}$ to be completed. Size of code for this service is not estimated but rather an actual deadlock detection algorithm is coded and a counter is used to count the number of actually executed instructions while calling this code. The restarter server releases locks held by an aborted transaction and advances the block queues. This service takes a time delay $\Delta_r$ to be completed. Size of actually executed code for this service is found to be about 5000 Instructions. Assuming one MIPS processor, this service takes about 0.005 seconds to be completed. It should be noted that modeling of the concurrency controller as a set of servers allows the utilization of multiprocessing whenever possible. In case of one processor computer, at most one server is functioning at any time.

The parameters which control and drive the simulation are the following.

1- Number of database granules (items): M

2- Number of transactions in the system (the degree of multiprogramming or load): T

3- Number of granules accessed by a

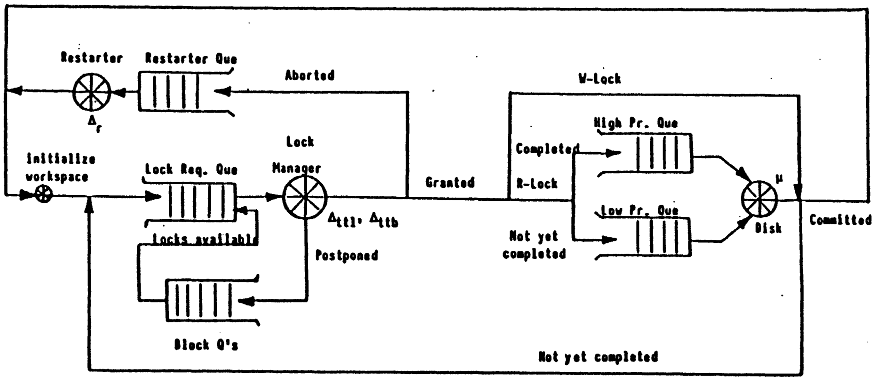

Figure 1 Performance Model of the 2PL Algorithm

transaction: I
4- Read/Write ratio: THRESHOLD
5- Disk average service rate: $\mu$
6- Lock Management CPU time delay: $\Delta_{ttl}$
7- Restart time delay: $\Delta_r$
8- Processor Power in MIPS

The following performance indices are measured for each simulation run (experiment).

1- Average transaction response time (RT) : seconds
2- System throughput (TP) : Transaction/Second
3- Degree of concurrency (DC)
4- Deadlock rate (DR) : deadlock/second
5- Conflict rate (CR) : conflicts/second
6- Maximum number of times a transaction was restarted (MXRST)

The degree of concurrency is defined as follows. Let $T_n$ be the duration of time through which the number of active transactions in the system was n. The degree of concurrency is then given by:

$$DC = 1/(T*T_s) * \sum_{n=1}^{T} n*T_n$$

where $T_s$ is the system time and T is the number of transactions in the system. Clearly, $0 < DC \leq 1$.

## 3. Simulation of the Commit-Time Validation

A fixed number of transactions are continuously cycled around the model shown in figure 2. Initially, all transactions are put on the low priority disk queue. A transaction then goes through the following stages.

(1) Each time a transaction submits a read operation, it is put on the low priority disk queue. No disk write operation takes place when a transaction submits a write operation (as the two-phase commit is employed, all writes take place at commit time). When a read or a write operation is complete, the transaction immediately submits its next read or write operation, if any.

(2) When the transaction completes, it is validated to see whether its writes could be committed or not. The transaction is put on the validator queue. When the transaction is considered by the validator, a validity test is performed.

(3) If the transaction is successfully validated, it is put on the committer queue in order to commit its writes. If the transaction is a pure query (read only), no commitment occurs and the transaction finishes and it terminates.

(4) If the validation test fails, the transaction is restarted by the restarter. The transaction workspace is reset and it reexecutes from the beginning.

(5) When a transaction is committed, it finishes execution and it then terminates. When a transaction terminates, another one instantaneously arrives at the system.

The concurrency control is modeled by a set of servers. These are the validator, the committer, and the restarter. The validator tests the completed transaction against all recently committed transactions. If the readset of the former intersects with the writeset of at least one recently committed transaction, the test fails, otherwise it succeeds. The validation service takes a time delay $\Delta_v$ to be completed. The committer inserts information about the committing transactions into the tables of the recently committed transactions and it also maintains these tables by deleting obsolete entries (entries with timestamps smaller (older) than the smallest timestamp of all active transactions are deleted). The commitment service takes a time delay $\Delta_c$ to be completed. The restarter resets the workspace of the unsuccessfully validated transaction and inserts it back into the system to reexecute from the beginning. The restarter service takes a time delay $\Delta_r$ to be completed. $\Delta_v$, $\Delta_c$ and $\Delta_r$ are estimated in a similar way as $\Delta_{ttl}$ and $\Delta_r$ of the 2PL. $\Delta_v$, $\Delta_c$, and $\Delta_r$ are all estimated to be around 0.005 seconds. Again, the concurrency

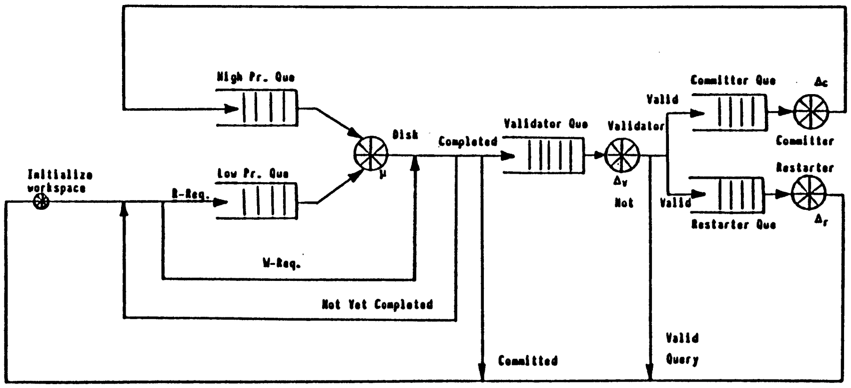

Figure 2 Performance Model of the CTV Algorithm

controller is modeled as a set of servers so that multiprocessing may be utilized.

The parameters which control and drive the simulation are the following.

1- Number of database granules (items): M
2- Number of transactions in the system (the degree of multiprogramming or load): T
3- Number of granules accessed by a transaction: I
4- Read/Write ratio: THRESHOLD
5- Disk average service rate: $\mu$
6- Validation test time delay: $\Delta_v$
7- Commitment time delay: $\Delta_c$
8- Restart time delay: $\Delta_r$
9- Processor Power in MIPS

The following quantities are measured for each simulation run (experiment).

1- Average transaction response time (RT) : Seconds
2- System Throughput (TP) : Trans./Sec.
3- Conflict rate (CR) : Conflict/Second
4- Maximum number of times a transaction was restarted (MXRST).

## 4. Unified Model Assumptions

Following is the set of model assumptions made in constructing the performance model of both the 2PL and the CTV algorithms.

(1) Two-Phase commit is incorporated with the 2PL(CTV) algorithm, thus a write operation is treated as a non-disk operation, and on transaction completion, two-phase commit begins by issuing 1 + |Writeset| disk operations(one in the first phase and |Writeset| in the second phase).

(2) Resources are finite: the physical database is stored in one disk unit with a given service rate. The case of more than one disk unit can equivalently be studied by one disk unit with a higher service rate. Also, there is only one CPU.

(3) Elements of the readset and the writeset of a transaction are distinct.

(4) Computation time needed by each transaction is negligible. This is justifiable because most transactions are I/O-bound processes.

(5) Transaction size is large. This gives a worst case results for a system with mixed sized transactions. How large a transaction is, is explained in the next section.

(6) A Transaction workspace consists of two parts: the transaction definition and the transaction data section. When a transaction is restarted, only its data section (or part of it) is reset.

## 5. Experiments and Results

In all experiments, a fixed number of transactions is cycled around the 2PL(CTV) simulator. This number represents the system load. In 2PL, a given transaction j may be inactive (blocked) or actively running. An actively running transaction may be taking a service at some server (lock manager or restarter) or else be submitting a new lock request to the simulator. This lock request is denoted $L_{ijk}$ (transaction j requests a lock on item i in mode k $\varepsilon$ [Read,Write]). In CTV, a transaction j is always actively running taking a service at some server (validator, committer or restarter) or submitting a new access request to the simulator. This access request is denoted $R_{ijk}$ (transaction j submits an access request on item i in mode k $\varepsilon$ [Read,Write]). The process of submitting an $L_{ijk}$ ($R_{ijk}$) is repeated for an "Observation Interval" number of times. Observation interval ranges from 2000 to 40,000 lock (access) requests. In the following set of experiments, the database size (M), was assumed to be a total of 640 items. The effect of granularity on the performance was investigated by studying granularities of 80, 160, 320, and 640 granules.

According to Yao [Yao77], the value of the effective transaction size changes with varying the granularity. In these experiments, the effective transaction size is almost invariant to changing granularity over [80,160,320,640] for a database of 640 items and for transactions of 15 items size.

The size of each transaction, I, was assumed to be large (15 granule lock (access) requests). This amounts to about 2.5% of the whole database (640 granules). Usually, a transaction accesses less than 1% of a database, so the 2.5% figure represents a large size transactions. This gives a worst case study of a database system with transactions of mixed sizes.

The effect of the Read/Write mix associated with the transactions was investigated by conducting experiments for mixes of 100/0, 90/10, 80/20, . . ., and 0/100.

The hardware parameters were assumed to be a disk average service rate of 20 access requests/second and one MIPS processor. These figures were fixed in all the experiments but were doubled and reduced to a half in one experiement in order to understand its effect on the performance.

In 2PL(CTV) an actively running transaction j submits an $L_{ijk}$ ($R_{ijk}$) by uniformally selecting an item i$\varepsilon$ [1 ... M] from the set of items not yet accessed by j and by selecting k$\varepsilon$ [ Read , Write ] according to a predefined Read/Write ratio (K is selected to be a "Read" with Probability less than Threshold and "Write" otherwise).

The domain of settings for all experiments conducted is listed below.

1- Number of transactions (T): [ 5,10,20,30,40 ]
2- Number of Database granules (M): [ 80,160,320,640 ]
3- Transaction size in granules (I): [ 15 ]
4- Read/Write mix (THRESHOLD): [ 100/0, 90/10,...,0/100 ]
5- Disk average service rate (μ): [ 20,40 ] access/second
6- Processor Power in MIPS : [ 1, 2 ]

### 5.1 Response time and Throughput

Response time and throughput of the 2PL and the CTV are studied under variation of three parameters. These are the system load, the transaction Read/Write mix and the granularity. In these experiments, Response time and throughput are plotted for various Read/Write mixes, while the degree of multiprogramming is fixed. This process is repeated for various degrees of multiprogramming (loads) and the resulting curves are grouped into a frame. The frame is repeated for various granularities. Thus the effect of the Read/Write mix, the effect of granularity, and the load effect are all incorporated into detailed design curves. Only response time curves are included (Fig 3).

### 5.1.1 Load Effect

In both the 2PL and CTV, increasing the system load (T) results in the following:

1- Response time linearly increases
2- Throughput linearly decreases.

This effect is shown in figure 4.

### 5.1.2 Effect of the Read/Write mix:

In both the 2PL and the CTV, the R/W mix affects the response time as follows:

1- The R/W mix has a great impact on the RT, especially when the system is loaded (T=30,40).

2- For small loads (T=10), R/W mix has a negligable effect on RT.

3- Starting from the 100% read (query) case, increasing the write percentile first impairs the RT till R/W mixes of 70/30-50/50, after which the RT improves, and in the case of the 2PL it reaches its minimum value at the pure update case.

Explanation:

The Third observation about Response Time is explained below.

(a) For query-dominant transactions (R>50, W<50), unresolvably conflicting transactions are restarted after accessing most of their requests. Restarting a mostly finished transaction contributes to an increase in the useless I/O percentile.

(b) For update-dominant transactions (R<50,W>50), since two-phase commit is incorporated with the 2PL and the CTV, no write disk operation takes place during trasaction execution and hence most of the transactions disk access operations will not be done by the time it is restarted because of an unresolvable conflict. Thus, we have the case of restarting a transaction that accessed a small fraction of its requests. This results in small useless I/O percentile. On the other hand, for update-dominant transactions, unresolvable conflict rate increases resulting in so many restarts. However, the restart operation neither contributes to high useless I/O percentile nor incurs high setup cost.

### 5.1.3 Granularity Effect

In both the 2PL and the CTV, granularity affects the response time as follows:

1- For small loads (T=10), granularities of 160,320, and 640 have almost the same RT. Granularity of 80 incurs higher resnonse time. This is further illustrated in figure 5.

2- Granularities of 80 and 160 highly impairs the RT, especially when the system is loaded (T=30,40).

3- For the 2PL, the effect of doubling the granularity from 320 to 640 (that is from M/2 to M, where M is the database size) is almost negligible. This is true for the CTV only for small loads (T=10).

### 5.1.4 Effect of Hardware Parameters

The effect of doubling the disk average service rate and the Processor speed was presented on the response time only. The observation is shown in figure 6. It is observed that doubling the disk power results approximately in reducing the response time by half, whereas doubling the processor speed results in a trivial improvement in the response time.

### 5.2 The Comparison

In this section, we compare the response time incurred by the 2PL and the CTV algorithms. In this comparison, a load of 20 transactions is fixed. However, conclusion of this comparison is similar to that for all other loads. Figure 7 depicts the response time of both the 2PL and the CTV. From these curves the following are observed:

1- CTV is better than the 2PL for granularity of 80, whereas 2PL is better than the CTV for granularities of 320 and 640. For

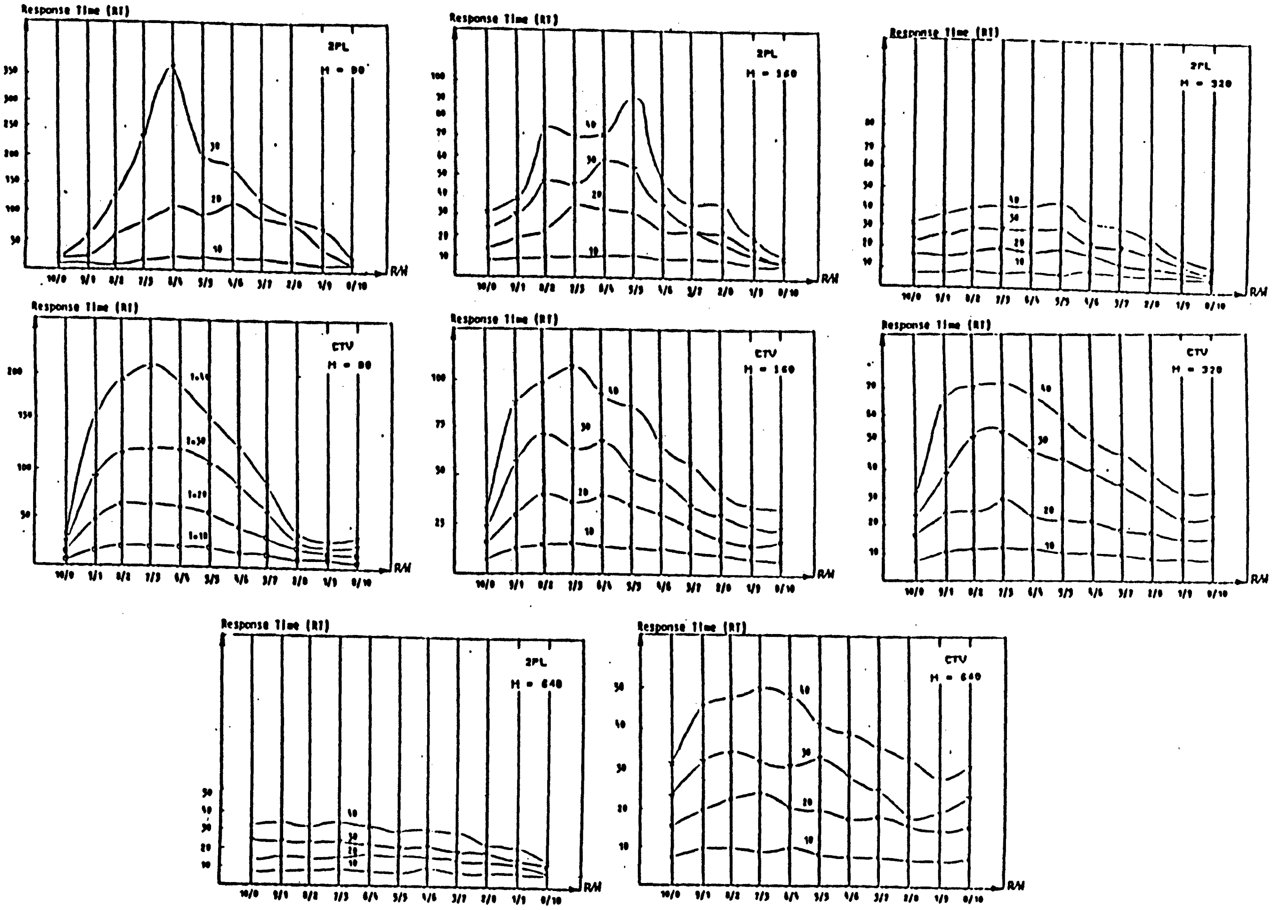

Figure 3 Response Time Design Curves

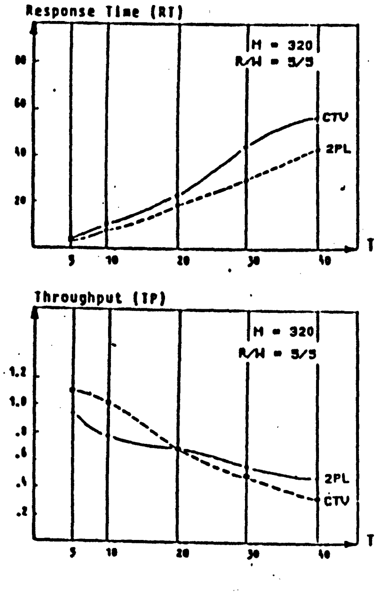

Figure 4 Load Effect

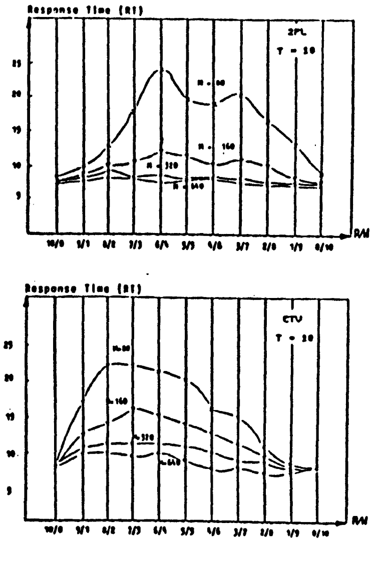

Figure 5 Small Loads

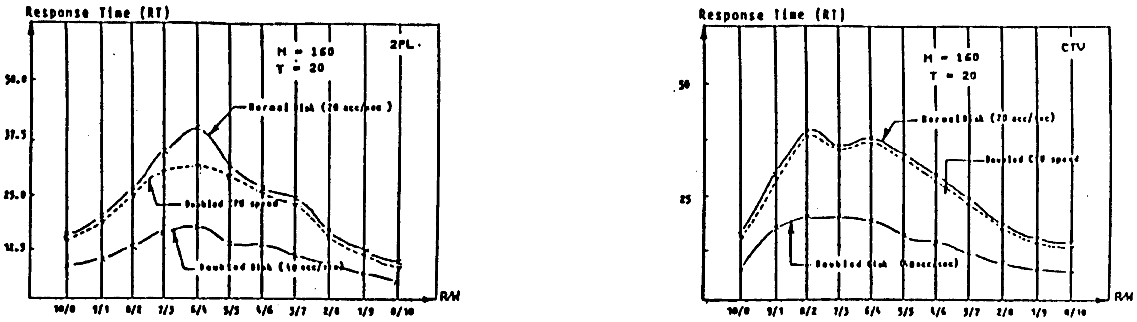

Figure 6 Effect of Hardware Parameters

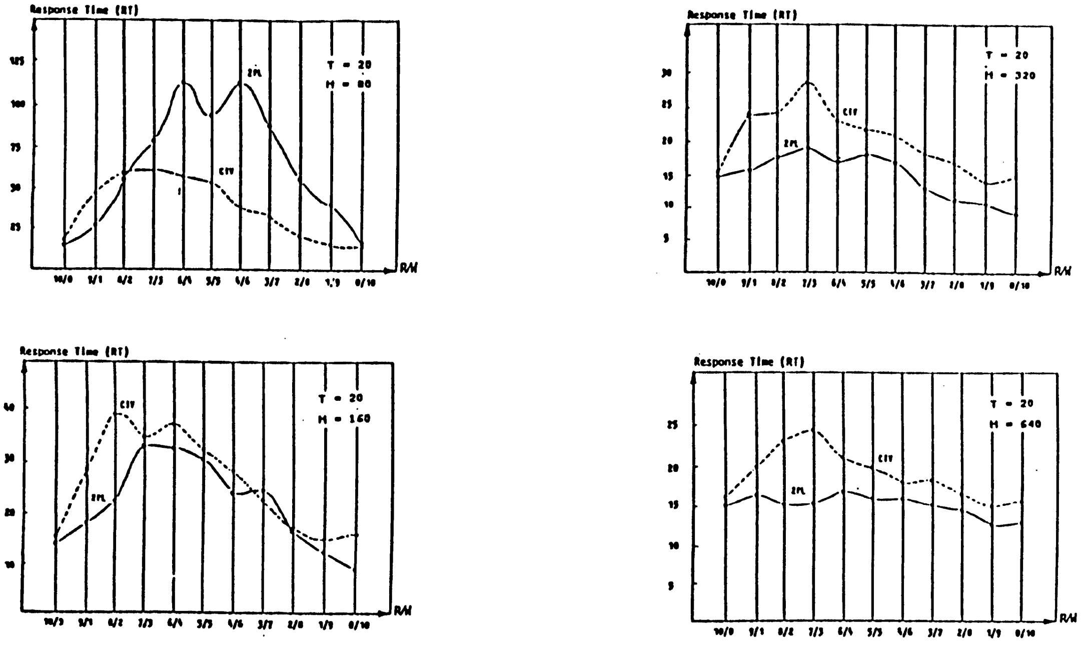

Figure 7 Comparison between the 2PL and the CTV

granularity of 160, 2PL is better for high read percentile of the R/W mix, and for write percentiles greater than 50%, the two algorithms incur approximately the same response time.

2- For granularity of 80, 2PL incurs unacceptable response time.

3- In the 2PL with granularity of 640, the R/W mix has almost no effect on the response time.

4- For high granularities, and for high read percentiles of the R/W mix, the two algorithms incur reasonable (acceptable) response time.

## 6. Conclusion

We have presented two simulation models for each of the dynamic two-phase locking and the commit-time validation. Model assumptions were unified and a comparison was made. We concluded that CTV can work better than 2PL under very coarse granularity whereas 2PL performance is not acceptable for the same very coarse granularity. On the other hand, 2PL outperforms the CTV for granularities of 320, and 640. Also, we concluded that for query dominant transactions, the two algorithms incur the same performance.

In 2PL, we have found that for large size transactions, the response time incured by a granularity M is almost the same of that incured by a granularity M/2, where M is the database size.

Under the assumption that two-phase commit is incorporated with the 2PL and the CTV, the Read/Write mix associated with transactions was found to affect the performance as follows: query dominant and update dominant transactions result in better performance than transactions with nearly equal read and write percentiles.

## Acknowledgements

We would like to thank Prof. Yahia El-hakim, Chairman of the Computer Science Department at Alexandria University, Prof. T.M. Ozsu from the University of Alberta, Dr. Jai Menon of IBM Almaden Research Center and Mr. D. Mannai for their careful reading of the manuscript and many valuable suggestions. They have improved the contents and presentation of this paper, and to them we are grateful.

# INCREASING PROCESSOR UTILIZATION DURING PARALLEL COMPUTATION RUNDOWN

William H. Jones

National Aeronautics and Space Administration
Lewis Research Center
Cleveland, Ohio 44135

Abstract -- Some parallel processing environments provide for asynchronous execution and completion of general purpose parallel computations from a single computational phase. When all the computations from such a phase are complete, a new parallel computational phase is begun. Depending upon the granularity of the parallel computations to be performed, there may be a shortage of available work as a particular computational phase draws to a close (computational rundown). This can result in the waste of computing resources and the delay of the overall problem.

In many practical instances, strict sequential ordering of phases of parallel computation is not totally required. In such cases, the "beginning" of one phase can be correctly computed before the "end" of a previous phase is completed. This allows additional work to be generated somewhat earlier to keep computing resources busy during each computational rundown. This paper identifies the conditions under which this can occur, reports the frequency of occurrence of such overlapping in an actual parallel Navier-Stokes code, suggests a language construct, and discusses possible control strategies for the management of such computational phase overlapping.

## Introduction

General purpose parallel computations are usually divided into phases that must execute sequentially in order to guarantee algorithmic integrity. For instance, the checkerboard approach to the successive over-relaxation solution of the potential field problem divides into two such phases: the "odd" locations phase and the "even" locations phase. On the parallel phase level, the iterated values of the previous phase must be complete before the new values of the next phase can be correctly computed.

In the checkerboard algorithm, the execution time of each location is definite (nominally, the time for four additions and a divide). Thus, the distribution of work among processors can be accurately planned. Under ideal conditions (involving the number of checkerboard locations in comparison to the number of processors), the distribution of work can be arranged so that each processor shares an exactly even portion of the work and, as a consequence, each processor completes its work at exactly the same time. Perfect computation resource utilization is realized (at least in a practical sense) since the next computational phase can begin immediately.

Unfortunately, ideal conditions are infrequently found in real applications. Continuing with the checkerboard algorithm, consider the situation when the potential grid is 1024 points on a side (2**20 grid points) and 1000 processors are available. Each computational phase will provide 524, 288 individual computations, or 524 computations for each of the 1000 processors; however, 288 computations will be left over for distribution among the 1000 processors. This will leave 712 processors with nothing to do while the final 288 computations are carried out.

The burden of experience gained by the author suggests that even this example is optimistic. Most computations carried out by the author's parallel Navier-Stokes solver (the Combined Aerodynamic and Structural Dynamic Problem Emulating Routines or CASPER [1] which was controlled by the Parallel, Asynchronous Executive or PAX [2]) could not even be ascribed with definite execution times. In some instances, whether or not the computation was even to be carried out in a particular instance was a conditional part of the algorithm. No control over the computation-count-to-processor ratio was attempted -- processors were allocated as they became available on a the-more-the-merrier basis. Also, shared information access times were unpredictable and unrepeatable from instance to instance. As a result, there was no assurance that individual processors could be kept busy as a particular computational phase drew to a close.

The PAX/CASPER project provided the experience base cited later in this paper. PAX/CASPER was focused on a parallel, general purpose, Navier-Stokes solver. Thus, this experience base is presented not as a grand generalization for all of parallel processing, but as a specific example in practical parallel processing.

Certain other situations that might seem of interest in the overlapping of computational phases (for instance, the possibilities for overlapping in a tight iterative loop) are not treated for the simple reason that they did not occur in the PAX/CASPER project. PAX/CASPER was not so much a research project in parallel processing as an exploratory development of a far-term aerodynamic tool. Thus, the motivation was to solve the problems that occurred rather than to solve the problems that one could imagine.

It has been suggested that scheduling and overhead problems will be a particular problem in PAX/CASPER. So far, this has not been the case. Operational experience shows that the ratio of computation to management has been running at something in the neighborhood of 200. This paper is an effort to chart a method of improving upon this situation so as to stave off any backsliding that might occur as the ratio of computational to management resources increases. There are additional strategies which have been identified for development. These include a middle management scheme to parallelize the serial management function, a direct worker-to-worker lateral communication scheme, and a data-proximity work assignment algorithm. These strategies combined with the overlapping of computational phases should enhance the management overhead situation.

Various solutions to the computational rundown problem may be acceptable. Some parallel processing schemes for general purpose computation may choose simply to accept the lower processor utilization as a minor design flaw. Another alternative is to create a multi-parallel-job-stream environment that allows computational work of one job stream to fill in when another job stream enters a computational rundown situation. This will bring processor utilization up; however, it should be recognized that the primary goal of parallel processing is to reduce elapsed wall-clock time for a given job. The introduction of such a "batch" environment will inevitably distribute processor resources among the several job streams and, thus, reduce the total processing power on any particular job and lengthen its elapsed wall-clock time.

### Overlapping Computational Phases

The goal then is to find more ready-to-compute work from the parallel algorithm that is being computed. As mentioned previously, this is not possible at the parallel phase level: each phase must be completed before the next is begun in order to guarantee algorithmic integrity; however, if an examination is made at a deeper (sub-phase or, in the terminology of the author, task) level, it is frequently discovered that the completion of portions (tasks) of one phase will allow the correct computation of portions (tasks) of the succeeding phase.

Consider again the checkerboard algorithm. If all the "odd" locations adjacent to a particular "even" location have been updated with new values from the current computational phase, then the new value for that particular "even" location for the next computational phase can be correctly computed. Additionally, since all the computations requiring as an input the current value of that particular "even" location have been completed, the value for that "even" location can be updated without affecting the results of the current computational phase.

At this point, it is necessary to make certain assumptions (or, alternatively, set certain system design constraints) about the nature of computational phase rundown. Two basic situations arise: one in which task assignments and releases are statically determined and one in which such matters are dynamically determined.

The static situation is much simpler from the standpoint of next-phase task release timing since everything is determined ahead of time. In this case, it can be acceptable for computational rundown to begin almost immediately since the scheduling of the next-phase task has already been statically determined. No completion processing of current-phase tasks is required to schedule the release of the next-phase task. (In fact, work in this area for the purposes of real-time simulation has been conducted for some years at NASA Lewis [3, 4]).

The dynamic scheduling situation is substantially more interesting. Some time delay must be available between the completion of the first current-phase tasks and the onset of computational rundown. This delay is needed to provide time to process the completion of the early current-phase tasks and, in so doing, schedule the next-phase tasks that are thus enabled. During this delay, there must be enough current-phase tasks to keep the processing resources busy in order to avoid a computational load dip while the next-phase tasks are scheduled.

In the dynamic scheduling situation, enablement relationships between the current-phase tasks and the next-phase tasks (i.e., the relationship that enables a next-phase task based upon the completion of a current-phase task) may be either static or dynamic. That is, the completion of a particular current-phase task may always enable the same next-phase task (the static enablement case) or it may enable some next-phase task that can only be identified at the time of execution (the dynamic enablement case). The nature of the enablement relationships is important because it is involved in setting the time delay from the completion of the first current-phase tasks to the availability of the first enabled next-phase tasks.

Considering these characteristics of the dynamic scheduling situation (i.e., the time to process current-phase task completion, the time to recognize enablement relationships, and the time to schedule enabled next-phase tasks), it can be observed that the number of tasks should substantially outnumber the number of processors. Certainly, there should be at the outset of the current-phase work at least two tasks for each processor so that at least one task execution time will be available to process the completion of the first task assigned to the processor and to schedule the enabled next-phase task. This presumes that completion processing and task scheduling time is small with respect to task execution time. In particular, it assumes that one such completion, enablement, and scheduling cycle for each of the processors in the system can be completed in a single task execution time. (The author's experience with PAX suggests that this is reasonable even for dynamic managerial style parallel processing systems. Systems that use hardware-level synchronization primitives presumably would be at even greater advantage in this area.)

The conditions under which this overlapping of computational phases can correctly occur are the same as those that allow parallel computations within a particular phase. Let the logical predicate PARALLEL(x,y) return the condition TRUE when x and y are such that parallel computations are allowed. Clearly, PARALLEL(n,m) must always be TRUE if n and m are distinct computational granules of the same parallel computational phase. Let q be an uncompleted granule of the current phase and r be a granule of the next phase that has been enabled by some completed granule, p, of the current phase. If PARALLEL(q,r) necessarily returns the value TRUE, then the current-phase and next-phase can be correctly overlapped.

The exact nature of the logical predicate PARALLEL(x,y) is, of course, of substantial practical interest; however, it has no direct impact upon the ability to overlap phases as outlined above. Different parallel systems may identify different logical predicates.

### Identifying Enabled Granules

The first challenge to be met is to find a way of identifying enabled next-phase granules for overlapping. It is easy to postulate that some mapping function exists either to map from the set of completed granules, p, to the set of enabled granules, r, or to map from the set of uncompleted granules, q, to the set of enabled granules, r. It is very difficult to establish what this mapping function might be in any general way. Fortunately, this mapping function is much more easily identified when each concrete situation is faced.

First, consider the simplest imaginable case as represented by the following Fortran code segment:

```
      ...
      DO 100 I=1,N  ! First computational phase
      B(I)=A(I)     !
  100 CONTINUE      !
      DO 200 I=1,N  ! Second computational phase
      D(I)=C(I)     !
  200 CONTINUE      !
      ...
```

Assuming that there are not shared output area constraints, it can be observed that these two parallel computational phases can be computed in parallel with each other. This represents what might be called a universal mapping function wherein any granule of the second computational phase is enabled by any granule or set of granules (including the null set) of the first computational phase.

PAX/CASPER experience shows that 6 out of 22 (or 27 percent) of the parallel computational phases allow universal mapping enablement of the succeeding phases. This represents 266 out of 1188 lines (or 22 percent) of the code that is executed in parallel in PAX/CASPER.

This universal mapping usually occurs in PAX/CASPER when the nature of the larger computational process is changing. For instance, the change over from power of compression computations to interpolator matrix generation is one such character change. The two computations do not involve shared information of any kind and, thus, they can be entirely overlapped. Of course, the two phases could be merged into one by a preprocessor of the parallel control stream; however, since the mechanisms necessary to handle this case would be a subset of those needed for the following case, it might well be simpler to support this enablement mapping.

For the next case, consider the following Fortran fragment that is to be computed in parallel as two succeeding computational phases:

```
      ...
      DO 100 I=1,N  ! First computational phase
      B(I)=A(I)     !
  100 CONTINUE      !
      DO 200 I=1,N  ! Second computational phase
      C(I)=B(I)     !
  200 CONTINUE      !
      ...
```

Again assuming that there are not shared output area constraints, it can be observed by inspection that the identity mapping function (I = I) maps from completed granules, p, to enabled granules, r. This is also a simple and easily identified mapping.

PAX/CASPER experience indicates that it applies in 9 out of 22 (or 41 percent) of the parallel computational phases (representing 551 of 1188 code lines, or about 46 percent of the parallel code in PAX/CASPER). Combining this direct mapping with the simpler universal mapping above indicates that (at least in PAX/CASPER experience) 68 percent of the parallel computational phases and 68 percent of the code executed in parallel can be easily overlapped to defeat computational rundown. These two enablement mapping possibilities are the most frequently occurring situations in PAX/CASPER experience.

The next most frequently occurring enablement mapping in PAX/CASPER experience is what could be called null mapping, that is, the situation in which no overlapping is possible. This occurs in 4 out of 22 (or 18 percent) of the computational phases and represents 262 out of 1188 (or 22 percent) of the lines of code executing in parallel. In all cases the cause was not that such an overlapping did not exist between the parallel computations but was, in fact, that serial actions and decisions had to occur between the phases. This is important since it allows one to assess how often the extra effort of supporting overlapping features will be entirely defeated, regardless of the sophistication of the overlapping phase support features.

Another enablement mapping occurring in PAX/CASPER experience is a reverse indirect mapping. Consider the following Fortran fragment:

```
      ...
      DO 10 I=1,N         ! Set up source mapping
      DO 10 J=1,10        !
      IMAP(J,I)=IRAND()   ! IRAND produces an integer
   10 CONTINUE            !   in the range 1 to N
      DO 100 I=1,N        ! First computational
      A(I)=FUNC(I)        !  phase generates some
                          !  number in A(x)
  100 CONTINUE            !
      DO 200 I=1,N        ! Second computational
      DO 200 J=1,10       !  phase sums subsets of
      B(I)=A(IMAP)(J,I))! the results of the
                          !  first computational
                          !  phase
  200 CONTINUE            !
      . . .               !
```

Clearly, this computation can be overlapped; however, determining the enablement mapping is very difficult. This is because knowing that a particular first phase granule is complete does not directly identify any distinct second phase granule as computable; however, a reverse mapping from desired second phase granule to required first phase granules is possible.

In PAX/CASPER experience, this situation occurs in 2 of 22 (or 9 percent) of the computational phases representing 78 out of 1188 (or 7 percent) of the lines of code executing in parallel. While this is not a frequently occurring situation in PAX/CASPER experience, it cannot be ignored out of hand. Some engineering judgement must be made to weigh the cost (in terms of management overhead, computational resource transferred from workers to management, etc.) of some reverse enablement mapping solution against the cost of computational rundown in 9 percent of the parallel computational phases.

Certainly, a solution exists for the reverse, indirect enablement mapping. Once the values of the information selection map (represented in the code fragment by the array IMAP) have been determined, it is a simple matter to produce a composite map of first phase granules that must be completed in order to enable a particular second phase granule. The executive can then use this map upon each first phase granule completion to determine the computability of particular second phase granules. This map could also be used to direct a preferred order of first phase granule dispatching so as to enable a known second phase granule as early as possible.

Two important facts about this reverse enablement mapping must be included. First, both occurrences of this situation involved a dynamically generated information selection map. Thus, the composite granule map would have to be generated by the executive at or after first phase initiation but before any second phase enablements. Second, the impact of executive computation must be considered. In the PAX/CASPER UNIVAC 1100 test bed, executive computation was done at the direct expense of worker computation. Thus, extensive composite granule map generation could be self defeating. Some real parallel machines may provide separate executive computing resources, in which case the generation and use of composite granule maps would not be out of the question.

A final enablement form was observed in PAX/CASPER that could be characterized as a forward, indirect mapped situation. Consider the following Fortran fragment:

```
      DO 10 I=1,M           ! Generate forward
      IMAP(I)=IRAND()       !  map
   10 CONTINUE              !
      DO 100 I=1,M          ! Use forward map
                            !  to operate on a
      B(IMAP(I))=A(IMAP(I)) !  subset of the
  100 CONTINUE              !  arrays
      DO 200 I=1,N          ! Perform some further
      C(I)=B(I)             !  further opera-
  200 CONTINUE              !  tion on the

      ...
```

This situation is somewhat easier than the reverse, indirect mapping in that the identification of a particular granule in the first phase can be directly mapped to an enabled granule in the successor phase; however, much of the complication of a mapped enablement remains. This form was the least frequently occurring situation in PAX/CASPER showing up only once (5 percent of the phases) and accounting for only 31 of 1188 lines of code executed in parallel.

No other forms of enablement mapping were observed in PAX/CASPER. Certainly, extensions of the forms already presented can be imagined. Additionally, a seam mapping problem (such as would be appropriate for the checkerboard approach to the successive over-relaxation problem) can be foreseen. These other forms are beyond the scope of the present paper.

## Language Construction

The developing PAX/CASPER language is simple and requires the user to make specific statements concerning choices for the management of each parallel computational phase. Statements involving the enablement of a succeeding phase could be made at two times: during the definition of a computational phase to the management system and during the invocation of the phase for actual computations. The difficulty to be faced is that the statements no longer apply solely to the phase being referenced, but rely also on the characteristics of the succeeding phase.

The simplest approach is to require the user to specify the appropriate enablement mapping method when the phase in invoked. It might appear as in the following PAX parallel language fragment:

```
...
DISPATCH  phase-name
          ...
          ENABLE/MAPPING=option
          ...
```

This is simple and explicit; however, it leaves the door wide open to user mistakes. There is no interlock between this phase and the next that can be verified by the executive. A simple solution to this would be to identify the name of the enabled next phase so that the executive system (or language processor) can verify that, in fact, that phase is following. This might appear as follows:

```
...
DISPATCH  phase-name
          ...
          ENABLE [phase-name/MAPPING=option]
          ...
...
```

This allows the desired verification, but also brings up a new possibility. Occasionally, a conditional branch that is not dependent on the computational phase separates that phase from two or more succeeding phases, each of which may (or may not) be overlappable. If each of these phases were identified in the above construct, the executive could preprocess the branch and overlap the appropriate phase. This could look as follows:

```
...
DISPATCH phase-name
         ...
         ENABLE/BRANCHINDEPENDENT
          [phase-name-1/MAPPING=option
            phase-name-2/MAPPING=option]
         ...
IF       (IMOD(LOOPCOUNTER,10).NE.0)
THEN     GO TO branch-target
DISPATCH phase-name-1
         ...
GO TO    rejoin
branch-target:
DISPATCH phase-name-2
rejoin:
...
```

Finally, the matching of mapping selections and phases and the invocation of the appropriate overlapping services is something that could be done when the parallel phase is defined to the system; however, it would still be necessary to identify pre-processable branches at the computation invocation site. This could appear as follows:

```
DEFINE   PHASE phase-name
         ...
         ENABLE [
                phase-name-1/MAPPING=option
                phase-name-2/MAPPING=option
                phase-name-3/MAPPING=option
                ]
...
DISPATCH phase-name
         ...
         ENABLE/BRANCHDEPENDENT
...
```

The ENABLE/BRANCHINDEPENDENT would be deleted when branch pre-processing was either not appropriate or not needed. The executive system could perform the appropriate lookahead to see whether any of the named succeeding phases was actually following and apply, as appropriate, the specified enablement mapping.

## Control Strategies

Control strategies for enabling and scheduling overlapped parallel computational phases are, of course, highly dependent upon the overall parallel processing strategies. As alluded to earlier, some approaches to parallel processing may do all of this before any computations are begun. Indeed, the entire process may be done manually by a human being when the pattern of parallel processing is fixed for the life of the system.

Within the PAX system, the opposite is true: the identification and scheduling of computable granules is entirely automatic. A scheduling mechanism for enabled computational granules already exists within the PAX system. It was developed to schedule dynamically created computations that conflicted (usually in terms of shared data access) with pre-existing computational granules.

Within PAX, each internal description of one (or more) computational granules included a queue head for a double circularly-linked list of computable but conflicting computational granules. Upon completion of the described computation, all the queued conflicting computations became unconditionally computable and were placed in the waiting computation queue. The waiting computation queue was kept in a known order and, for the purposes of the conflicting computation problem, it was determined that such conflicting computations would be placed ahead of the normal computations in the queue and, thus, given higher priority.

The scheduling of universally mapped successor phases within this system is very easy indeed. At the time of phase initiation, the successor phase is also initiated and the resulting computation description placed in the waiting computation queue behind the current phase description.

The scheduling of directly enabled successor phases is similarly easy at first sight. At the time of phase initiation, the successor phase is also initiated and the resulting computation description placed in the conflicted computation queue of the current phase description. Thus, when the current phase computation is completed, the now-enabled successor computation will be placed in the waiting computation queue to be considered for scheduling.

The above approach for directly enabled successor phases is fine if each indivisible granule of computation is described separately. Unfortunately, this is usually not economical (in terms of storage space and task search times, among other things) and was not the choice taken in PAX design. Computations were, instead, described as large, contiguous collections of granules. The descriptions were split apart as necessary to produce conveniently sized tasks for workers and then merged back into single descriptions when the work was completed. This splitting of descriptions reqiuires that queued computation descriptions also be split so that each queued description will accurately reflect the enablement relationship between the computation and its queued successor computation.

While this is certainly possible, it forces a further design decision for the executive software. PAX computation splitting was demand-driven by the presence of an idle worker. It was felt that the delay while splitting a task description was acceptable; however, the additional delays of splitting queued successor computation descriptions may represent an unacceptable situation. Two possible solutions exist. One possibility is to pre-split the tasks before idle workers present themselves to the executive. This would allow the executive to work ahead in otherwise idle time. Alternatively, the splitting of a computation could generate a successor-splitting task that could be quickly queued for later attention when the executive would again be idle.

The successor computation description could be removed from the current computation description and included in the successor-splitting task information. When the successor-splitting task is executed the successor computation could be split and requeued to the appropriate current computation descriptions.

Management of indirectly (both forward and reverse) mapped successor computations is a good deal more interesting. The description of the successor computation cannot simply be queued to the description of the current computation since there is no guarantee of the enablement relationship. Additionally, it would seem wise to get the current phase into execution without the delay of constructing the necessary information for enabling successor computations. Both forward and reverse indirection would seem well handled by much the same mechanisms since the only significant difference is the direction of the indirection. Each leads naturally to a list of current phase granules that must be completed to enable a particular successor phase granule.

It would seem appropriate to identify a subset group of successor-phase granules that are to be the subject of the enablement operation so as to avoid solving an unnecessarily large enablement problem. Once this subset has been identified, the current-phase granules that enable the successor subset can be identified. Since these are not necessarily the current phase granules that would be naturally selected by the scheduling mechanism, they should be split into individual descriptions and placed in the waiting computation queue in such a manner as to elevate their computational priority.

It is important to note that the description of the successor subset cannot simply be queued to any one of the identified current-phase granules since it is enabled not by the completion of any one such granule but by the completion of all the identified granules. This enablement on completion of all identified current-phase granules can be handled by any number of simple mechanisms. For instance, during completion processing, a status bit (set when the current-phase granules were identified and split into individual descriptions) can be checked and, if it is set, an enablement counter decremented. When the enablement counter reaches zero, it can be taken as a signal that the successor-phase granules are computable.

## Concluding Remarks

This paper has discussed the possibilities for overlapping parallel computations in a general purpose parallel-computation environment so as to minimize loss of computational resources. Practical experience with PAX/CASPER, a parallel Navier-Stokes solver, suggests that simple and plausible steps could provide such overlapping in 68 percent of the computational phases and that, with extended effort, more than 90 percent of the computational phases are amenable to some form of phase overlapping.

# A SYSTEM FOR COMPUTING THE SPEEDUP OF PARALLEL PROGRAMS

**Bruce P. Lester**

Department of Computer Science
Maharishi International University
Fairfield, Iowa 52556

## ABSTRACT

New analytical techniques are presented for probabilistic systems with concurrency and applied to computing the expected execution time and speedup of parallel programs. These new techniques are formulated for a program description language called PEL (Performance Evaluation Language), which allows essential control and timing characteristics of parallel programs to be expressed in a precise manner. The analysis techniques for PEL are an extension of standard linear system techniques to the realm of concurrency, based on the development of a new mathematical operator called the "join product." Efficient approximation techniques are also introduced for estimating the execution time and speedup of parallel programs.

## 1. INTRODUCTION

Since the main purpose of concurrency is improved performance, it is important to have analysis tools for evaluating the expected performance of various concurrent algorithms with respect to their sequential counterparts. One practical analysis technique is to simply write the program and run it on the target computer. However, the execution time for different input data may vary considerably, and it may be difficult to generalize the results from a small number of data sets. Also, the execution time will be highly dependent on uncontrollable environmental factors such as system load and placement of data files on the disk. Another common analysis technique is to do a direct complexity analysis of the abstract algorithm itself. This method has proved useful in computing overall relative complexity of algorithms in terms of "big O" properties, but is not exact enough for performance prediction of real programs. Also, this type of complexity analysis is difficult for large programs, especially those involving disk access.

This paper presents an alternative analysis technique for concurrent programs which is somewhere in between these two techniques. The actual program is written out in a special language which allows the programmer to specify the estimated execution time of primitive operations, and to model the effect of differing input data with conditional branching probabilities. One of the earliest efforts to use probabilistic analysis techniques for computer programs is found in a paper by Ramamoorthy [1], in which traditional flow graph techniques for Markov processes are used to estimate the execution time of programs expressed as flow charts, with conditional branches represented by probabilities. Using traditional z-transform techniques, the complete probability distribution for the execution time of the whole program is calculated, from which important statistics such as average execution time and variance are easily computed. Deo [2] gives an efficient technique for finding the expected execution time using a stochastic model of a program in conjunction with the standard mean first passage time techniques used for Markov processes [3]. Similar techniques are also presented by Trivedi [4]. However, none of these sequential program techniques is directly applicable to programs with concurrency.

With the increasing importance of parallel computation, there is a growing body of research on performance evaluation of parallel systems. Most of this research uses timed or stochastic Petri nets as the underlying model for the parallel system. Research results are encouraging and show that analytical or simulation techniques can be used to analyze the behavior of parallel systems represented as a Petri net with timed transitions and probabilistic choices. Zuberek [5] and Molloy [6] present techniques and examples of application to communication protocols, and Marsan [7] applies Petri net techniques to performance evaluation of multiprocessor systems. The disadvantage of these techniques is they are based on generating the reachability graph of all possible states of the Petri net, which may be exponential in the size of the net. Thus, these techniques are not practical for analyzing concurrent computer programs, typically involving large numbers of potentially concurrent operations. Sahner and Trivedi [8] describe a tool for performance evaluation of concurrent systems called SPADE, which uses an acyclic directed graph to model precedence constraints among events. SPADE is useful for analyzing concurrent program task structures, but is not general enough for detailed internal analysis of concurrent programs.

## 2. PERFORMANCE EVALUATION LANGUAGE

For the purpose of performance evaluation of computer programs, a simple language called PEL (Performance Evaluation Language) is used to represent important characteristics of the program, including the basic control structure of the program, concurrency, operation execution times, conditional branching probabilities, and loop repetition counts. A description of a program in PEL may be written directly by the programmer, or created by a compiler from the source code of the original program. If the compiler technique is used, then the programmer must supply additional information about branching probabilities and loop repetition counts in the program. Individual operation execution times may be already known to the compiler or may also be specified by the programmer.

0190-3918/86/0000/0145 $01.00 © 1986 IEEE

A similar technique is used by the Parafrase system [9] at the University of Illinois to measure program execution times for the purpose of analyzing speedups resulting from various types of program restructuring techniques that create concurrency. In the Parafrase system, the user may specify conditional branching probabilities in Fortran programs with special "assertions". If no assertion is made concerning a given branch, then Parafrase assumes that all branches have equal probability. Parafrase also estimates the number of iterations of each DO-loop, with the help of user assertions and user-definable global default values. Estimates for operation execution times such as arithmetic operations, logical operations, subscript calculations, store operations, and memory fetches are built into Parafrase, and thus not specified by the user.

The syntax of PEL is quite simple with five basic types of statements: *delay, if-then-else, sequence, loop,* and *fork-join.* The three statement types *if-then-else, sequence,* and *loop* correspond to the traditional control structures found in any block-structured language like PASCAL. The *delay* statement is used to model the execution time delays associated with primitive operations in the program such as arithmetic or assignment operations. The *fork-join* statement is used as the basic control structure for concurrency. PEL is used to create a probabilistic model of the program control structure and timing delays, in order to evaluate the overall execution time of the whole program. PEL programs have no input data, and their execution is based entirely on probabilities, which are supposed to represent average values for typical input data sets of the original program. Figure 1 shows an example of a simple PEL program.

```
PROGRAM;
  IF RANDOM < .3
    THEN  BEGIN  DELAY(5); DELAY(2); DELAY(7)  END
    ELSE
      FORK
        IF RANDOM < .5 THEN DELAY(20)
                 ELSE DELAY(35);
        LOOP 10  DO  DELAY(3);
        IF RANDOM < .4 THEN DELAY(5)
                 ELSE DELAY(10)
      JOIN;
END.
```

**Figure 1 - A Sample PEL Program**

Each time an if-then-else statement in PEL is executed a new random number between 0 and 1 is generated (represented by the word "RANDOM") and then compared with a constant, which represents the probability of choosing the "THEN" clause. In the above program, the outer "IF" chooses the "THEN" clause with probability .3 and the "ELSE" clause with probability .7 . The "THEN" clause consists of a sequence of three "DELAY" statements whose execution time is given in parenthesis. The "ELSE" clause contains a fork-join statement which executes three separate statements concurrently. The loop statement executes its body the number of times specified by the fixed constant loop count (in this example the loop count is 10). Statements may be nested to an arbitrary depth as in ordinary block-structured languages like PASCAL.

The use of fork-join primitives for specifying concurrency in programming languages originated with Dennis and VanHorn [10], and has become a standard which is found in many languages and operating systems today [11]. There are three types of fork-join statements in PEL to represent some of the major types of concurrency primitives used in existing programming languages: *fork-list, fork-n,* and *fork-gen.* The *fork-list* statement is simply a list of statements which are all executed concurrently — this is similar to the "cobegin-coend" concurrency primitive found in languages such as Concurrent Pascal [12], or the "PAR" constructor in the parallel programming language OCCAM [13]. The *fork-n* statement has the following form:

FORK(n):  statement ; JOIN   (where n is any positive integer)

The *fork-n* statement creates n concurrent executions of its statement body, and is used to model the "forall" statement which is very common among concurrent programming languages such as SISAL [14], ARGUS [15], and OCCAM [13]. The major use of this "forall" construct is as a parallel form of a DO-loop for doing highly parallel operations on vectors and arrays, and is found in many parallel array languages [16].

The *fork-gen* statement in PEL consists of a list of labeled statements along with a partial ordering giving the execution precedence constraints. Such partial orderings result when flow analysis is performed on ordinary sequential programs by a compiler to automatically locate potential parallelism (see Kuck [17]). Figure 2 shows an example of a *fork-gen* statement:

```
FORK
  1: LOOP 5  DO DELAY(4);
  2: IF RANDOM < .6  THEN DELAY(23)
               ELSE DELAY(10);
  3: DELAY(5);
  4: DELAY(3);
  5: IF RANDOM < .7  THEN DELAY(15)
               ELSE DELAY(5)
PREC
  1 < 4 ; 2 < 3 ; 2 < 5 ; 3 < 4
JOIN
```

**Figure 2 - A Fork-gen Statement**

The statement labels are used in the "PREC" section to specify the precedence constraints for executing the statements. The symbol "<" is used to represent an execution precedence constraint and may be interpreted as "is an immediate predecessor of." For example, in the above *fork-gen,* statement 1 and 2 may be executed concurrently, but statement 4 may begin only after 1 is completed and statement 2 must precede both 3 and 5. The PREC list for this *fork-gen* statement defines the execution precedence graph shown in figure 3.

## 3. EXECUTION TIME OF PROGRAMS

A system has been developed to compute the probability distribution for the overall program execution time of any PEL program, including the average execution time and the speedup resulting from concurrency. In PEL, all of the execution time delays in the program are assumed to be represented by the delay statements. The control operations such as IF branching, LOOP, FORK, and JOIN are assumed to involve no time delays. However, if it is desired for the PEL program to model time delays in these statements, then delay statements may be added to account for actual execution times of these control operations.

The program execution time is represented by a probability mass function $f(t)$, which gives the probability that the program executes in exactly $t$ time units. For simplicity only integral values of $t$ are permitted. (Fractional values of $t$ can be accomodated by using a smaller time unit.) The function $f$ satisfies the usual rule for probability distributions that the sum of all probabilities gives 1:

$$\sum_{t=0}^{\infty} f(t) = 1$$

For the purposes of computing the overall program execution time, the probability mass functions will be represented by their geometric transform:

$$f^g(z) = \sum_{t=0}^{\infty} f(t)z^t$$

In the literature on probability theory, this is sometimes called the z-transform, discrete transform, or generating function. Transform techniques are useful in the analysis of all stochastic processes, especially Markov processes. The value of the transform is that it turns a stochastic process into a linear system, which can then be analyzed using a powerful set of linear system techniques such as flow graph analysis [3]. When parallelism is allowed, however, then the system is no longer strictly *linear*, and so the standard linear flow graph techniques are not directly applicable. To analyze PEL programs, we have developed new flow graph techniques which can be used to analyze probabilistic systems with parallelism.

For any PEL statement $S$, $T(S)$ is used to denote the transform of the probability mass function for the execution time of $S$. The transform for any PEL statement may be computed recursively from its component statements according to the following rules:

1. If S is a delay statement of the form $DELAY(t)$, then $T(S) = z^t$.
2. If S is a sequence statement of the form $BEGIN\ S_1;S_2;...;S_n\ END$, then $T(S) = T(S_1)T(S_2)...T(S_n)$.
3. If S is an if-then-else of the form $IF\ RANDOM<p\ THEN\ S_T\ ELSE\ S_F$, then $T(S) = p\ T(S_T) + (1-p)\ T(S_F)$.
4. If S is a loop statement of the form $LOOP\ n\ DO\ S_1$, then $T(S) = [T(S_1)]^n$.

These rules for the sequential portions of the program are derived from the standard properties of geometric transforms. Similar formulas are given in Appendix E of ref. [4] for the Laplace transforms of structured program control statements. However, in order to compute the transform for the concurrent fork-join statements, an entirely new operation on transforms is needed called a "join product."

*Definition*: The *join product* (denoted $\circ$) is a binary infix operator with the following properties:

A. Let $F^g$ denote the set of all geometric transforms. $\circ : F^g \times F^g \to F^g$

B. $\circ$ is commutative and associative

C. $\circ$ distributes over addition

D. Let $a,b,x,y$ be any real numbers. Then $az^x \circ bz^y = abz^{max(x,y)}$

Properties A-C of the join product are identical to multiplication. The only difference is in property D where the maximum of exponents is used instead of the sum. This simple join product operation is used to help compute the execution time transform for fork-join statements according to the following rules:

5. If S is a fork-list statement of the form $FORK\ S_1;S_2;...;S_n\ JOIN$, then $T(S) = T(S_1)\circ T(S_2)\circ \cdots \circ T(S_n)$
6. If S is a fork-n statement of the form $FORK(n)$: $S_1$; $JOIN$, then $T(S) = \underbrace{T(S_1)\circ T(S_1)\circ \cdots \circ T(S_1)}_{\text{n repetitions}}$

For a more complete presentation of all of these rules including proofs of their validity, the reader is referred to Lester [18]. Applying rules 1-4 to the program of figure 1 gives the following transforms for the execution time of each of the three statements inside the fork-join:

$$.5z^{20}+.5z^{35}$$
$$(z^3)^{10}=z^{30}$$
$$.4z^5+.6z^{10}$$

Performing a join product on these three transforms according to rule 5 gives the transform for the whole FORK-JOIN as follows:

$$\begin{aligned}&(.5z^{20}+.5z^{35})\circ z^{30}\circ(.4z^5+.6z^{10})\\ &= (.5z^{20}\circ z^{30}+.5z^{35}\circ z^{30})\circ(.4z^5+.6z^{10})\\ &= (.5z^{30}+.5z^{35})\circ(.4z^5+.6z^{10})\\ &= .5z^{30}\circ .4z^5+.5z^{30}\circ .6z^{10}+.5z^{35}\circ .4z^5+.5z^{35}\circ .6z^{10}\\ &= .2z^{30}+.3z^{30}+.2z^{35}+.3z^{35} = .5z^{30}+.5z^{35}\end{aligned}$$

For the outer IF of the program, the true branch has transform $z^5z^2z^7 = z^{14}$ according to rules 1 and 2. Combining this with the FORK transform from the false branch using rule 3 gives the following:

$$.3z^{14}+.7(.5z^{30}+.5z^{35}) = .3z^{14}+.35z^{30}+.35z^{35}$$

This is the transform for the execution time of the whole program. The expected (average) execution time of the program can be computed directly from the transform to be 26.95 time units.

The transform computation rule for *fork-gen* statements is more complex and is only summarized here. The reader is referred to Lester [18] for a more complete detailed presentation. The transform for a *fork-gen* is computed recursively from the transform for each of the component statements $S_i$ having the following form:

$$T(S_i) = \sum_{t=0}^{\infty} f_i(t)z^t$$

In a transform, the coefficient of each power of z is a real number representing a probability. For the purposes of computing the overall transform of a *fork-gen* statement, these coefficients are represented symbolically as a character string called an *f-symbol* of the form $f_i(t)$, where i and t are positive integers. This symbolic form of the execution time transform is called the ***transmission***. For example, the transmission for statement 2 in the *fork-gen* of figure 2 is $f_2(10)z^{10} + f_2(23)z^{23}$. There is a special multiplication rule for these *f-symbols* as follows:

Let $f_i(t_a)$ and $f_i(t_b)$ be any *f-symbols*, then

$$f_i(t_a)\, f_i(t_b) = \begin{cases} f_i(t_a) & \text{if } t_a = t_b \\ 0 & \textit{otherwise} \end{cases}$$

Using the execution precedence graph for the *fork-gen* statement, the ***flow*** is computed for each arc in the graph according to the following rules:

1. The flow on the input arc to the *fork-gen* is 1.
2. The flow on each output arc of a statement is the join product of all its input flows multiplied by the statement transmission.

The execution time transform for the whole *fork-gen* is found by computing the flow on the output arc of the execution precedence graph and then substituting the corresponding numerical values for the *f-symbols*. For example, the above flow computation rules can be used on the *fork-gen* of figure 3 to compute the following flow for the output arc:

$$f_2(10)\, f_5(5)z^{23} + f_2(10)\, f_5(15)z^{25} +$$
$$f_2(23)\, f_5(5)z^{31} + f_2(23)\, f_5(15)z^{38}$$

Substituting the specific values of the f-symbols gives the transform for the whole fork-join:

$$.12z^{23} + .28z^{25} + .18z^{31} + .42z^{38}$$

The expected execution time for the whole *fork-gen* can easily be computed from this transform as 31.3 time units.

## 4. PARALLEL SPEEDUP FACTOR

For large programs, the computation of the complete transform may be very time consuming since the number of terms in the transforms may grow quite large, especially if there are lots of complex loops with high repetitions. For such programs it is necessary to have an efficient approximation technique for estimating bounds on the expected execution time. Since the branching probabilities, delay times, and loop repetition counts are usually only approximations themselves, a good approximation technique for analyzing the whole program may be sufficient in many cases. The parallel speedup factor may be computed exactly using transforms or approximated efficiently with one of these approximation techniques.

The recursive definition of PEL statements allows a simple recursive computation rule for the lower and upper bounds on the expected execution time: the bounds for each statement are computed from the bounds of its component statements. The lower bound will be calculated by using expectations or averages, and the upper bound by using maximums. For most programs, the lower bound will be much tighter than the upper — in fact, for purely sequential programs with no parallelism, the lower bound will be exactly the expected execution time. However, we shall see later that for certain programs with a high degree of concurrency, the actual expected execution time may be nearer to the upper bound. Similar approximation techniques were introduced for performance evaluation of asynchronous systems in Lester [19].

*Definition*: Let $S$ denote any PEL statement. The ***average approximation*** (denoted $AVE(S)$) is a nonnegative number defined recursively as follows:

(a) If S is a delay statement of the form $DELAY(t)$, then $AVE(S) = t$.

(b) If S is a sequence statement of the form *BEGIN* $S_1;S_2;...;S_n$ *END*, then $AVE(S) = AVE(S_1) + AVE(S_2) + \cdots + AVE(S_n)$.

(c) If S is a loop statement of the form *LOOP* $n$ *DO* $S_1$, then $AVE(S) = n\ AVE(S_1)$.

(d) If S is an if statement of the form *IF RANDOM*$<p$ *THEN* $S_T$ *ELSE* $S_F$, then $AVE(S) = p\ AVE(S_T) + (1-p)\ AVE(S_F)$.

(e) If S is a fork-join statement with component statements $S_1, S_2, ..., S_n$, then $AVE(S)$ is length of the longest path through $S$ (critical path), where path length is the sum of $AVE(S_i)$ for all statements $S_i$ encountered on the path.

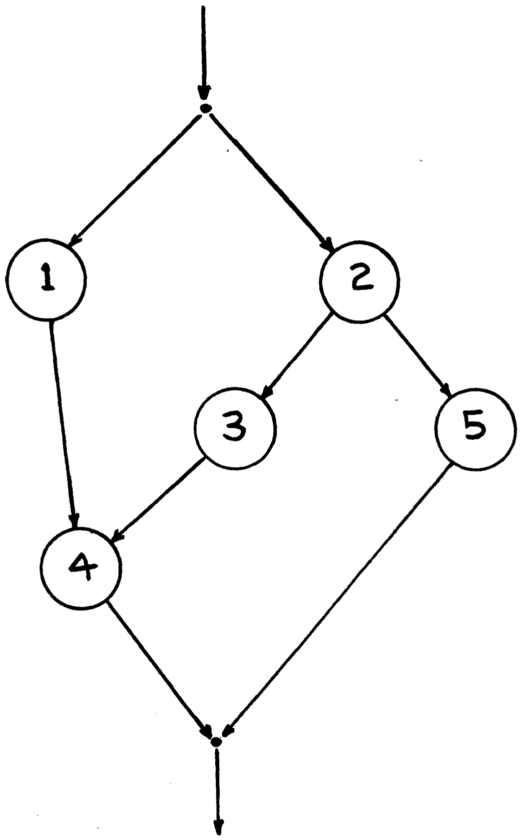

Figure 3 - Execution Precedence Graph

For any PEL statement S, the *maximum approximation* (denoted $MAX(S)$) is defined according to the same rules as $AVE$, except for rule (d) where the maximum of the true and false branches is used instead of the average. It is possible to show that for any PEL statement $S$, $AVE(S)$ and $MAX(S)$ represent lower and upper bounds on the expected execution time $E(S)$:

$$AVE(S) \leq E(S) \leq MAX(S)$$

In fact, $MAX(S)$ is also an upper bound on the execution time itself, not just the expectation. The definition of $AVE$ and $MAX$ provides a linear time recursive algorithm for computing an upper and lower bound on the expected execution time of any PEL program. Recall for the program of figures 1, the exact expected execution time was calculated earlier as 26.95 time units. For this program, $AVE$ is 25.2 and $MAX$ is 35. The reason that $AVE$ is so close to the actual expected time is that the program has a relatively low level of parallelism. For the ***fork-gen*** statement of figure 2, the exact flow methods and ***f-symbol*** technique were used to calculate the expected execution time as 31.3 time units. Using the approximation techniques, $AVE$ is computed as 29.8, which compares favorably to the exact expected time, and $MAX$ is 38.

For any PEL statement S, the *sequential execution time* (denoted $SEQ(S)$) is defined according to the same rules as $AVE$, except for rule (e) where the sum of the times for all the component statements of each fork-join is used instead of the critical path. It is easily shown that $SEQ$ corresponds exactly to the expected execution time assuming that fork-join statements are executed sequentially rather than concurrently. So far in our computation of the execution time, we have assumed an unlimited number of processors so that all the concurrency represented in the fork-join statements may be exploited. $SEQ$ is the expected execution time assuming the program is executed on a one processor system with no concurrency. Just as for the $AVE$ and $MAX$ approximations, $SEQ$ can also be calculated in time which is linear in the number of statements in the program.

For any PEL program, the ***parallel speedup factor*** is defined as the expected sequential execution time divided by the expected execution time. That is, the parallel speedup factor is the expected execution time assuming one processor divided by the expected time assuming an unlimited number of processors. The expected parallel execution time can be calculated exactly by using the transform method, or it can be approximated using the $AVE$ or $MAX$ approximations. The parallel speedup factor can then easily be calculated by dividing into $SEQ$. For the example program of figure 1, $SEQ$ is 50.05 and the parallel speedup factor is therefore (1.86). For the ***fork-gen*** of figure 3, the sequential execution time ($SEQ$) is 57.8 and the parallel speedup factor is (1.85).

## 5. NORMAL APPROXIMATION TECHNIQUE

The methods of section 4 provide a linear time algorithm to compute upper and lower bounds on the expected execution time of any PEL program. For programs with a relatively low level of parallelism, the lower bound ($AVE$) is a good approximation to the actual expected execution time; and for purely sequential programs, $AVE$ is the exact value of the expected time. However, programs with moderate or high parallelism may have expected execution times that differ significantly from $AVE$, and in some cases even approaches the $MAX$ approximation. This section introduces an additional approximation technique called the "normal approximation," which uses the degree of parallelism to compute a more exact approximation to the expected execution time somewhere between the upper and lower bounds provided by $MAX$ and $AVE$.

The normal approximation improves significantly on the $AVE$ approximation by considering both the expectation and the variance of the execution time for each statement. There is a simple recursive computation rule for the normal approximation that is similar to the $AVE$ approximation, except that two numbers are computed for each statement: the $NORM$ (an approximation to the expectation) and the $VAR$ (an approximation to the variance). It is interesting that for purely sequential programs, the variance does not effect the expected execution time, but for highly parallel programs, changes in the variance may significantly effect the overall expectation. Thus, by considering the variance, the normal approximation is much more accurate than the AVE or MAX approximations, and yet is still efficiently computable.

For delay, sequence, loop, and if statements in PEL, standard probabilistic techniques provide simple formulas for computing the expectation ($NORM$) and the variance ($VAR$) from the component statements. For the fork-join statements, a new technique has been developed which assumes a normally distributed execution time for each component statement and then uses the exact transform techniques outlined in section 3 to compute the overall expectation and variance. To reduce the complexity of the transform computation, a discrete approximation to a normal distribution is used for each component statement. This discrete approximation has only seven nonzero terms computed directly from the expectation and variance of the component statement, thus insuring that the transform techniques are fast and efficient.

*Definition*: Let S be any PEL statement. The ***normal approximation*** is a pair of numbers $NORM(S)$ and $VAR(S)$ defined recursively by the following rules:

(a) If S is a delay statement of the form $DELAY(t)$, then $NORM(S) = t$ and $VAR(S) = 0$.

(b) If S is a sequence statement of the form $BEGIN\ S_1;S_2;...;S_n\ END$, then $NORM(S)=NORM(S_1)+NORM(S_2)+ \cdots +NORM(S_n)$ and $VAR(S) = VAR(S_1)+VAR(S_2)+ \cdots + VAR(S_n)$.

(c) If S is a loop statement of the form $LOOP\ n\ DO\ S_1$, then $NORM(S) = n\ NORM(S_1)$ and $VAR(S) = n\ VAR(S_1)$.

(d) If S is an if statement of the form $IF\ RANDOM{<}p\ THEN\ S_T\ ELSE\ S_F$, then $NORM(S) = p\ NORM(S_T) + (1-p)\ NORM(S_F)$ and $VAR(S) = p(NORM(S_T)^2 + VAR(S_T)) + (1-p)(NORM(S_F)^2 + VAR(S_F)) - NORM(S)^2$

(e) If S is a fork-join statement, then for each component statement $S_i$, let $N$ denote $NORM(S_i)$ and $D$ denote $(VAR(S_i))^{1/2}$. Create the following discrete normal approximation to the transform of $S_i$:
$T(S_i)=.00621z^{N-3D}+.0606z^{N-2D}+.2417z^{N-D}+ .3829z^{N}+.2417z^{N+D}+.0606z^{N+2D}+.00621z^{N+3D}$
(where the exponents of z in $T(S_i)$ are rounded to the nearest whole number). The usual transform techniques

of section 3 are applied to these approximate transforms to compute an approximate transform $T(S)$ for the whole fork-join. $NORM(S)$ is defined as the expectation for $T(S)$, and $VAR(S)$ is defined as the variance for $T(S)$.

The accuracy of this normal approximation technique depends on how closely the actual execution time distributions of the individual statements follow a normal distribution. There is an important result in standard probability theory called the *central limit theorem*, which states that the probability distribution for a sum of n independent random variables approaches a normal distribution as n grows large. Thus, if the individual statements in the fork-join contain a loop or have many component statements, then chances are good that their execution time will indeed begin to approach a normal distribution. We have found that loop statements with anything in excess of a few repetitions, can be approximated by normal distributions with an accuracy of 1-2% . Our empirical studies of a wide range of parallel programs have shown that the normal approximation is accurate within 1-5%, representing a significant improvement over the $AVE$ and $MAX$ approximations, and yet still efficiently computable even for large programs.

## 6. IMPLEMENTATION

For research purposes, a prototype system has been developed for analyzing PEL programs using the exact transform techniques and the various approximation techniques presented in this paper. The system is written in LISP and is currently running on a VAX 11/780 under the VMS operating system. The PEL program is entered into the system as a simple text file in a format similar to that shown in the figures of this paper. To illustrate the practical use of this system in designing and analyzing real parallel programs, we give two simple examples here: highly parallel vector division and parallel file processing with double buffering. For both these examples, the process of formulating the algorithm and creating the PEL program are illustrated, then the actual results from the prototype PEL analysis system are given.

The first example is a simple vector division function with a special rule for handling division by zero: if the divisor and dividend are both zero, then the quotient is one, but if the dividend is nonzero, then the quotient is positive or negative infinity (represented by the maximum size number for the computer). Using the standard "forall" primitive to represent the parallel form of a loop, the function to compute a vector C by dividing the sixteen component vector A by vector B is as follows:

```
FORALL i := 1 TO 16 PARDO
  IF B[i]<>0 THEN C[i] := A[i]/B[i]
    ELSE IF A[i] := 0 THEN C[i] := 1
                  ELSE C[i] := MAXNUM * SIGN(A[i])
```

In the above statement, there are sixteen concurrent activations of the body of the "forall", one for each value of the index i. "MAXNUM" is a predefined constant, and "SIGN" is a predefined system function. To translate this statement into PEL, some estimates are needed for the relative execution time of the primitive operations in the language. Let us assume that assignment requires 5 time units, array subscripting and the forall setup each require 10 time units, the SIGN function requires 40 time units, and division, multiplication, and boolean comparison each require 10 time units each. Also, assume that 80% of the vector entries are nonzero in a typical input data set. The "forall" primitive can be represented in PEL by a fork-n statement, and the above statement is translated into the following PEL program:

```
PROGRAM;
  BEGIN
    DELAY(10);
    FORK(16):
      DELAY(25);
      IF RANDOM > .8 THEN DELAY(50)
                ELSE BEGIN
                  DELAY(25);
                  IF RANDOM > .2 THEN DELAY(15)
                            ELSE DELAY(80)
  END.
```

For this program, the PEL analysis system computed the following results:

Expected Execution Time: 136.6
Sequential Execution Time: 1494.4
Parallel Speedup Factor: 10.93

In a second example, we consider a file processing program which reads a sequence of student records from a disk file, computes the grade point average of each student, and stores the results as a new sequential disk file. The program uses double buffering of records for both files so that all three activities of reading, computing, and writing can occurr concurrently. The overall flow of activity is shown in figure 4. It seems from this diagram that the parallel speedup factor will be a maximum of three since there are three concurrent activities. However, a more detailed analysis reveals that the parallel speedup factor is highly dependent on file storage techniques, disk access times, and execution times for language primitives.

Let us assume that the Student File is sequential and contains three student records per disk block, so that a disk access to read in a new block is required with probability (.25) for each student record on the average. Also, assume that the G.P.A. file is sequential with a much smaller record size for which 19 records can be stored in each disk block. Thus, the probability that writing a single G.P.A. record will require a disk access is (.05) on the average. When the program issues an operating system call to read the next record for a sequential disk file, let us assume that the execution time is 2000 time units if a disk access is required, but only 500 time units if the needed block is already in memory and no new disk access is required. Thus the PEL statement for reading each student record is as follows:

```
IF RANDOM < .25 THEN DELAY(2000) ELSE DELAY(500)
```

The PEL statement for writing each G.P.A. record is as follows:

```
IF RANDOM < .05 THEN DELAY(2000) ELSE DELAY(500)
```

The execution time for computing the G.P.A. of each student will depend on some timing assumptions for the primitives of the source programming language and the size of the student record. Assuming that each student record contains an average of 40 course grades, and the primitive arithmetic and other operations of the language vary from 8 to 12 time units, a simple looping program for the "Compute G.P.A." activity shown in figure 4 translates into the following PEL statement:

```
BEGIN
  DELAY(8);
  LOOP 40  DO BEGIN  DELAY(12); DELAY(28)  END;
  DELAY(8);
  DELAY(8)
END;
```

To execute the Read, Compute, and Write activities concurrently, a fork-list statement is needed in PEL, and this statement will be executed once for each student record. Assuming there are 1000 student records in the file, there will be an outer loop with 1000 repetitions. Finally, some timing assumptions are needed regarding file and buffer initialization times: opening a sequential file for input requires 2500 time units, opening a new sequential file for output requires 600 time units, and initializing buffers requires 40 time units. From all of the above assumptions, the following PEL program results:

```
PROGRAM;
 BEGIN
   DELAY(2500); DELAY(600); DELAY(40); DELAY(40);
     LOOP 1000 DO
       BEGIN
         DELAY(12);
         DELAY(12);
         FORK  DELAY(8); DELAY(8)  JOIN;
         DELAY(12);

         FORK
           IF RANDOM < .25 THEN DELAY(2000)
                          ELSE DELAY(500);

           BEGIN
             DELAY(8);
             LOOP 40 DO
               BEGIN
                 DELAY(12);
                 DELAY(28);
               END;
             DELAY(8);
             DELAY(8)
           END;

           IF RANDOM < .05 THEN DELAY(2000)
                       ELSE DELAY(500);
         JOIN
       END;
 END.
```

Using the prototype PEL analysis system for this program results in the following output:

```
Expected Execution Time:  17.79 × 10^5
Sequential Execution Time: 31.18 × 10^5
Parallel Speedup Factor: 1.75
```

Thus, it is seen that waiting time and lack of balance between the execution time of the three concurrent activities in figure 4 has reduced the apparent concurrency factor of 3 to an actual parallel speedup factor of only (1.75). If the time unit used in making the initial estimates for the basic operations is 10 microseconds, then the expected execution time for the program is 17.8 seconds.

## 7. CONCLUSIONS

The PEL language is a formal system for describing the overall control structure and timing delays in a parallel program, as an aid in computing the parallel speedup factor. Real parallel programs are sufficiently large and complex that such a formal description language is useful as a supplement to standard algorithm analysis techniques. The transform techniques and efficient approximation techniques presented in this paper for PEL programs can then be used to compute the expected execution time and parallel speedup factor for the program. The mathematical complexities introduced by program parallelism make formal analysis techniques necessary even for small programs.

There is a large body of standard analysis techniques for sequential probabilistic systems using z-transforms and linear flow graph reduction. The major contribution of this paper is the extension of these techniques to parallel systems in the form of PEL programs. This paper also presents efficient approximation techniques for estimating the expected execution time and parallel speedup factor for large programs. Future work in this area will focus on the development of compilers to translate parallel programs directly into PEL for analysis. Also, future research is needed to extend the PEL primitives to allow message passing between parallel processes, a feature which is contained in many concurrent programming languages.

# PARALLEL STRUCTURING OF CONTROL AND RESOURCES MANAGEMENT SYSTEMS FOR PARALLEL PROGRAMS

Robert O'Dell[1] and J. C. Browne
Department of Computer Sciences
The University of Texas at Austin
Austin, Texas 78712

## Introduction

Execution of parallel programs on parallel computer architectures requires scheduling, coordination, and resource management. These control activities themselves consume computer resources. Centralized resource serial control will become the performance bottleneck when large numbers of processes must be scheduled and managed.

This paper studies parallel structuring of process control and resource management. The environment for the study is the Run-time System of the Computation Structures Language (CSL) parallel programming system. The approach has been to design and evaluate a parallel version of the control and resource management functions of the CSL run-time system. The performance characteristics of the parallel version are predicted and an algorithm for determining the optimal degree of parallelism for the run-time system is given.

Parallel structuring of resource management is essential in order to alleviate the well-known serialization bottleneck that occurs whenever a large number of parallel processes must access a shared resource through a serial monitor [MAD74, CEZ83].

The serialization bottleneck of a centralized resource management system can be demonstrated by considering the fact that the resource manager is a shared resource of the tasks. The resource manager can impose a constant upper bound on the speedup obtainable in the system even if the tasks themselves run completely in parallel without interdependencies and have a linear speedup potential.

The Computation Structures Language (CSL) is a language for specifying the structure of parallel computations and controlling the execution of these structures. (The next section gives an introduction to and examples of CSL programs.) The CSL Run-time System (RTS) thus forms a serialization bottleneck when the execution of a complex computation structure must be managed, and limits the maximum speedup obtainable in parallel programs in the CSL system. The design of a Parallel Run-time System (PARTS) consists of a method of parallelizing the resource management functions of the original Run-time System. It consists of a restructuring of the system tables such that they support multiple copies of the original RTS along with specifications for these access procedures.

A simulation model for PARTS executing on a certain class of CSL programs was developed. The data used to parameterize the modes is taken from a working RTS on a real system where appropriate. The performance of the model under varying conditions is shown.

An analytical equation that closely approximates the performance of the simulation is presented. The equation is used to predict the performance characteristics of PARTS under variations of degree of parallelism and to develop a schedule for creating multiple copies of the RTS to execute in parallel that maximizes the speedup under the condition that all tasks have equal execution times. The restriction to tasks with equal execution times is not as limiting as it might seem at first glance. We have found that execution of CSL programs is often dominated by execution of replicated arrays of processes which will have closely similar execution times.

The results reported here should have at least conceptual application to any system for control and source management of complex dynamic parallel computation structures.

## Parallelizing the Centralized RTS

The Computation Structures Language (CSL) is a language for expressing the synchronization and communication requirements of a set of tasks [Browne 82]. CSL specifies the traversal of a computation graph. The CSL program does not, however, perform any of the computations associated with the parallel program. A simple CSL program for the producer/consumer problem is shown below.

```
JOB Sample-CSL;

CONSTRUCT
    TASKS
        T[i] : File1;  RANGE i=1 to 2;
        T3   : File2;

    CHANNELS
        Ch[i] : DATACHANNEL from T[i] to T3;
                          RANGE i=1 to 2;

END; (* Construct *)

BEGIN   (* Executable Code *)

  COBEGIN
      // EXECUTE T[1];
         SEND X to Ch[1];
         RECEIVE Y from Ch[1];

      // EXECUTE T[2];
         SEND Y to Ch[2];
         RECEIVE Y from Ch[2];
   COEND;
   EXECUTE T3;

END. (* CSL Program *)
```

[1] The first author is now employed by Advanced Micro Devices, 5900 East Ben White Blvd., Austin, Texas 78741.

In this program it is specified that T[1] and T[2] may execute in parallel. The three statements following each "//" comprise a parallel stream. Each statement within a stream is executed serially. After T3 receives both X and Y, the Cobegin completes and T3 may execute.

The CSL RTS is the resource manager for a running parallel program. It can be thought of as defining a local operating system for the parallel program. When a Cobegin is encountered, the RTS sends messages to tasks telling them to begin (Initializing), waits for completion, and determines status information through a message sent back from the completed task (Finishing). The RTS also coordinates the passing of data between tasks. The result of any action by the RTS is a modification of the global state of the parallel computation. The global state of the computation is recorded in a set of system tables maintained by the run-time system.

By definition of CSL, tasks only communicate with each other before or after their execution. Thus the computation granularity of the tasks depends on the frequency of communication among the tasks. In programs written in the CSL environment, this has varied from 2 MS to 1000 MS.

The set of statements managed within the Cobegin at a given time are serviced in a Round-robin fashion with time being allocated on the basis of what work needs to be done. Thus when a statement is ready to be Initialized or Finished, it may have to wait for service. This causes a serialization bottleneck to develop within the system.

The PARTS system partitions the Cobegin into groups of statements, each managed by a separate RTS. The partitioning process attempts to balance the workload between RTS's. When a Cobegin is encountered, the current RTS "Initializes" the other RTS's telling each to commence execution. This is an overhead factor in the PARTS system. As soon as the RTS's are Initialized, they begin managing their portion of the Cobegin statements. Since a global state is preserved, the system tables are made available for access by all RTS's in the system. Since RTS's modify the global state, the system tables must be accessed serially which may introduce wait time into RTS execution.

In summary, the serialization bottleneck of Initializing and Finishing statements in the Cobegin has been parallelized in PARTS, but has been compromised somewhat by the time to Initialize and Finish the new RTS's plus the additional wait time due to shared memory contention for system table access. However, the first-order serialization point has been removed.

## Simulation Model

The simulation model developed for PARTS is an extension of a model of a single RTS managing a given number of streams. Since the Cobegin is the major feature of the language, and the schema by which parallel computation may take place in CSL, the simulation models just this activity. (Often an entire parallel program structure can be described by a series of Cobegin statements.)

The simulation was constructed using the Performance Analyst's Workbench System [IRA84], an event driven simulation language especially designed for modelling computer and information systems. The operation of PAWS is described here through Information Processing Graphs (IPG's).

Figure 1 shows the IPG of a single RTS managing 3 computation streams comprised of a single statement. This, for instance, would model the following:

```
COBEGIN
      // EXECUTE T1;
      // EXECUTE T2;
      // EXECUTE T3;
COEND;
```

The result of a Cobegin being encountered is a transaction leaving Source and proceeding to Fork. There, 3 new transactions are generated with phases 1, 2, and 3. After waiting in series in the Queue IANDF for Initialization, the transactions cause the operation of the stream to commence. E1 through E3 model the execution times of each of the three streams. When a stream completes, a transaction passes through the Compute node for routing purposes, enters the IANDF Queue to be Finished, and then waits at Join for the rest of the streams to complete and be Finished. When all 3 transactions enter Join, the simulation completes. For large numbers of streams IANDF will be nonempty for the duration of the simulation.

An implicit assumption made within the model is that the streams execute independently. This was done deliberately to expose the severe performance degradation experienced by parallel computations without sufficient parallel resource management, even when the underlying computation is experiencing optimal performance. Any communication between streams would increase the workload of the RTS's, increasing the serialization bottleneck.

Figure 2 shows the extension of the model to a PARTS configuration with 3 RTS's each managing their portion of a partitioning of the streams in a Cobegin. In this model, RTS1 Initializes RTS2 and RTS3 before proceeding on to manage its streams. Since RTS2 and RTS3 are tasks themselves, they must pass through the IANDF node of RTS1 to be Finished. When all three RTS's have completed, the Cobegin is complete.

An allowance for the effect of shared memory contention between RTS's is made by introducing a delay node representing the time taken by each RTS to acquire control of the shared tables. In PARTS this is nearly constant for any given stream.

The parameters of the model, then, are:

1. X - the number of streams in the Cobegin
2. Y - the number of RTS's defined to execute in parallel
3. I - the task Initializing time
4. F - the task Finishing time
5. RTSi - the RTS Initializing time
6. RTSf - the RTS Finishing time
7. E - the execution time of a given stream (task)
8. SM - the shared memory access time

## An Analytical Model

An analytical model is shown that describes the behavior of the PARTS system when all streams have equal execution times. CSL allows for convenient methods of executing tasks in parallel that are replicas of each other. This feature has been used extensively in CSL programs written to date.

Speedup in PARTS is defined as:

$$(I + E + F) \ / \ f(X, Y, SM)$$

where "I + E + F" is the time for a single RTS to execute 1 stream of execution time E. The function "f" is the completion time of a PARTS configuration (for a given Cobegin) normalized to that of a single stream.

$$\begin{aligned} & f(X, Y, SM) = (A + B + C + D) \ / \ X \\ \text{where:} & \\ A &= (X/Y) \ (I + F) \\ B &= (Y-1) \ (RTSi + RTSf) \\ C &= 2 \ (X/Y) \ SM \ (Y-1) \ p \\ & p = MIN \ [((y-1)SM) \ / \ (SM + I) \ , 1 \ ] \\ D &= MAX \ [ \ 0 \ , \ E - \ ((X/Y) - 1)F \ ] \end{aligned}$$

"A" represents the savings achieved by parallelizing the resource management functions of Initializing and Finishing tasks. "B" is derived from the fact that (Y-1) RTS's must be Initialized and Finished by the master RTS. "C" models the added time due to the serialization of shared memory access. When p=1, the queue for shared memory access is saturated. D models the idle wait time an RTS spends waiting for work before the first task completes, but after all streams have been initialized. If an RTS is kept completely busy, then D=0.

## Results

Simulation runs were made for many values of the parameters. Space precludes detailed presentation of results. Additional results may be obtained from the authors by request.

Figure 3 shows the speedups for tasks with a typical execution length (25 MS) observed in the CSL environment. The values for I, F, RTSi, and RTSf were determined to be 4 +- 1.25 MS on a Dual Cyber 170/750 system. This time was comprised mainly of Cyber operating system overhead in the message passing system. The value of SM was given the pessimistic value of 0.5 MS.

If the right choice is made for the number of RTS's to be used in a given configuration, PARTS is an effective way to increase the speedup potential. This scheduling choice can be easily accomplished by differentiating the speedup equations with respect to Y. This gives the schedule of RTS's for maximum speedup as:

$$Y = SQRT \ ( \ X \ \ (I - 2 \ SM \ p)/ \ (RTSi + RTSf))$$

With this choice of schedule, the speedup can be shown to be proportional to SQRT(X). This holds even though the performance curve of any given RTS reaches an upperbound. If the execution time of each task is the same (as we have assumed above), the maximum speedup is independent of the execution time. Of course, the speedup using that schedule may vary widely

An arena in which PARTS turns out not to be so promising is when increasing numbers of tasks compute over a constant workload (decreasing granularity of units of computation). (In the previous examples, increasing X implied increasing the problem size. Each task continued to have the same execution time regardless of the number of tasks.) In this case, we define the sum of the execution times of all tasks to be constant.

A nonintuitive result is shown in Figure 4. In this case the simulation of Figure 5 is modified by allowing the execution times of the tasks to vary in a hyperexponential distribution around a mean of 25 MS. An increase in the variance-to-mean ratio to 0.4 caused the results shown. For a certain range of X, the speedup is actually better for a larger variance!

This is explained in the following way. The initial performance decrease is due to the fact that the increased variance causes some streams to finish much later than others. Time is lost while an RTS waits for it to complete. When more streams are introduced, however, the sheer number of streams causes each RTS to have no idle wait time in finishing streams. The higher variance, then means that the RTS has a higher probability of "starting" the finishing work earlier and thus "completing" it earlier. This results in greater parallelism among RTS's and less contention for system tables.

## Conclusion

This paper has presented a study of the effect of parallel structuring of control and resource management algorithms upon the execution of parallel computations. A simple analytic model of general parallel computation incorporating overhead effects was developed and applied to this example. Speed-up shows a square root dependency on the degree of parallelism in the control and resource management algorithms.

Variance in processing time for the tasks being controlled was observed to be beneficial over certain ranges of execution to the parallelism obtainable by the control system.

Abstract. A method for estimating the speedup for asynchronous bottom–up parallel parsing has been presented. Two models for bottom–up parallel parsing are proposed, and the speedup for each of the two models is estimated using the technique developed here. The speedup obtained for one model is very close to the simulation result already available in literature. The second model shows a greater speedup than the first.

Index Terms: compilers, parallelism, parsing

## I. INTRODUCTION

The term parallel computer means different things to different people. In this paper it is an MIMD machine – a general–purpose, tightly–coupled, collection of a fixed number of identical processors, working asynchronously under one operating system to solve a single computational problem. Such parallel machines have been in existence for some time. Two primary types of such machines seem to be emerging (i) the fixed–connection model, such as Intel's iPSC family and (ii) the shared–memory models, such as the HEP computer. When a large number of processors are to be connected together, the former has an advantage from the hardware point of view, but the latter is more convenient to construct an algorithm on.

It is too early to tell which of the two organizations is going to be the dominant commercial machine. For a good introduction to various architectural issues see [11, 13]. For this paper either of two models can be assumed.

Although a good deal of work has been reported on parallel algorithms in various application areas, the amount of work done on compilation in parallel has been relatively meager. From the results of the earlier work it is clear that parallelism in compilation is promising. But the questions of speedup, efficiency, and so forth are yet to be answered satisfactorily. In this paper we consider one such aspect of parallel compilation.

The compilation can be divided, broadly, into three tasks – lexical analysis, parsing, and code generation [1,2]. Lexical analysis and code generation appear more parallelizable than parsing [7,8,12]. Therefore, we deal only with parsing in this paper.

Cohen and Kolodner [5] proposed an asynchronous bottom–up parallel parsing model and estimated, by simulation, the speedup obtainable for Pascal–like languages. If the processors are connected as a linear array (as they have implied), their model may not always parse a string successfully, because a processor goes into inactive mode when its stack becomes empty, and a processor can directly communicate only to its adjacent processors. For example, let $P_1, P_2$, and $P_3$ be three processors, arranged in that order, parsing a string. If the stack of $P_2$ becomes empty before those of $P_1$ and $P_3$ then the parsing cannot be completed, because $P_1$ and $P_3$ can no longer communicate.

We modify the model proposed in [5], to run on a linearly connected array of processors, as well as propose a new model that yields higher speedup. Both these models can be realized on a shared–memory machine as well as on a fixed–connection machine.

In Section II related previous work is surveyed briefly. In Section III two parallel parsing models are proposed. A technique to estimate speedup in asynchronous bottom–up parallel parsing is presented in Section IV, while in Section V we estimate the speedup that can be obtained with the two models proposed in Section III. It is shown that the new model gives a greater speedup than the model presented in [5]. Our result also shows that the conjecture made about the average speedup for bottom–up parallel parsing in [4] is true for one of the models proposed here.

## II. PREVIOUS WORK

For parallel computer architecture, and programming the readers are referred to Hwang and Brigs [11], and Kuck [13]. Ellis [9] presented two algorithms for compilation which can be implemented on a parallel machine with ILLIAC IV–type cellular architecture. Various techniques for lexical analysis and parsing, using the CDC–STAR–100 vector instruction set, were introduced by Donegan and Katzke [8]. Krohn [13] also exploited the vector processing capability of CDC–STAR–100 to generate object code in parallel for Fortran–like languages. The program slicing mechanism discussed in [16] can also be used for parallel compilation.

Baer and Ellis [3] have shown that by modelling an existing sequential compiler we get an understanding of modifications necessary to transform the sequential structure into a pipeline of processes. They have evaluated a pipelined compiler through measurement and simulation. But the pipeline of processes has a limitation that only a fixed and small number of processors can be used, and that the speedup obtainable is not large.

Dekel and Sahni [7] considered the translation of infix arithmetic expressions into their postfix or syntax tree

form using synchronous parallel processors, sharing common global memory. The speedup obtainable is high. Mickunas and Schell [15] extended the LR parsing technique [1,2 ] for a multiprocessor environment so that many processors can be used to parse a given string starting at different tokens in the string. Fischer [10] has proposed algorithms for bottom–up synchronous parallel parsing and has shown through simulation that appreciable speedups can be achieved with these algorithms. Ligett et al. [14] extended the LR technique to allow arbitrarily many processors to build parse tree simultanteously and measured the performance of the algorithm experimentally.

Cohen and Hickey [4] made the first attempt to compute upper and lower bounds for the speed- up that can be obtained by asynchronous, bottom–up, non–backtracking parsing of strings generated by a context–free grammar. They analytically found upper and lower bounds for speedup in parallel parsing. To develop these bounds they ignored the processor coordination and communication time. A practical asynchronous parallel parsing model to parse Pascal–like languages was proposed in [5]. The simulation result presented in [5] was compared with the bounds in [4]. The comparison showed a wide gap between the two.

## III. MODELS

In this section two models for asynchronous bottom–up parallel parsing are presented. These models are used in later sections to estimate speedup.

As pointed out in Section I the asynchronous parallel parsing model proposed in [5] may not, under certain situations, complete parsing successfully. We modify this model to run on a linearly connected processor array and call it Model A, to distinguish it from a second model, called Model B, presented later in this section.

Model A: Let there be $q$ processors $P_1, P_2, \ldots, P_q$ arranged in a linear array, such that processor $P_i$ is directly connected with processor $P_{i+1}$ and $P_{i-1}$ (see Fig. 1(a)). A processor $P_j$ is called a predecessor of the processor $P_k$ if $j < k$ and processor $P_k$ is referred to as a successor of $P_j$. Thus, processor $P_i$ has $(i-1)$ predecessors and $(q-i)$ successors. Processor $P_1$ has no predecessor and processor $P_q$ has no successor. Every processor $P_i$ has a stack, which is referred as $STK_i$.

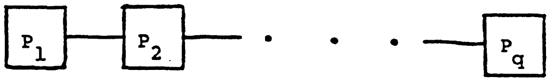

Fig. 1(a) A Linear Array of Processors

The given input string of length $L$ is divided into approximately $q$ equal parts. The ith processor $P_i$ starting at token $\lfloor (i-1)L/q \rfloor$ scans to the right for the next synchronizing token (e.g., semi–colon, end, etc.) and initiates parsing from the next token. A processor can be in one of the four states – active, wait, merge–only, and inactive.

A processor remains in the active state if it is able to perform either of the two parse steps – namely, shift or reduce; or it is performing the stack–merge operation. Stack–merge is the process in which a processor $P_i$ transfers the contents of its stack, from bottom, to the stack of another processor $P_j$ until $P_i$ encounters a stack–separator or its stack becomes empty. (Stack–separator is a special symbol used as a marker to separate the content of the stack of a processor.) When a processor cannot reduce due to insufficient information in its stack, but has received the next synchronizing token, it places a stack separator on the top of the stack and continues parsing. By placing a stack separator a new stack is simulated.

When the end processor $P_q$ has completed parsing its part and is left with a nonempty stack, it enters into merge–only state. When any other processor $P_i, 1 \leq i < q$, has completed parsing its part and is left with nonempty stack, it requests a merge to its successor $P_{i+1}$ and enters into wait state. In the wait state processor $P_i$ may be acknowledged by the processor $P_{i+1}$ or may get merge request from processor $P_{i-1}$. In the former case the state of $P_i$ is changed to active and $P_i$ receives tokens from $P_{i+1}$, while in the latter case processor $P_i$ cancels its merge request to the processor $P_{i+1}$. If a processor $P_i$ is not in wait state and receives a merge request from $P_{i-1}$, then $P_i$ sends acknowledgement to $P_{i-1}$. After sending acknowledgement processor $P_i$ starts stack–merge with $P_{i-1}$. Processor $P_1, 1 < 1 < q$, with nonempty stack goes to merge–only state when its successor processor $P_{i+1}$ is inactive. In merge–only state a processor $P_i$ waits for a merge request from its predecessor $P_{i-1}$. Processor $P_i$ becomes inactive if its stack is empty and $P_{i+1}$ is inactive. A processor $P_i$ in wait state with empty stack does not acknowledge merge request immediately but waits for the contents of the stack of $P_{i+1}$ and transfers them to $P_{i-1}$.

Model B: In this model every processor can communicate directly with every other processor. As expected, the extra cost of interconnection provides an enhancement in parsing speed by reducing the interprocessor coordination and communication time. In such a completely connected system, although there is no predecessors and successors of a processor in strict sense, to identify each processor and its substring we number them as in Model A and use the same terms predecessor and successor. The processors of this model also have four states (as in Model A), but the state transition is different in a few cases, as discussed below.

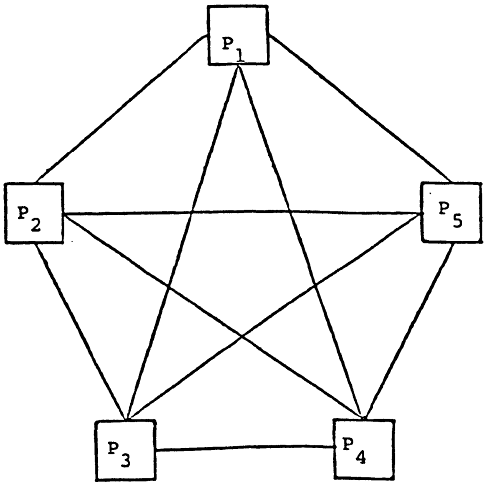

Fig. 1(b) A Completely Connected Five Processor System.

Processor $P_{i+1}$ is called the immediate successor of $P_i$. As soon as the stack of a processor becomes empty, it enters into inactive state irrespective of the state of its immediate successor. A processor $P_i$ knows which processor $P_k$ is its immediate active successor. Before a processor $P_i$ enters into inactive state it informs its immediate active predecessor $P_j$ the index of its immediate active successor $P_k$. For example, let the immediate active successor of $P_3$ be $P_5$ and that of $P_5$ be $P_{10}$. Consider the situation where $P_5$ becomes inactive before $P_3$ and $P_{10}$. In this situation, before $P_5$ becomes inactive it informs $P_3$ that $P_{10}$ is henceforth the immediate active successor of $P_3$.

A method to estimate the speedup for asynchronous bottom–up parallel parsing is presented in the next section.

## IV. ESTIMATING THE SPEEDUP

In this section we develop a technique to estimate speedup for parallel parsing. We divide the parsing time into three parts as in [5].

Let $T_{pq}$ be the total time of parsing a string of tokens in parallel using $q$ processors. In parallel parsing, time is spent for processor coordination and communication, besides the reduction time $T_{rq}$ and shift time $T_{sq}$. Let $T_{cq}$ be the time spent for processor coordination and communication. (The second suffix $q$ is the number of processors used.) We assume that the parse tree has a level $h$ such that for levels 1 to $h$ the number of nodes at each level is smaller than the number of processors, and all processors are not being utilized. The nodes at levels $(h+1)$ and below are sufficient so that all $q$ processors work simultaneously and independently with negligible coordination and communication. From level $h$ to level 1, processor coordination and communication time is significant. Therefore, we consider coordination and communication time, $T_{pq}$ for this part only.

The total time to parse in parallel, $T_{pq}$ can be expressed as

$$T_{pq} = T_{sq} + T_{rq} + T_{cq}$$

Since the coordination and communication time is zero in case of a single processor, the parse time $T_{P1}$ with a single processor is

$$T_{p1} = T_{r1} + T_{s1}$$

Therefore, the speedup obtained with $q$ processors is

$$SP(q) = \frac{T_{r1} + T_{s1}}{T_{rq} + T_{sq} + T_{cq}} \qquad (1)$$

Now, let $L$ be the length of the input, the estimated number of nodes in its parse tree be $N$ and the number of internal nodes in levels 1 to $h$ be $N_c$. The number of shift operations is the length $L$ of the string, which is also the number of leaves in the parse tree. The number of reduce operations is the number of internal nodes in the parse tree. If $t_r$ and $t_s$ be the average reduce and shift time, respectively, (for one operation) then we can express the total parse time $T_{p1}$ with a single processor as

$$T_{p1} = (N - L) \cdot t_r + L \cdot t_s$$

In parallel parsing shift operations are executed in parallel. The reduction operations corresponding to the internal nodes below level $h$ are executed almost independently and in parallel (as the number of nodes at each level exceeds the number of processors). The internal nodes at levels 1 to $h$ require $h$ units of reduction time [4], apart from the processor coordination and communication time. Therefore,

$$T_{pq} \simeq \frac{(N - L - N_c) \cdot t_r}{q} + \frac{L \cdot t_s}{q} + h \cdot t_r + T_{cq}$$

which gives the speedup with $q$ processors as

$$SP(q,L) \simeq \frac{(N - L) \cdot t_r + L \cdot t_s}{((N - L - N_c) \cdot t_r + L \cdot t_s)/q + h \cdot t_r + T_{cq}} \qquad (2)$$

The number of nodes, $N$, depends on the length of the string and the language. The level $h$ depends on the number of processors, and the language. The processor coordination and communication time, $T_{cq}$, depends on the number of processors as well as on the connection topology. First we determine $N$, $N_c$, and $h$. Then $T_{cq}$ will be estimated for both models in the next section.

Consider a deterministic, context–free language with $m$ production rules and $v$ nonterminals. Let the production rules be numbered as $1, 2, \ldots, m$. In derivation of a string of length $L$, let the ith production rule be used $r_i$

times. Then we can express the number of internal nodes in the parse tree as,

$$N - L = \sum_{i=1}^{m} r_i \tag{3}$$

In [6] a method was developed for evaluating $r_i$ in terms of occurrences of $(m-v)$ terminals $\Upsilon_1, \Upsilon_2, \ldots, \Upsilon_\alpha$, where $\alpha = (m - v)$. Using this method, the number of uses of each production in terms of the occurrences of the terminals if, else, case, while, repeat, ;, +, *, > and () for a Pascal–like language (as in [5]) is shown in Table 1, where $n_{\Upsilon_i}$ is the number of times terminal $\Upsilon_i$ occurs.

| Rule No. | Rule | Number of uses in a successful parse |
|---|---|---|
| 1 | P := S | 1 |
| 2 | S := S; I | $n_;$ |
| 3 | S := I | $n_{if} + n_{else} + n_{while} + n_{repeat} + n_{case} + 1$ |
| 4 | I := id ← E | $n_; + n_{else} + 1$ |
| 5 | I := if B then S fi | $n_{if} - n_{else}$ |
| 6 | I := if B then S | |
| | else S fi | $n_{else}$ |
| 7 | I := while B do S od | $n_{while}$ |
| 8 | I := repeat S until B | $n_{repeat}$ |
| 9 | I := case E of S end | $n_{case}$ |
| 10 | E := E + T | $n_+$ |
| 11 | E := T | $n_; + n_{else} + n_{case} + n_{()} + 2n_> + 1$ |
| 12 | T := T * F | $n_*$ |
| 13 | T := F | $n_+ + n_{()} + n_; + n_{else} + n_{case} + 2n_> + 1$ |
| 14 | F := id | $n_* + n_+ + n_; + n_{else} + n_{case} + 2n_> + 1$ |
| 15 | f := (E) | $n_{()}$ |
| 16 | B := E [> / ≥ / < / ≤ / = / ≠]$E$ | $n_>$ |

TABLE 1 Syntax of Pascal–Like Language and Count Relations Between Terminals

If the frequency of occurrence of the terminals is known, we can estimate $N - L$. Two methods are discussed in [6] to determine the average frequency of the terminals. Using these techniques we can approximate the number of internal nodes as a fraction of $L$, as $N - L = k' \cdot L$, where $k'$ depends on the language. Therefore, we can write

$$N = k \cdot L, \quad \text{where} \quad k = k' + 1 \tag{4}$$

The average number of sons of an internal node is

$$d = \frac{N-1}{N-L} = \frac{k - 1/L}{k-1}$$

The average number of sons for internal nodes at levels 1 to $h$ is also assumed to be $d$. Assuming that at level $h$ there are exactly $q$ internal nodes, we can write

$$q = d^{h-1}$$

From which we get

$$h = log_d(q) + 1 \tag{5}$$

Similarly, $N_c$, the number of nodes at levels 1 to $h$, can be expressed in terms of $q$ and $d$ as follows:

$$N_c = \frac{d^h - 1}{d - 1} \quad \text{i.e.,}$$

$$N_c = \frac{d \cdot q - 1}{d - 1} \tag{6}$$

Substitutions of (4), (5), and (6) in (2) gives,

$$SP(L,q) \simeq \frac{k' \cdot L \cdot t_r + L \cdot t_s}{((k' \cdot L - (d \cdot q - 1)/(d-1))t_r + L \cdot t_s)/q + (log_d(q) + 1)t_r + T_{cq}} \tag{7}$$

In the next section we estimate the coordination and communication time $T_{cq}$ for Model A and Model B and derive expressions for speedup for a Pascal–like language.

## V. SPEEDUP FOR MODELS A AND B

In [4] it was shown that the upper bound for speedup for parallel parsing increases monotonically with the number of processors and reaches a limiting value. Beyond this critical number of processors no further speedup is obtained. In obtaining this result Cohen and Hickey [4] neglected the processor coordination and communication time. Furthermore, they conjectured that the average speedup curve for strings of a given length would be of the same shape as their maximum speedup curve.

In this section we show that the Cohen–Hickey conjecture holds for Model B; but for Model A we get an expression for speedup which is close to the simulation result obtained in [5], but quite different from the speedup conjectured in [4].

The processor coordination and communication time depends on the model for the parallel parsing. We determine the value of $T_{cq}$ for each of the two models and then substitute them to get the expression for the speedup.

Model A: In Model A the average coordination and communication time $T_{cq}$ is determined by the average number of tokens left in $STK_q$ and the number of processors, $q$. For a merge request to travel to $P_q$ from $P_1$, it takes $(q-1)$ units of time, and for the first token to reach $P_1$ takes $(q-1)$ units of time, where the unit of time is the period required by two adjacent processors to exchange a merge or datum. If $k_1$ is the average number of tokens in processor $P_q$'s stack (when it enters into merge–only state) then next $(k_1 - 1)$ tokens can be passed to $P_1$ in next $(k_1 - 1)$ units of time using pipeling. This gives

$$T_{cq} = 2(q-1) + (k_1 - 1)$$

Model B: In this model every processor can communicate with every other processor directly. Hence, to collect all irreducible tokens from $P_q$, in $h$ reduction steps, $P_1$ may need $(h-1)$ request and $k_1$ data transfers. Hence,

$$T_{cq} = (h-1) + k_1$$
$$\text{or,} \quad T_{cq} = log_d(q) + k_1$$

Next we estimate $k_1$, the average number of unparsed tokens on a stack.

Estimating $k_1$, the Average Number of Tokens: Let $\sigma_i$ be the number of tokens left on $STK_i$ when $P_i$ completes parsing its part of the input. We define,

$$\sigma = Max(\sigma_i,\ i \in \{1,2,\ldots,q\})$$
$$\text{Then,} \quad k_1 = \sum_{i=1}^{\sigma} ipr(i) \tag{8}$$

Where $pr(i)$ is the probability that at least one stack has $i$ tokens and no stack has more than $i$ tokens.

Assuming that a processor has any number of tokens between one and $\sigma$ with equal probability of $\frac{1}{\sigma}$, we derive an expression for $pr(i)$.

Probability that $STK_1$ has $\sigma$ tokens when $P_1$ completes parsing the input to it is $\frac{1}{\sigma}$. Probability that $STK_1$ has fewerer than $\sigma$ tokens but $STK_2$ has $\sigma$ tokens is $(1-\frac{1}{\sigma}) \cdot \frac{1}{\sigma}$. Similarly, the probability that $(q-1)$ stacks have fewer that $\sigma$ tokens and $STK_q$ has $\sigma$ tokens is given by,

$$(1 - \frac{1}{\sigma})^{q-1} \cdot \frac{1}{\sigma}$$

The probability that at least one stack has $\sigma$ tokens,

$$\text{i.e.,} \quad pr(\sigma) = \frac{1}{\sigma} + (1-\frac{1}{\sigma}) \cdot \frac{1}{\sigma} + \cdots + (1-\frac{1}{\sigma})^{q-1} \cdot \frac{1}{\sigma}$$
$$= 1 - (1-\frac{1}{\sigma})^q$$

Similarly we get,

$$pr(\sigma - 1) = (1-\frac{1}{\sigma})^q (1 - (1-\frac{1}{\sigma})^q),$$

In general,

$$pr(\sigma - i) = (1-\frac{1}{\sigma})^{i \cdot q}(1 - (1-\frac{1}{\sigma})^q),$$
$$\text{for} \quad i \in \{1,2,\ldots,\sigma-1\}$$

and

$$pr(1) = 1 - \sum_{i=2}^{\sigma} pr(i) = (1-\frac{1}{\sigma})^{(\sigma-1)\cdot q}$$

Substitution of $pr(i)$ in equation (8) gives

$$k_1 = \sum_{i=0}^{\sigma-2}(\sigma - i)(1-\frac{1}{\sigma})^{i\cdot q}(1-(1-\frac{1}{\sigma})^q) + (1-\frac{1}{\sigma})^{(\sigma-1)\cdot q}$$

$$= (1-(1-\frac{1}{\sigma})^q)\sum_{i=0}^{\sigma-2}(\sigma-i)(1-\frac{1}{\sigma})^{i\cdot q} + (1-\frac{1}{\sigma})^{(\sigma-1)\cdot q}$$

$$= \frac{\sigma - (\sigma+1)(1-\frac{1}{\sigma})^q - 2(\sigma-2)(1-\frac{1}{\sigma})^{(\sigma-1)\cdot q} + (2\sigma-3)(1-\frac{1}{\sigma})^{\sigma\cdot q}}{1-(1-\frac{1}{\sigma})^q}$$

In practical situations $\sigma \geq 2$ and if the number of processors is large then we can approximate $k_1$ by

$$k_1 \simeq \sigma - \frac{(1-\frac{1}{\sigma})^q}{1-(1-\frac{1}{\sigma})^q}$$

When $\sigma = \frac{L}{q}$, then we get $k_1 \simeq \frac{L}{q} - \frac{L}{q^2}$.

In the rest of the paper this expression for $k_1$ is used.

Nature of Speedup Function: The expression for average speedup for Model A is

$$SP1(L,q) \simeq \frac{k' \cdot L \cdot t_r + L \cdot t_s}{((k' \cdot L - (d \cdot q - 1)/(d-1))t_r + L \cdot t_s)/q + (log_d(q) + 1)t_r + 2(q-1) + \frac{L}{q} - \frac{L}{q^2} - 1} \tag{9}$$

The general shape of the speedup curve for a given length of the string with varying number of processors can be obtained as follows.

The numerator in $SP1(L,q)$ does not depend on the number of processors. Hence, we consider only the denominator. Let the denominator be denoted by $DSP1$. Taking the first derivative of $DSP1$ with respect to $q$ and equating this to zero, (after removing those terms that asymptotically go to zero), the value of $q$ is

$$q = ((k' \cdot t_r + t_s + 1)L/2)^{1/2} = q_0$$

Substituting $q_0$ in the second derivative of $DSP1$ (with respect to $q$) an expression with positive value is obtained. Therefore, $q_0$ is the number of processors which parse a string of length $L$ in a minimum time. The speedup increases with the number of processor up to a maximum and then decreases.

Similarly, the expression for speedup for Model B is given by

$$SP2(L,q) \simeq \frac{k' \cdot L \cdot t_r + L \cdot t_s}{((k' \cdot L - (d \cdot q - 1)/(d-1))t_r + L \cdot t_s)/q + (log_d(q) + 1) \cdot t_r + log_d(q) + \frac{L}{q} - \frac{L}{q^2}} \tag{10}$$

It can be shown that $SP2(L,q)$ increases to a maximum value monotonically, and then it remains constant. Unlike $SP1(L,q)$, $SP2(L,q)$ does not decrease as the number of processors increases beyond the critical number.

Speedup for Pascal–like Languages: To find the speedup for Pascal–like languages we calculate $N$, estimated number of nodes and $d$, estimated degree in the parse tree as follows.

From Table 1 we get,

$$N - L = \sum_{i=1}^{16} r_i$$

$$=(5n_{;} + 2n_{if} + 5n_{else} + 2n_{while} + 2n_{repeat} + 5n_{case}$$

$$+ 3n_{+} + 4n_{()} + 7n_{>} + 2n_{*} + 6) \qquad (11)$$

| Terminals | Frequency of occurrence (every 100 terminals) |
|---|---|
| id | 60 |
| ← | 6 |
| if | 2 |
| else | 0.9 |
| while | 0.1 |
| repeat | 0.05 |
| case | 0.15 |
| () | 6.6 |
| ; | 12 |
| + | 4.6 |
| * | 4.6 |
| > | 4.6 |

TABLE 2 Average occurrence of some terminals in Pascal like languages Ref. [5]

Using expression (11) and the frequency of occurrence of each terminal shown in Table 2 we get

$$N = 2.4175L$$

$$d = 1.70547$$

Substituting these value of $N$ and $d$ in (9) and (10) we get

$$SP1(L,q) \simeq \frac{1.4175L \cdot t_r + L \cdot t_s}{((1.4175L - (1.7047q - 1)/0.7047)t_r + Lt_s)/q + (log_{1.7047}(q))t_r + t_r + 2(q-1) + \frac{L}{q} - \frac{L}{q^2}}$$

and,

$$SP2(L,q) \simeq \frac{1.4175L \cdot t_r + L \cdot t_s}{((1.4175L - (1.7047q - 1)/0.7047)t_r + L \cdot t_s)/q + (log_{1.7047}(q) + 1)t_r + log_{1.7047}(q) + \frac{L}{q} - \frac{L}{q^2}}$$

In Fig. 2 the speedup curves are given with $t_r = t_s = 1$ and $L = 1000$. The dotted curve presents the speedup obtained by simulation in [5].

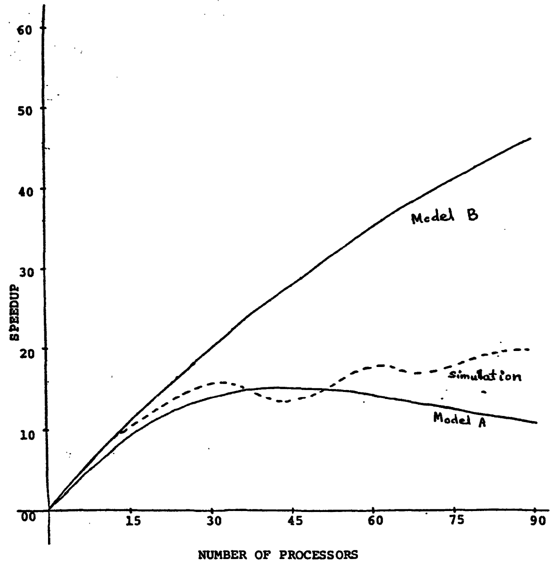

Fig. 2. Number of Processors vs Speedup Curves for Pascal–like Languages with $k_1 = \frac{L}{q} - \frac{L}{q^2}$

## VI. CONCLUSION

We have presented a method for estimating the speedup for asynchronous, bottom–up, parallel parsing. To develop this result we have made a few simplifying assumptions about the nature of the parse tree. Hence the expressions may not give exact speedup, but the closeness of the estimated speedup using the method developed here and the simulation result in [5] indicates that the assumptions are realistic, and that the significant parameters have been taken into account.

Next, it may be useful to investigate how the structure of a language determines the speedup in parallel compilation. Parallelization of the existing sequential code–generation techniques may be useful for speedup and machine utilization.

The Model A is restrictive in that a processor can directly communicate with its immediate left and immediate right neighbors only. This increases the processor coordination and interprocessor communication time. On the other hand, Model B is expensive to construct if the number of processors is large. A model which is a combination of the two, for example $Cm^*$ [11], should also be investigated.

## Abstract

We present a new parallel programming assistant, called PTOOL, that identifies loops suitable for parallel execution. It employs a theory of dependence to determine which loops in a FORTRAN program will produce the same answers when iterations are scheduled in an arbitrary order. When a loop fails the test, an explanation is provided in the form of a report of the dependences that can be violated by some schedule. PTOOL also provides assistance in the allocation of variables between local and shared global memory. Interprocedural data flow analysis techniques extend its scope of applicability to whole programs. PTOOL, which is in use at Los Alamos National Laboratory, represents a first step toward a sophisticated interactive programming system based on incremental dependence analysis.

## 1. Introduction

Humans and machines bring very different strengths to bear on the problem-solving process. Humans make effective use of abstraction to develop broad strategies and are adept at simplification of complex situations and at generalization from simple principles. Unfortunately, they are not good at exhaustive search and seem unable pay rigorous attention to details—areas where the computer excels. As a result, programmers often fail to precisely specify the details of their intended solutions to the machine, inevitably leading to "bugs" in their programs.

The advent of parallel machine architectures has added a new level of complexity to the debugging process. Parallelism implies nondeterminism; nondeterminism, in turn, implies nonrepeatability. In other words, program sections that are executed in parallel do not necessarily follow the same execution path every time the program is run—even when the program is run on the same data. This additional complexity requires additional precision from the programmer. Not only must he ensure that the computations performed by the sequential sections are those that he intended, but he must also ensure that the computations indicated in parallel regions perform the desired calculations regardless of the order in which they are executed. This increased complexity permits some very elusive bugs.

Given the difficulties that can arise in parallel programming, it seems clear that new methods and tools will be needed [18]. There are several possible lines of attack. At one extreme, a parallel program might be repeatedly run on the same test data to ensure that it computes the same answers on each execution. Although this approach is easy to implement, it is inelegant and probably would not be effective, since the conditions required to produce an error need not arise during the test. At the opposite extreme, formal correctness proofs could be applied to a parallel program. In spite of significant levels of activity on verification over the past decade, complete automatic proofs for realistic programs appear impractical for the time being.

A third approach would be to develop an automatic system to convert implicit parallelism within a sequential program into an explicit form. The advantage of this method results from the ability to debug the program using standard techniques on sequential machines prior to parallel conversion. Since the conversion involves provably correct transformations, the parallel version should execute correctly, thereby avoiding the need for a complex parallel debugging phase. Additionally, this approach provides a mechanism for converting "dusty deck" programs.

In spite of these advantages, fully automatic conversion to parallelism is not practical using current language processing technology. Although many promising techniques have been developed [10,22,21,6], the programmer is still an essential ingredient in the exploitation of parallelism. There are several reasons for this. First, most programs contain a large number of potential parallel regions. Searching all regions for parallelism can be an extremely expensive task. In addition, synchronization overhead on many machines can easily overwhelm the advantages of parallel execution [12], unless the granularity of the parallel regions is very large. Often, this determination depends upon values that are known only at run-time. Hence, the programmer's judgement is an important part of the parallel programming process.

This paper describes a new parallel programming assistant, called PTOOL, that combines the advantages of the manual and automatic approaches. When using PTOOL, a programmer develops and debugs a program on a sequential machine using traditional techniques. Once the program is debugged, the programmer identifies the regions, usually separate iterations of loops, that should be executed in parallel. PTOOL then reports whether the results of execution ***depend in any way on the order of execution of the regions.*** If not, the regions can be safely executed in parallel. Otherwise, the programmer can ask PTOOL for diagnostic information to help identify problems. This information is presented as reports on potential conflicts in the use of variables shared by different parallel regions.

The discussion of PTOOL begins in Section 2 with an overview of the parallel programming approach it supports. Section 3 gives an introductory treatment of dependence theory, the primary tool for analyzing programs. The method used by PTOOL to determine loops that can be executed in parallel is described in Section 4, while details of the system design are presented in Section 5. The user interface is discussed in Section 6. Finally, Section 7 summarizes the work and suggests future directions.

## 2. Parallel Programming Process

This section introduces a model for the parallel programming process that PTOOL is intended to support. Fundamentally, PTOOL is a system designed to help programmers transform sequential loops in FORTRAN to parallel loops. Although this model is not universal, it covers many interesting cases.

Multiprocessors are the most efficient when each processor is able to compute at full speed, without requiring synchronization with other processors. To achieve this ideal, we not only must identify a collection of program fragments that can be executed in parallel, but we must also schedule the computation in a manner that balances the execution load across processors. In FORTRAN, the lingua franca of scientific computation, the construct most likely to give rise to a large number of parallel regions with comparable execution times is the DO loop. There

[†] This research was supported by IBM corporation.

0190-3918/86/0000/0164 $01.00 © 1986 IEEE

are two reasons why. First, if they can be made to execute correctly in parallel, the separate iterations of a DO loop can provide enough computation to keep a significant number of processors busy. Second, since each iteration of a DO loop should take roughly the same time to execute, the load will be automatically balanced across the processors. Experience with actual multiprocessors strongly supports the importance of loops in the parallel programming [19].

In the light of these observations, we have designed PTOOL to determine the conditions that inhibit parallel execution of loops. In doing so, we have been careful not to restrict the analysis to DO loops, because iterative regions in FORTRAN are often coded using backward GOTO statements.

In deciding whether or not the iterations of a given loop can be executed in parallel, it is important to decide which variables mentioned in the loop body must be shared by parallel tasks and which can be allocated to storage local to the processor. This decision is important because shared variables can be accessed in different orders by different processors. If we wish to compute the same results every time the program is run, all possible schedules for a set of parallel tasks must lead to a functionally equivalent access sequence for shared variables. For example, it should not be possible to have two schedules in which the order of a load and store of a shared variable are reversed. If we are to avoid the insertion of explicit synchronization between loop iterations, we must establish that, without synchronization, such a reversal can never happen. In performing the requisite analysis, we need not concern ourselves with local variables, since the relevant loads and stores happen on the same processor.

Since PTOOL was developed to support parallel programming research at Los Alamos National Laboratory, where FORTRAN code was being converted to the Delnelcor HEP and the Cray X-MP[1], the methods for expressing parallelism on those machines strongly influenced its design. The standard method on those machines is to express a parallel body of code as a subroutine, because that expression provides a natural encapsulation of the code to be broadcast to the different processors. Furthermore, reentrant code is straightforward to generate.

In the subroutine model, the loop body is replaced by a parallel subroutine invocation that takes as parameters an indication of the loop iteration to execute and variables that have to be globally available to all processors. PTOOL assumes that subroutine parameters and variables in COMMON are shared, but all other variables used in the loop body are assigned to storage local to each processor. As we shall see, PTOOL offers a suggestion, based upon dependence analysis, of the variables which should be parameters. The programmer is free to ignore this suggestion and select his own parameters. PTOOL will accept this modification and tailor its advice to the set of shared variables specified by the user.

Under the model we have introduced, the principal requirement that must be preserved when converting a program for parallel execution is the access order to shared variables. The main tool for analyzing patterns of loads and stores in a program is a powerful theory of dependence, the subject of the next section.

## 3. Data Dependence

In a sequential language such as Fortran, the execution order of statements is well defined. Therefore, the behavior of the program under sequential execution order can be used as a basis for evaluating other execution orders. Specifically, it is possible to examine alternative execution orders to see whether they will also produce the same results. Parallel execution implies that the statements in a collection of parallel regions (iterations of a loop, for our purposes) can be executed in any order so long as the statements within a particular region are executed in sequence. Hence, for a collection of parallel regions to be suitable for parallel execution, there must be no dependences between statements of different parallel regions. In our model, there must be no dependences that cross loop iterations.

To determine whether this condition holds, we must identify the pairs of statements whose relative execution order *must* be preserved under any program transformation if the results are to be preserved. This relationship is represented by a collection of ***dependences*** among the statements of the program. A statement $S_2$ is said to ***depend upon*** a statement $S_1$ if $S_2$ follows $S_1$ in dynamic execution of the sequential program and it must follow $S_1$ in any reordering that preserves the correct results.

There are two ways for a statement $S_2$ to depend on statement $S_1$. First, $S_1$ can cause a change in the control flow that determines whether $S_2$ is executed, creating a ***control dependence*** of $S_2$ on $S_1$. Second, the two statements may access the same variable in a way that requires that their order be preserved. A dependence created to prevent incorrect access order to a variable is called a ***data dependence***. Although both types of dependence must be considered when rearranging statements, programs can always be transformed so that all control dependences become data dependences[1]. Therefore, we restrict the remainder of this discussion to data dependences.

Data dependence arises most naturally when one statement defines a variable that is later used by a second statement. However, Kuck has identified three types of data dependence [17]:

(1) *true dependence* — $S_1$ stores into a variable that $S_2$ later uses.

(2) *antidependence* — $S_1$ fetches from a variable that $S_2$ later stores into.

(3) *output dependence* — two statements both store into the same variable.

All three types of data dependences must be considered to safely reorder a program.

It is also useful to distinguish dependences that cross loop iteration boundaries from those that do not. To see this, consider the following example.

```
              DO 100 I = 1, N
S1                A(I) = ...
S2                ... = A(I)
        100   CONTINUE
```

$S_2$ quite obviously has a true dependence upon $S_1$, implying that $S_1$ must be executed before $S_2$ in order for the computation to be correct. However, this dependence in no way precludes the separate iterations of the loop from executing in parallel, because values created within the loop are used on the same iteration, and need not be saved for later iterations. Such a dependence is said to be ***loop independent*** [2]. On the other hand, consider a slightly different loop.

```
              DO 100 I = 1, N
S1                A(I) = ...
S2                ... = A(I-1)
        100   CONTINUE
```

In this case, we may ***not*** safely transform the loop to execute in parallel, because the dependence crosses loop iterations; that is, values created on one iteration are used on a later iteration. A dependence of this sort is said to be ***loop carried***, because it exists only by virtue of the iteration of the loop—if the loop body is executed only once, the dependence ceases to exist.

It is useful to observe that a loop carried dependence arises because of the iteration of a particular loop. For instance, in the following nest of loops

[1] HEP is a trademark of Denelcor Corporation and X-MP is a trademark of Cray Research.

```
                DO 200 I = 1, M
                      DO 100 J = 1, N
S1                         A(I,J) = ...
S2                         ...  = A(I-1,J)
          100         CONTINUE
          200   CONTINUE
```

iteration of the outer loop (on I) gives rise to the dependence. So long as the outer loop is iterated sequentially, the dependence will be satisfied. In the light of this observation, we classify carried dependences by indicating the particular loop that creates the dependence.

Loop carried and loop independent dependence provide a precise characterization of the execution orders that are important within a program. So long as these dependences are preserved, the results of a computation will also be preserved. This fact is extremely important in vectorization as performed in PFC, an automatic vectorization system written at Rice [3,16]. PFC constructs a complete dependence graph for the program to which it is applied, in order to distinguish the statements that can be executed as vector operations from those that cannot. This graph can also be used to determine parallel loops, as the next section shows.

## 4. Identifying Parallel Loops

From the parallel programming paradigm presented in section 2, it should be clear that there are two tasks to be performed in converting sequential code: 1) identifying local and global variables, and 2) finding loops suitable for parallel execution. These two tasks are highly interdependent as the following loop illustrates:

```
          DO 100 I = 1, N
                 T = ...
                 ... = T
    100   CONTINUE
```

If T is a variable that can be kept in the local memory of individual processors, as above, then there is no dependence that prevents parallel execution of the loop. If, on the other hand, T must be globally available (as would happen if there were a use of the last value of T after the loop), then the loop would not execute correctly in parallel. Once T becomes a global variable, different processors may intermix intermediate computations involving T, with unpredictable results.

Identifying the variables that must be global to a parallel loop turns out to be a relatively straightforward process. Simply stated, a variable must be globally available if it holds a value that is used outside the loop, or, in the symmetric case, if a definition from outside the loop reaches into the loop. Given the dependence graph described in the previous section, recognition of variables that must be globally allocated becomes a fairly trivial task. The system need only analyze the true dependences coming into and going out of a loop; any variables that give rise to such a dependence must be made globally available. In actual practice, the problem is somewhat more complicated, because full dependence graphs are normally constructed only over loop bodies. However, definition-use chains [15] are quite commonly constructed over an entire program (as they are in PFC), and can be used in the absence of stronger dependence information.

The second aspect of parallel programming is the identification of loops suitable for parallel execution or, more correctly, determination of loops which cannot be executed in parallel. Recall that parallel execution, as used in this paper, means execution of different iterations of a loop on different processors. We can achieve this without synchronization only so long as one processor does not compute a value needed by another processor (or one processor does not store on top of a value needed by another processor, etc.). Accordingly, the key restraints to parallel execution are dependences carried by the candidate loop that involve a global variable. For instance, in the following example

```
          COMMON   A(100,80)
          DO 100 I = 1, 80
                DO 100 J = 1, 100
                      A(J,I) = ...
                      ... = A(J-1, I) + ...
    100   CONTINUE
```

the I loop carries no dependences, and may be safely executed in parallel. The J loop, however, is a different matter. If it is executed on multiple processors, each processor will create values needed by a different processor. Hence, a loop may be executed correctly in parallel if and only if that loop carries no dependences based on a global variable [4].

These two principles are the fundamental considerations in converting a sequential code for parallel execution. Because both conditions are tedious to verify, a human converting a code for parallel execution may easily overlook an important problem. More specifically, a human programmer might not notice that a variable must be globally allocated or might miss a loop carried dependence. Since the resulting faults may manifest themselves as errors only under specific schedules, they can be extremely difficult to locate.

## 5. PTOOL Design

### 5.1. Overview

PTOOL divides quite naturally into two subcomponents: one to construct the dependence graph and the other to answer queries about potential parallelism in the program. The first of these components, called PSERVE, is a modified version of PFC running on an IBM 370. When PTOOL is invoked, the user submits the program source, including all the subroutines, to PSERVE for analysis. PSERVE constructs the dependence graph and saves it in a database of two files. This database is shipped back to the user for interactive analysis.

The user then conducts an interactive dialog with the display facility, called PQUERY. PQUERY shows the actual program source on the screen and permits the user to select a loop for analysis. It uses the database constructed by PSERVE to identify the global variables in the proposed parallel region and it presents any dependences that might impede parallel execution.

While the division of PTOOL's functions into two relatively independent components prohibits incremental reanalysis of the program as the user eliminates problems, it does permit PQUERY to be run on a variety of machines. In fact, we have already implemented versions for an IBM PC and a SUN workstation.

### 5.2. PSERVE

### 5.2.1. PFC Modifications

Before computing a dependence graph, PFC employs a number of preliminary transformations to enhance the precision with which it can determine dependences. These transformations can radically change the structure of a program. Since the purpose of PTOOL was to display the dependences as they exist in the *user's* source program (and not in a transformed program), it was necessary to carefully alter the transformations so that dependences could be accurately calculated for the original program.

The two main preliminary transformations in PFC are "induction variable substitution" [24, 3] and "IF conversion" [1]. Induction variable substitution is the process of replacing auxiliary induction variables in a loop with a direct expression based on the loop induction variable. For instance, in the following example

```
        DO 100 I = 1, 100
              IX = IX - 1
              A(IX) = A(IX) - 1
100     CONTINUE
```

IX is used as an auxiliary induction variable to run the loop "backwards". The difficulty with such variables is also illustrated above—an automatic system cannot easily determine whether the references to A are independent. This difficulty can be removed as follows:

```
        DO 100 I = 1, 100
              A(IX - I) = A(IX - I) - 1
100     CONTINUE
        IX = IX - 100
```

This process, which is essentially the inverse of the classic optimization *strength reduction* [15], is normally performed in PFC so that the array dependences of A may be accurately calculated. The problem with this transformation is that it eliminates some scalar dependences that inhibit parallel execution.

In order to correctly handle induction variables, PTOOL must use multiple passes to add dependences to the graph. Dependences for induction variables must be added before induction variable substitution is performed. After induction variable substitution, array dependences can be accurately calculated and added to the graph. As PTOOL adds dependences for the induction variables, it flags the edges so that it can inform the user that these dependences can be removed by substitution.

Control dependences are transformed into data dependences by a process known as "IF conversion" [1]. The basic idea is to transform a statement whose execution is affected by a transfer of control to a conditional statement, controlled by a Boolean "guard" that exactly represents the conditions under which control flow would have reached the statement

GOTO's can be quite naturally classified into two categories: forward GOTO's and backward GOTO's. Each of these categories may possess the further property of being an *exit* branch, meaning that the branch exits one or more loops. Although non-exit forward branches cannot directly cause any problems with parallelization, they can cause indirect problems by forcing some variables under their control to be global. Thus, while not strictly necessary, forward branches are converted because of this problem.

Backward branches are converted via IF conversion into DO WHILE loops, which permit more effective analysis by PFC. Because of the conversion, the user can select a backward GOTO when analyzing the program in exactly the same manner that he selects a DO loop. IF conversion as implemented in PFC is powerful enough to convert any sequence of branches into an equivalent branchless program.

Transformations are only one of the ways in which PFC attempts to produce a precise dependence graph. Another technique that has proved extremely successful is interprocedural analysis.

### 5.2.2. Interprocedural Analysis

Most automatic vectorizers make no attempt to trace dependence edges across procedure boundaries. As a result, they either ignore loops containing procedure calls (declaring them unvectorizable), or assume that all possible variables (i.e. parameters and COMMON) are modified. PFC employs a more sophisticated approach: it uses iterative data flow analysis on the program call graph to determine the side effects of procedure calls [5]. This additional information permits a substantially more precise dependence graph in the presence of subroutines.

The most significant advantage of this approach is the reduction in size of the dependence graph. On GAMTEB, a 504 line program written at Los Alamos, the dependence graph computed without interprocedural analysis contained 22,998 edges. With the application of interprocedural analysis, the graph was reduced to only 2,605 edges. The smaller graph is beneficial to PTOOL's user both directly and indirectly. Directly, the user no longer sees spurious edges associated with variables in COMMON; hence he is able to narrow his focus to real problems. Indirectly, the user experiences a performance improvement in PQUERY because the database is substantially smaller.

A second benefit of the interprocedural information has been the identification of COMMON variables actually used in calls. A fairly standard programming practice for large programs is to have the same COMMON blocks across all subprograms, thereby avoiding the problems of determining which variables have to be passed as parameters and of determining how actual parameters line up with formal parameters. Since all COMMON variables have to be in global memory, it is possible that a temporary value placed in such a variable at the beginning of a loop iteration will prevent parallel execution. Additionally, access to global memory is usually slower than access to local memory. Because PTOOL is able to pick out precisely the variables that are used and modified across procedures, it can aid a user in moving these variables to local memory.

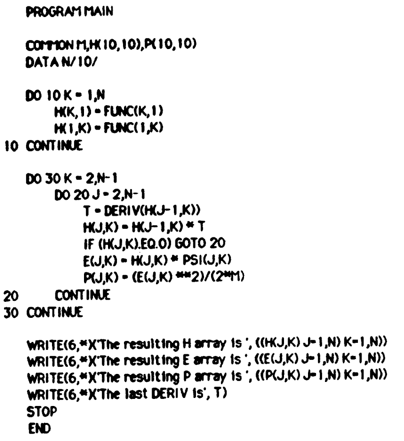
In those situations where a procedure's source code is not available, PFC assumes that all parameters and COMMON variables are both used and modified.

### 5.2.3. Constructing the Graph

Recall that the original goal of PFC was to vectorize FORTRAN programs. It proceeds by generating a dependence graph and then producing a vector FORTRAN equivalent of the input FORTRAN program. For PSERVE, PFC has been modified to execute up to the point that the dependence graph and definition-use chains are assembled. Loop independent edges are then filtered out of the dependence graph and each loop carried edge is annotated with additional information (such as nesting level, whether the variable is in COMMON, etc.) before being added to PSERVE's dependence graph file. In addition, a second file, containing information about loop structure and definition use chains, is built. This information allows the display process to discern which lines make up a loop and identify the parameters of a given loop.

### 5.3. PQUERY

The primary novelty of PTOOL is the interactive display of a dependence graph in PQUERY. This section illustrates the power of PTOOL's display through the example in Figure 1, which captures a number of important characteristics from scientific applications. The code itself can be viewed as solving a wave equation, or computing an unknown function at a mesh of points given only its partial derivative in one direction. The first



```
      PROGRAM MAIN

         H(K,1) = FUNC(K,1)
         H(1,K) = FUNC(1,K)
   10 CONTINUE
C
      DO 30 K = 2,N-1
         DO 20 J = 2,N-1
            T = DERIV(H(J-1,K))
            H(J,K) = H(J-1,K) * T
            IF (H(J,K).EQ.0) GOTO 20
            E(J,K) = H(J,K) * PSI(J,K)
            P(J,K) = (E(J,K) **2)/(2*M)
   20    CONTINUE
   30 CONTINUE
C
      WRITE(6,*)('The resulting H array is ', ((H(J,K) J=1,N) K=1,N))
      WRITE(6,*)('The resulting E array is ', ((E(J,K) J=1,N) K=1,N))
      WRITE(6,*)('The resulting P array is ', ((P(J,K) J=1,N) K=1,N))
      WRITE(6,*)('The last DERIV is', T)
      STOP
      END
```

Figure 1: Test Program

loop initializes boundary conditions at the border of the mesh. The next loop nest sweeps the calculation across the array. The inner loop moves up a column, calculating the value at any particular location *j* by using the value calculated at location *j*-1. It also performs some auxiliary computations, based on the value at the location. The outer loop sweeps the computation across all the columns. The calculations moving up the columns are all dependent upon previous values, and must proceed sequentially. However, nothing prevents parallel computation of different columns.

In addition to the code that is shown in Figure 1, the source for all of the function and subroutine calls was included when the code was run though PSERVE. The only important property of these procedures was the fact that they were "pure"; that is, they did no READs or WRITEs, and did not access global memory.

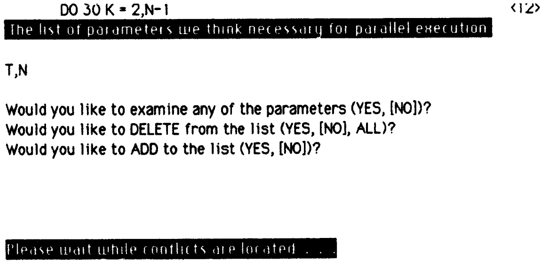
Once PSERVE has constructed the dependence database and downloaded it to the PQUERY machine, the system is ready for an interactive session. The user begins by browsing the complete FORTRAN source file. The first task is to identify loops that are likely candidates for parallelization. For example, in Figure 1, we can see that either of the two outer loops (DO 30 and DO 20) should execute correctly in parallel. A cursory examination of the code reveals no obvious problems with this conclusion.

The PQUERY browser provides a typical set of editor commands for moving about the file (eg. search, go-to-line, page-forward), The user can thus proceed to the first loop to be checked. Once the DO statement (or backwards GOTO) defining this loop is visible on the screen, the loop can be selected by placing the cursor on the appropriate line (using either a mouse or cursor keys) and hitting a selection key.

When a loop is selected, PQUERY displays a list of variables not in COMMON that need to be global to the loop. As stated earlier, these variables must be parameters to the resulting parallel subroutine call. Figure 2 presents the screen that a user would see after selecting the DO 30 loop (from the code in Figure 1) for parallel execution. PTOOL has detected two variables that must be shared—T and N. T is somewhat surprising, since it appears to be a local temporary.

Since it is natural for the programmer to question PTOOL's decisions, we provided a simple explanation facility. For example, if the programmer questions the global allocation of T, he will be presented with the screen in Figure 3. The figure shows that T is used on line 32 after being defined in the selected loop (lines 12-20)—a use outside the loop. The variable, if present in the source (it is possible that COMMON variables will not appear at a call site), is highlighted and the reason that the variable must be global is given.

After reviewing the parameters, the user can add or delete any parameters. This permits PTOOL to solve a number of problems. For instance, on one pass over a loop, a user can allow all of the parameters to remain and discover the scope of the overall problem. Then he can delete all parameters to investigate dependences on variables in COMMON. If dependences are present, the user can attempt to eliminate them by transforming the program source. When no dependences arise from COMMON variables, the user can examine parameters singly, using transformations to eliminate each of the problems. PSERVE can then be invoked on the transformed source to verify that the process has been successful.



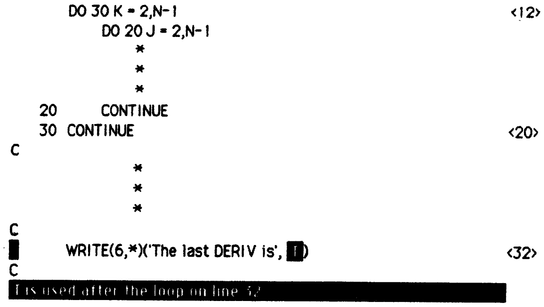
```
          DO 30 K = 2,N-1                                  <12>
 The list of parameters we think necessary for parallel execution

 T,N

 Would you like to examine any of the parameters (YES, [NO])?
 Would you like to DELETE from the list (YES, [NO], ALL)?
 Would you like to ADD to the list (YES, [NO])?

 Please wait while conflicts are located . . .
```

Figure 2: Global variables as displayed by PTOOL



```
      DO 30 K = 2,N-1                                  <12>
         DO 20 J = 2,N-1
             *
             *
             *
  20     CONTINUE
  30  CONTINUE                                         <20>
C
             *
             *
             *
C
█     WRITE(6,*)('The last DERIV is', T)               <32>
C
T is used after the loop on line 32
```

Figure 3: PTOOL's explanation of the parameter list

Figure 4 illustrates PTOOL displaying dependence problems after the user is satisfied with the parameter list. PTOOL has highlighted the variable T in two statements, because there is a dependence (caused by the global allocation of T) that can cause incorrect parallel execution. If the dependence can be eliminated by forward substitution or induction variable substitution, PTOOL will inform the user of that fact. In the example program, all problem dependences arise because T must be in global storage. If the programmer eliminates that requirement by changing the code (or simulates it by removing T from the parameter list), no conflicts will appear.

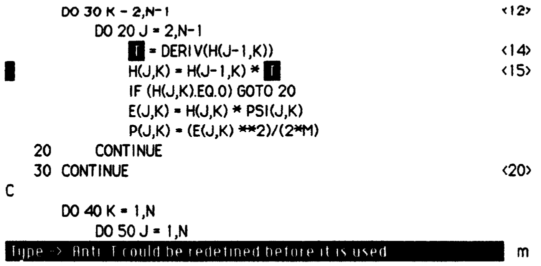
## 6. An Assessment

A number of studies have observed that there are two general classes of errors introduced in converting programs for parallel execution [20,7].

1) Errors due to unintentional data sharing or access to shared variables in an improper order.

2) Errors due to incorrect synchronization code.

PTOOL is effective in helping the programmer identify the causes of errors in the first class. By displaying dependences in an understandable manner, PTOOL can immediately pinpoint problems that might require enormous amounts of unaided human time to find. In fact, in the first demonstration it found a problem that had consumed three man-months of effort at Los Alamos. Interprocedural analysis has been an essential element in the success of PTOOL, because it eliminates most of the spurious dependences caused by large COMMON blocks. Furthermore, it makes it possible to analyze complete Fortran programs of substantial size.



```
      DO 30 K = 2,N-1                                  <12>
         DO 20 J = 2,N-1
            T = DERIV(H(J-1,K))                        <14>
█           H(J,K) = H(J-1,K) * T                      <15>
            IF (H(J,K).EQ.0) GOTO 20
            E(J,K) = H(J,K) * PSI(J,K)
            P(J,K) = (E(J,K) **2)/(2*M)
  20     CONTINUE
  30  CONTINUE                                         <20>
C
      DO 40 K = 1,N
         DO 50 J = 1,N
Type -> Anti  T could be redefined before it is used   m
```

Figure 4: An anti-dependence displayed by PTOOL

In this context, it is useful to contrast PTOOL with the DAPP (Data Flow Analysis for Parallel Programs) system of Appelbe and McDowell [7]. When completed, DAPP will accept a Fortran program in which synchronization code has already been inserted and produce a report of *parallel access anomalies*—pairs of statements that can access the same location simultaneously during a legal schedule. DAPP has the advantage over PTOOL of applicability to a variety of concurrent structures. On the other hand, it uses an analysis technique that is potentially exponential in the size of the program (the single-procedure analysis of PTOOL is proportional to the square of the procedure size and the interprocedural analysis runs in time almost linear in the size of the call graph). Another drawback of DAPP is that it presents an exhaustive report of potential anomalies. Our experience with PTOOL and the experience of other researchers [9] is that exhaustive reporting produces an enormous amount of information in which the important facts can be lost. The selective display provided by PTOOL permits the programmer to focus on one problem at a time. For these reasons, we think that PTOOL will be more useful in analyzing large programs.

On the other hand, PTOOL is of no help whatever for problems of the second class—errors in synchronization code. It is our belief that writing synchronization code is inherently difficult and that programmers should be able to deal with parallelism at a higher level of abstraction. There are several systems of language extensions, implemented through preprocessing, that provide a higher-level interface [8,14,11].

Another approach would be to extend PTOOL to support parallel programming in a more direct fashion. For example, once the programmer has dealt with all dependences that prohibit parallel execution of a given loop, he might request that the system generate the code required to initiate and synchronize the parallel execution. Such a facility would be the first step in evolving PTOOL from a debugging aid to a programming system. Dependence analysis can be a very powerful tool during the program development process. When displayed in an informative way, dependences can provide information about how effectively the program is making use of parallel hardware.

One major drawback to using PTOOL as a programming support system is that it is not sufficiently interactive, since it cannot redisplay dependences immediately after a change. Redisplay requires that PSERVE be invoked again on the whole program, an expensive process. If PTOOL is to be a truly effective programming support tool, it must be converted to an interactive system. But an interactive programming system must also support other functions, such as editing, compilation, and execution. In short, the system must be a complete programming environment.

An interactive programming environment is appealing for other reasons. One of the main hindrances to accurate dependence analysis is variables whose values are known only at run-time. A compile-time analysis must make worst case assumptions about the values of such variables, resulting in dependences that may not be present at run-time. An interactive system can query the programmer regarding values of such variables, and can embed the information provided into the dependence graph and into the resulting code (in case a programmer's assertion turns out to be false). Additionally, a programming environment makes reasonable an enhanced form of interprocedural analysis, in which the effects of procedures on portions of arrays and vectors can be summarized. Such analysis can be especially beneficial on a parallel multiprocessor, since the ability to run procedure invocations in parallel is one of its primary advantages[23].

For these and other reasons, we are convinced that the proper context in which to employ dependence analysis is a programming environment such as $\mathbf{R}^n$[13]. Such a system takes advantage of the strengths of the system and the programmer: the programmer is able to concentrate on developing highly parallel algorithms, with prompting from the system when he strays from parallelism, while the system is able to focus on the mundane aspects of uncovering and scheduling parallelism, with help from the programmer when some information regarding the run-time values of variables is necessary. The resulting system should provide a highly effective mechanism for developing parallel programs.

Although PTOOL is still a fairly primitive system, it has demonstrated that loop carried dependence, properly presented, can be an effective debugging tool. We see it as a first step toward more powerful parallel programming tools based on interactive computation of loop carried dependence.

## Acknowledgements

Version 0.0 of PTOOL was a two inch thick paper listing of the data dependences in TRAC placed on Paul Fredrickson's desk in 1984. The system described in this paper evolved from version 0.0 due to the efforts of many people. Most influential were a number of Los Alamos personnel who are intimately involved with parallel machines, and who provided insight into the problems encountered in parallel programming. These people include Paul (who conceived of PTOOL in its first incarnation), Olaf Lubeck, Margaret Simmons, Jim Moore, Bob Hiromoto, Elizabeth Williams, and Anne Hays. Vasanth Balasundaram has invested large amounts of coding time in an Xedit version of PTOOL. To these people go our heartfelt thanks.

**Abstract.** The KAP/ST-100 is a Fortran source translator that simplifies the task of programming the Star Technologies' ST-100 attached processor. The ST-100 can execute certain vector operations very quickly. It is programmed using a Fortran-like language, called APCL; APCL routines are invoked from the host through system library calls. The KAP/ST-100 locates parts of Fortran programs that will execute efficiently on the ST-100. An APCL routine is created for each of these regions, and the original code is replaced by system library calls to invoke these routines. This paper explains the complications which were encountered in translating for the ST-100 and the methods which were used to overcome them.

## 1. Introduction

The Star Technologies' ST-100 attached processor [1] is designed for high speed execution of single precision (32-bit) signal processing kernels. It also has a wide range of application areas, due to the high speed of its arithmetic unit. The ST-100 is attached to a host computer, such as a VAX, IBM or Control Data mainframe, to which it looks like an I/O device. Since the ST-100 has its own main memory, data items are transferred from the host memory to the ST-100 main memory. The ST-100 executes asynchronously from the host; routines for the ST-100 are written in a Fortran-like language called APCL (Array Processor Control Language) [2]. A program running on the host calls system library routines to schedule execution and acquire ST-100 resources, to send data from the host to the ST-100 main memory, to load the APCL routine to the ST-100, and to initiate execution of that APCL routine. The host program may continue execution or may wait for completion of the APCL routine. The host program then calls other system library routines to bring data back from the ST-100 to the host for further processing, printing, and so on. As with all array processors, writing a program for the ST-100 is a nontrivial project. Because of this, array processors are commonly restricted to special applications. Now with the KAP/ST-100, the power of the ST-100 is available to Fortran programmers.

The KAP/ST-100 is a Fortran translator that eases the task of programming the ST-100. The KAP/ST-100 generates APCL routines for the regions of programs which execute efficiently on the ST-100. Four output files are generated by the KAP/ST-100: an APCL file, a host program file, an auxiliary file to assist in linking the APCL routines, and a listing. The advantages of using the KAP/ST-100 are that the Fortran program remains portable and the user need not learn APCL.

The next section of this paper describes the ST-100 attached processor, focusing on those aspects of the machine that require special handling in the KAP/ST-100. The third section gives an overview of the KAP/ST-100. The fourth section focuses on how the KAP/ST-100 generates APCL code from the Fortran program. The fifth section explains how the KAP/ST-100 decides what sections of code to leave on the host and what sections to move to the ST-100. The sixth section relates some of the problems we encountered with the user interface of the KAP/ST-100. The last section gives an example of the use of the KAP/ST-100 on a simple matrix multiply routine.

## 2. The ST-100 Attached Processor

The ST-100 is composed of three asynchronous processors and three memories. The Control Processor (CP) executes the user's APCL routine. The CP controls the operation of the other two processors, the Storage Move Processor (SMP) and the Arithmetic Control Processor (ACP). The SMP and ACP are fast processors, with a 40 nanosecond clock period; the CP is a standard microprocessor with no floating point unit. The APCL code resides in Local Memory (LM), which is directly accessible by the CP. Data is sent from the host to the large Main Memory (MM). The ACP, which is the arithmetic engine, performs operations on data in a small, fast, reconnectable private memory, called the Cache Memory (CM). The SMP moves data between the MM and CM. The ACP and SMP are microprogrammed processors; the macro library for each processor can be customized for particular applications and even modified by users.

A block diagram of the ST-100 appears in Figure 1. The CP executes an APCL routine which issues SMP and ACP macros. These macros are loaded into the SMP and ACP queues; the queues allow the CP to continue execution without waiting for the SMP or ACP. Two types of synchronization are available. In the first type, the CP can wait until the queues are empty and activity is complete; this is useful when the CP needs to test a result in order to decide which branch to take in a program, or to end the program. Alternatively, the SMP and ACP synchronize with each other to reconnect the CM; the CM is divided into several banks, each of which is connected to either the SMP or ACP.

### 2.1 Speeds

In order to perform vector operations, data must be moved from the MM to the CM. The SMP can move one word in either direction per 40 ns clock. The ACP is pipelined, and can produce two floating point multiply and two floating point add results in each 40 ns clock.

For simple vector operations, the ST-100 is memory bandwidth limited; for each result produced by the ACP, the SMP must move two operands to the CM, and the result back to the MM. The speed payoff for this machine comes when there are many operations being performed on each datum, such as in a Fast Fourier Transform.

### 2.2 Programming Considerations

Since the CM is relatively small, *strip mining* [3] is required for long vector operations. The size of the strips is not fixed, as would be the case for vector register machines [4], but depends on the number of variables kept in the CM at one time; fewer variables allow longer strips.

To insure the best machine utilization, the SMP and ACP should be kept as busy as possible. This means that some banks of the CM should be connected to the SMP which is loading operands for the next operation or storing results from the previous operation, while other banks of the CM are connected to the ACP. The ACP has three bidirectional connections to the CM and can perform several operations simultaneously. Since the SMP has only one, the number of ACP operations per SMP operand must average at least three in order for the ACP and SMP busy times to be balanced. Temporary results which do not need to be saved in the MM can help increase this operation/operand ratio.

### 2.3 APCL

APCL is syntactically similar to Fortran, but there are special constructs and restrictions which have to do with the way the ST-100 works. For instance, there is no DOUBLE PRECISION data type, since the ST-100 works with only 32-bit floating point numbers. Also, all variables must be explicitly declared as residing in one of the three memories: LM, CM, or MM.

A single APCL routine is called a PROCESS. The APCL process is executed by the CP, just as a Fortran subroutine would be executed by a standard computer. To invoke ACP or SMP macros, the APCL programmer codes macro CALLs; these look like ordinary CALL statements. The APCL compiler compiles macro CALLs into the proper code to build a parameter block and issue the macro to the SMP or ACP queue.

Figure 2 shows a simple Fortran DO loop written in APCL with SMP and ACP macro calls. Figure 2(a) shows a vector multiply written as a Fortran subroutine. Figure 2(b) shows how this would be translated into APCL to use the fast ACP unit.

```
      SUBROUTINE MULT(X,Y,Z)
      REAL X(1000),Y(1000),Z(1000)
      DO 10 I = 1,1000
   10  Z(I) = X(I) * Y(I)
      RETURN
      END
```

(a)

```
      PROCESS MULT(X,Y,Z)
      MAIN MEMORY
      REAL X(1000),Y(1000),Z(1000)
      CACHE MEMORY
      REAL (C1,CZ(1000))
      REAL (C2,CX(1000))
      REAL (C3,CY(1000))
C
      CALL STSYNC (000000)
      CALL SMM2C  (X(1),1,4,0, CX(1),1, 1000)
      CALL SMM2C  (Y(1),1,4,0, CY(1),1, 1000)
      CALL STSYNC (111111)
      CALL AVMUL  (CX(1),1, CY(1),1, CZ(1),1, 1000)
      CALL STSYNC (000000)
      CALL SMC2M  (Z(1),1,4,0, CZ(1),1, 1000)
      CALL STWAP
      END
```

(b)

Figure 2. Vector multiply.

## 3. The KAP/ST-100

The KAP/ST-100 translator automatically translates parts of Fortran subroutines, functions or main programs into APCL code. This translation can proceed with or without help from the user. The KAP/ST-100 will decide what portions of the subroutine to translate, translate the code into APCL, and insert system library calls to move data to and from the ST-100. User directives can be used to tune the generated code in order to improve overall program performance.

The KAP/ST-100 uses the most sophisticated automatic Fortran vectorization technology currently available. The KAP/ST-100 vectorizer includes such advanced transformations as loop interchanging, loop distribution, vector optimization and recognition of many reduction operations. The KAP/ST-100 performs both exact data dependence tests for the most common types of loops and symbolic tests when appropriate. The rest of this section gives an overview of how the KAP/ST-100 works. The actual translation to APCL is explained in detail in the next section.

### 3.1 Scanner

The KAP/ST-100 accepts the Fortran-77 language [5]. Future versions of the KAP/ST-100 will accept certain Fortran extensions, such as VAX/VMS Fortran extensions [6] for VAX hosts. Acceptance of extensions is largely for the convenience of the user, and will not affect the quality of translation.

### 3.2 Candidate Finder

The *Candidate Finder* finds and marks DO loops which are candidates for vectorization. Notice that the KAP/ST-100 also converts IF loops to DO loops when appropriate. This pass is very machine specific, since different vector machines have very different vector instruction sets. For example, the ST-100 can not do DOUBLE PRECISION arithmetic, so the KAP/ST-100 candidate finder rejects any statement containing DOUBLE PRECISION constructs. Each DO loop is examined; if a DO loop has no candidate statements, then the whole loop is marked as unsuitable and vectorization will not be attempted.

Another pass is made that examines all statements, not just statements in DO loops. The KAP/ST-100 does more than convert vector DO loops to vector code; it converts scalar Fortran to scalar APCL. Thus, the KAP/ST-100 includes a pass that examines each statement to see if it can be converted to APCL. Any statement that cannot be converted to APCL is left on the host. This affects how the program gets translated into APCL later.

### 3.3 Preparation Phase

In order to improve vectorization, the KAP performs such common transformations as induction variable recognition [7] and promotion of scalars to arrays [8]. In addition, certain IF constructs are recognized, such as IFs which save the maximum of a vector, or which find the index of such a maximum.

### 3.4 Vectorization

The KAP/ST-100 finds the best method to vectorize each DO loop nest in the program for the ST-100. The vectorizer builds a high quality data dependence graph for each loop nest, which finds where data is generated and used. [9,10] The vectorizer then performs loop transformations such as loop interchanging and loop distribution to find the best loop to vectorize. The data dependence graph is used to check for legality of these operations. Preference is given to long vector lengths.

### 3.5 Process Finder

Up to this point, the KAP/ST-100 has not yet decided what part of the Fortran subroutine to translate to APCL. The *process finder* selects regions of code that will be converted to APCL PROCESSes. Statements that cannot be converted to APCL are left on the host, but not all of the rest of the program will necessarily be translated. Unvectorizable DO loop nests are left on the host computer, unless they appear between two vectorized regions. However, even some vectorized DO loops may be left on the host. For example, a DO loop that does just a vector multiply is not a good candidate for translation to APCL, since the translated program would most likely execute slower than the original program due to the cost of moving data to and from the ST-100. This subject is taken up in more detail in Section 5.

### 3.6 Cleanup

Certain minor cleanup passes over the program are performed at this time. These include a unique pass called *expanded array shrinking*. Since the KAP performs extensive loop interchanging, the loop which will finally be vectorized is not known at the time that scalars are promoted to arrays. To allow the most loop interchanging, the scalars are promoted into multidimensional arrays. After loop interchanging and vectorization, some of the loops will be left scalar, and some of the dimensions are not strictly necessary. The cleanup pass expanded array shrinking removes the unnecessary dimensions of the temporary arrays, reducing their size.

### 3.7 Translation to APCL

Finally, the parts of the subroutine which have been chosen for translation into APCL are examined and converted into APCL PROCESSes. The program segment is replaced with system library calls to properly invoke the APCL PROCESS. This is discussed in more detail in the next section.

## 4. Translation of Fortran into APCL

At this point in the KAP/ST-100, one or more segments of the Fortran subroutine may have been selected for conversion into APCL. Each such segment of the subroutine is converted into a different APCL PROCESS. This conversion takes place in two steps.

### 4.1 Host Interface

First, the segment is scanned to find all variables or arrays that are used or changed. Any variables or arrays whose values are used must be sent from the host to the ST-100, and any variables or arrays whose values are changed must be brought back to the host after the APCL PROCESS completes. Arrays which are assigned but not used in the segment are also sent to the ST-100, because the assignment may be conditional or may only assign part of the array. When the values are brought back from the ST-100, they will write over the values currently in the host.

At this point, the segment of Fortran code is removed from the subroutine and is replaced by library routine calls. A call to the library routine KSTSCH is inserted to reserve a block of ST-100 Main Memory and set time limits for the PROCESS. For each array that must be sent to the ST-100, a call to the library routine KSTARY is inserted to declare that array in MM. Any scalar parameters are packed into two arrays (REAL and INTEGER), and sent over all at once. Then each array is transferred to the ST-100 using a call to the library routine KSTWR. Then a call to KSTLGO is inserted to load and invoke the APCL PROCESS. After KSTLGO, any arrays (or variables) which were modified by the segment of code are brought back from the ST-100 using KSTRD calls. A final call to KSTPRG clears the ST-100 Main Memory for the next process; ST-100 resources are not released, so that they can be reused by the next KAP-generated process.

One problem encountered with many Fortran subroutines is that formal parameter arrays are often declared with an assumed size for the last dimension:

```
REAL A(100,*), or
REAL A(100,1).
```

In Fortran, the upper bound of the last dimension of formal parameter arrays is usually ignored, and may in fact be left unspecified. Thus, the true size of formal parameter arrays may not be known. For the KAP/ST-100 to work properly, all arrays must be explicitly declared to the proper size. A future version will examine loop bounds and array references to find the maximum size used for all arrays, rather than the declared size.

### 4.2 Process Creation

Next the KAP/ST-100 creates the APCL PROCESS out of the Fortran subroutine segment. Because of restrictions and limitations in the APCL compiler, certain scalar optimizations must be performed in the APCL source to get the best speed.

There are no implicitly declared variables in APCL, so all variables that are used in the PROCESS must be explicitly declared, and placed in one of the three memories (MM, LM or CM). The KAP/ST-100 will perform all floating point arithmetic on the ACP, rather than in software on the CP, since the ACP is so much faster; this includes any scalar floating point arithmetic in the "tissue code" between vectorized DO loops. All the code is translated into the appropriate ACPL; the control structure of the PROCESS (scalar IF tests, serial DO loops) will be similar to the structure of the Fortran subroutine. All floating point arithmetic causes SMP and ACP macros to be generated, to move values to the CM, compute some results, and occasionally bring the result back to the CP for testing.

Vectorized DO loops generate a sequence of macro CALLs to load the operands into CM, perform the computation, and store the results. Intermediate results are kept in the CM, so temporary MM arrays are not needed. If the DO loop bound is not known at compile time, or if it is very large, then the loop has to be strip mined, just as would be necessary for a vector register machine.

Since the CP is so much slower than the SMP and ACP, the CP code must be heavily optimized. The KAP/ST-100 helps in this matter by performing source-level optimization, similar to what an optimizing compiler might do. All arrays in the APCL PROCESS are linearized, that is, converted to single dimensional arrays by fully expanding the subscript expressions. This allows the KAP/ST-100 to remove most of the subscript evaluation through common subexpression discovery and code floating. Strength reduction is also important since multiplication on the CP is very slow, even for integers.

The cost of enqueueing a parameter block on the SMP or ACP queues is relatively large; much of this relates to the time taken by the software to build the parameter block. The KAP/ST-100 has no control over this, but it can help by reducing the total number of macro calls. Use of multioperation macros and elimination of unnecessary synchronization macros are two ways of doing this.

### 5. Process Selection

The ST-100 gives the best performance when the program performs many operations on each datum. While a simple vector multiply will execute very quickly in the ACP, the cost of moving the vector multiply from the host to the ST-100 is large:

1. Move the three vectors from host memory to MM
2. Invoke the APCL PROCESS
3. Move the output vector from MM to the host memory.

The APCL PROCESS itself must incur some overhead because it must move the vectors from MM to CM and the result back. Unless floating point multiplication is very slow on the host machine this process will run much slower than performing the operation on the host, regardless of the vector length.

The KAP/ST-100 computes the costs and benefits of using the ST-100 in terms of number of operations per operand. The number of operands is the number of data items that must be moved between the host and the ST-100. In the case of a vector multiply (with a vector length of N), 4N data items must be moved (2N for the input vectors, 2N for the output vector going over and back). In the case of a matrix multiply (with a matrix size of N×N), $4N^2$ data items must be moved (two input matrices and one output matrix of size N×N). The number of operations for a vector multiply is N (N multiplies); for a matrix multiply, it is $2N^3$. Thus, the operation/operand ratio for a vector multiply is N/4N, or 1/4; for a matrix multiply, it is $2N^3/4N^2$, or N/2. This is a very coarse measure of the amount of benefit relative to the overhead cost of moving a set of operations to the ST-100. It is somewhat oversimplified, in that it assumes that all operations are equal cost.

However, even this coarse measure may be used as a starting point in deciding whether or not a set of operations should be moved to the ST-100. Certainly, a large operation/operand ratio will produce more speedup than a small one. A segment of code with a ratio of less than one will never run faster on the ST-100. A segment of code with a ratio that grows with the size of the problem will get even more speedup with large problems than with small; these segments of code are especially suitable for moving to the ST-100.

Adjacent segments of code should be moved together, if at all possible, instead of making two or more adjacent APCL PROCESSes. The decision of whether to move a segment of code to the ST-100 must be made with consideration of the surrounding code. For instance, by itself the vector multiply above is not suitable to move to the ST-100; however, if it were surrounded by two operations that were very suitable for the ST-100, such as matrix multiplies, then the total cost of a PROCESS containing both matrix multiplies and the vector multiply may be less than two PROCESSes each containing one matrix multiply.

The KAP/ST-100 tries to estimate the speedup of moving each independent segment of code to the ST-100. It then looks at adjacent segments of code and combines them as long as there is still speedup. The goal is to generate a program which has the most potential speedup. This goal is made difficult since usually some important parameters, such as the loop bounds, are unknown at compile time. Thus, some loops which look particularly suitable may at run-time turn out to have very short vector lengths, resulting in poor speedup.

### 6. User Interface

The KAP/ST-100 must explain to the user somehow just what happened to his program. The KAP/ST-100 listing shows user's program with the sections that are ported to the ST-100 marked. Those statements that are executed in vector mode are also marked.

One of the problems facing KAP/ST-100 users is how to figure out why one section of code was ported and not another. A variety of conditions affect this decision, and user directives may change the result. One of two DO loops may not be vectorizable or may not fit any known macro set. In this case, it may be faster to leave that loop on the host, and still move the other loop. Another consideration is the amount of data to be moved. One DO loop may use many arrays; the KAP/ST-100 may decide that the operation/operand ratio was too low, and leave that loop on the host. The KAP/ST-100 leaves the last word with the user; KAP directives can force the conversion of a particular segment of code, as long as that segment can be fully converted to APCL.

Another KAP directive modifies the ratio at which code is considered suitable for conversion to APCL. Since the ST-100 is faster relative to a small host (such as a VAX 11/730) than it is to a larger host (like a VAX 8600), some segments of code may be faster on the ST-100 with one host and faster on the host in another configuration. This KAP directive can even be used to force the KAP/ST-100 to convert almost all code that can be converted; this situation may be useful in shops where the critical resource is not time but money, and host CPU time is expensive where ST-100 time is inexpensive.

### 7. Examples and Speeds

The KAP/ST-100 output from a matrix multiply subroutine is shown here, including execution times. The input subroutine is shown in Figure 3(a); the KAP-generated host subroutine is shown in Figure 3(b) and the APCL PROCESS is shown in Figure 3(c). The host program proceeds in seven steps:

1. Call KSTSCH to reserve $3N^2+1$ words of ST-100 MM;
2. Pack all scalars into a temporary array (just N here);
3. Call KSTARY to declare arrays in ST-100 MM;
4. Call KSTWR and KSTWRW to write data values to the ST-100;
5. Call KSTLGO to load and execute the PROCESS MATMU0;
6. Call KSTRDW to read results from ST-100;
7. Call KSTPRG to clear ST-100 MM.

For each array declared in ST-100 MM, a three word descriptor is kept in the host program. This is used to pass that array as a parameter to the APCL PROCESS. The parameters to the KSTLGO subroutine are the PROCESS name, the number of PROCESS parameters, and a "type field" and the descriptor for each of the PROCESS parameters.

The APCL PROCESS bears little resemblance to the original subroutine, but some things do remain similar. The DO J and DO K loops are still recognizable; notice that the DO I loop was interchanged and vectorized for the ST-100. This was done to get stride-one MM accesses; non-one strides on MM moves will run at full speed unless the stride is relatively prime to the number of MM banks (8). The KAP/ST-100 tries for stride-one MM accesses when it can, which are guaranteed to run at full speed. Note also that the parameter arrays are declared as single dimensional arrays with very large bounds (to bypass any bounds checking). All array accesses are done via subscript arithmetic; the IV variables in the code are used for strength reduction and code floating.

In this experiment, the host was an unloaded VAX 11/780 with a floating point accelerator running the VMS operating system. The times for running SUBROUTINE MATMUL on the VAX alone compared with the times for running the KAP/ST-100 processed subroutine are shown in Figure 4. The CPU times shown are the times charged to the batch job for this test; the real times shown are the elapsed times for the batch job and the page faults are also from the batch job log. Notice that the CPU time is the VAX CPU time; there is no way to find the actual time spent in execution on the ST-100, except to infer it from the elapsed time for the job. For matrix size of 100×100, the ST-100 version already runs at least as fast as the VAX version (comparing VAX CPU time to VAX/ST-100 real time). The ST-100 version gets better as the matrix gets larger. Notice also the page fault figure; the VAX has a paged virtual memory and the program begins to thrash when the matrix size gets large. This also seriously affects real time. The SUBROUTINE MATMUL could be optimized for the VAX by interchanging loops to make the array accesses all stride-one. When this is done, the VAX CPU times improve by a factor of two, and the matrix size at which page thrashing begins goes up to somewhere between 300 and 400. Even with that improvement, the ST-100 version will run several times faster than the VAX version, with that ratio increasing as the matrices get larger.

The ST-100 attached array processor offers programmers a low cost high performance computational engine. The KAP/ST-100 gives Fortran programmers a convenient method to access this power.

```
      SUBROUTINE MATMUL(A,B,C,N)
      INTEGER N
      REAL A(N,N),B(N,N),C(N,N)
      DO 100 I = 1,N
      DO 100 J = 1,N
      DO 100 K = 1,N
 100   C(I,J) = C(I,J) + A(I,K)*B(K,J)
      END
```

Figure 3(a). Matrix multiply.

```
      SUBROUTINE MATMUL(A,B,C,N)
      INTEGER N
      REAL A(N,N),B(N,N),C(N,N)
      INTEGER ISCLRS (1), ISCLR0 (3), C0 (3), B0 (3), A0 (3)
      CALL KSTSCH (3 * (N * N) + 1)
      ISCLRS(1) = N
      CALL KSTARY (ISCLR0,1,1)
      CALL KSTARY (C0,N * N,2)
      CALL KSTARY (B0,N * N,2)
      CALL KSTARY (A0,N * N,2)
      CALL KSTWR (C,N * N,C0)
      CALL KSTWR (B,N * N,B0)
      CALL KSTWR (A,N * N,A0)
      CALL KSTWRW (ISCLRS,1,ISCLR0)
      CALL KSTLGO ('(MATMU0)',4,2,ISCLR0,3,C0,3,B0,3,A0)
      CALL KSTRDW (C,N * N,C0)
      CALL KSTPRG
      END
```

# DISTRIBUTED LANGUAGES DESIGN:

# CONSTRUCTS FOR CONTROLLING PREFERENCES

by

Tzilla Elrad :: Illinois Institute of Technology

Fred Maymir-Ducharme :: AT&T Bell Laboratories

## ABSTRACT

This paper first classifies controls used in concurrent programming languages within nondeterministic constructs. These controls are classified as private control, consensus control and hybrid control. We then illustrate the need for new and separate control, which we introduce and classify as preference control. Implementations of preference control using pre-existing primitives are illustrated and analyzed with respect to software engineering principles. The difference between preference control and priorities are discussed. Other issues and extensions are also discussed. The classification of these controls will help programmers to better understand and control nondeterministic constructs. The addition of a preference control primitive to a concurrent programming language will increase the language's expressive power if it could not previously implement it; otherwise, the inclusion of preference control as a primitive will simplify the language and satisfy software engineering principles.

**Key Words and Phrases:** Nondeterminism, Concurrency, control classifications, private control, consensus control, hybrid control, preference control, Ada, CSP, Concurrent C, priorities, language design and the implementation of the "pref" primitive.

## 1. *INTRODUCTION*

Many concepts and notations for distributed programming languages have been discussed in the past. [1] [5] [6] [12] [15] [16] This paper suggests and implements the addition of "preference control" to distributed programming languages with nondeterministic constructs. The paper is structured as follows:

Section 2 defines our notations and classifications of controls used to restrict nondeterminism in concurrent programming languages, which we call: private control, consensus control and hybrid control.

Section 3 describes: the need for a primitive to implement "preference control" to constrain nondeterministic constructs; some alternative implementations with the use of pre-existing control primitives; and the introduction and implementation of the "preference control" primitive for further control of nondeterminism in concurrent distributed programming languages.

Section 4 then discusses further extensions and issues raised with the implementation of preference control such as: fairness, priorities and conflicting concepts.

Examples are used from the following concurrent programming languages: CSP [8,9], Ada [11], Concurrent C [7], and Concurrent Prolog[13]. These examples are then analyzed with respect to software engineering standards [3] [10].

## 2. *CONTROL CLASSIFICATIONS AND NOTATIONS*

### 2.1 *NONDETERMINISM*

Pure Nondeterminism: an unconstrained choice from a finite number of alternatives. The select statement in Ada implements nondeterminism. Concurrent C also implements nondeterminism using the select statement. CSP uses the symbols "[" and "]" to surround the nondeterministic choices. Pure nondeterministic constructs are not sufficiently structured; hence, various programming languages have introduced the following controls for nondeterminism, which we have classified as:

### 2.2 *PRIVATE CONTROL*

Private control: nondeterminism restricted by boolean constraints, which we classify as private. Private control is considered open if the boolean expression is true; it is closed otherwise. Example 1a below illustrates private control in CSP:

Example 1a

```
[
 [] B1  ==>  S1
 [] B1  ==>  S2
 [] B2  ==>  S3
]
```

Example 1b -
illustrates private control in Concurrent C:

```
select {
        B1: immediate: S1;
        or
        B1: immediate: S2;
        or
        B2: immediate: S3;
       }
```

Example 1c below illustrates how private control can be indirectly implemented in Ada

0190-3918/86/0000/0176 $01.00 © 1986 IEEE

( although private control was not meant to be allowed in Ada, it can be implemented using the delay construct with 0.0 as the time parameter. ) :

Example 1c

```
select
   when B1 => delay 0.0; S1;
   or
   when B1 => delay 0.0; S2;
   or
   when B2 => delay 0.0; S3;
end select;
```

In these examples, statements S1 and S2 can only be chosen if the boolean expression B1 is true, and S3 can only be chosen if B2 is true. The choice is nondeterministic, yet restricted by the private control.

### 2.3 *CONSENSUS CONTROL*

Consensus control: nondeterminism restricted by environmental/communication constraints, which we classify as consensus. The choices are restricted to only those for which the communication is available from the rest of the system. Consensus control is considered established if the **rendezvous** can be established. Example 2a illustrates consensus control in CSP:

Example 2a

```
[
 [] P1?x   ==>   S1
 [] P1!y   ==>   S2
 [] P2?x   ==>   S3
]
```

Example 2b -
illustrates consensus control in Concurrent C:

```
select {
        accept entry1(x); S1;
        or
        accept entry2(y); S2;
        or
        accept entry3(z); S3;
        }
```

Example 2c -
illustrates consensus control in Ada:

```
select
    accept entry1(x:type_x) do S1;
    or
    accept entry2(y:type_y) do S2;
    or
    accept entry3(z:type_z) do S3;
end select;
```

In example 2a, S1 can only be chosen if process P1 is sending a value for x; S2 can only be chosen if process P1 is ready to receive a value y; and S3 can only be chosen if P2 is sending a value for x. In examples 2b and 2c, S1 will only be executed if another task is calling the entry1 and sending the value x. Likewise, S2 will only be executed if another task is calling for entry2 and sending a value of type y. The choice is made nondeterministically, yet it is restricted by the consensus control.

### 2.4 *HYBRID CONTROL*

Hybrid control: nondeterminism restricted by both boolean and environmental constraints ( private control and consensus control ), which we classify as hybrid control. Hybrid control is available if private control is open and consensus control is established.

Example 3a -
illustrates hybrid control in CSP:

```
[
 [] B1, P1?x  ==> S1
 [] B2, P1!y  ==> S2
 [] B2, P1?z  ==> S3
 [] B1, P2!z  ==> S4
]
```

In example 3a: S1 can only be chosen if B1 is true and P1 is sending a value for x; S2 can only be chosen if B2 is true and P1 is ready to receive a value y; S3 can only be chosen if B2 is true and P1 is sending a value for z; and S4 can only be chosen if B1 is true and P2 is ready to receive a value z. The choice is made nondeterministically, yet it is restricted by private control and consensus control.

Example 3b -
also illustrates hybrid control, in Ada :

```
select
 when B1 => accept entry1() ; S1; end entry1;
 or
 when B2 => accept entry2() ; S2; end entry2;
 or
 when B2 => accept entry1() ; S3; end entry1;
 or
 when B1 => accept entry2() ; S4; end entry2;
end select;
```

Example 3c -
illustrates hybrid control in Concurrent C:

```
select {
        B1 : accept entry1() ; S1;
        or
        B2 : accept entry2() ; S2;
        or
        B2 : accept entry1() ; S3;
        or
        B1 : accept entry2() ; S4;
        }
```

In examples 3b and 3c: S1 can be chosen if B1 is true and if entry1 is being called; S2 can be chosen if B2 and entry2 is being called; and so on... Again, the choice is made nondeterministically, yet controlled by private and consensus controls.

An alternative is ready if all of the controls have been satisfied; that is: if the private control is open and/or if the consensus control is established or if the hybrid control is available. The nondeterministic construct will check all of the controls in each alternative and then choose one of the ready alternatives. The programmer can include one, all or any combination of the controls allowed within the language′s nondeterministic structure to attain the desired expressive programming power.

## 3. *PREFERENCE CONTROL*

We will classify preference control as nondeterminism restricted by preferences; preference control gives the programmer the power to assign preferences to the choices within the nondeterministic construct. Each entry inside a nondeterministic construct may (but need not) have a preference. A lower value indicates a lower degree of urgency; the range of preferences is implementation defined. ( ie. a ready entry with a preference = 2 is chosen before a ready entry of preference = 1).

### 3.1 *OTHER EXISTING MECHANISMS FOR CONTROLLING NONDETERMINISM*:

Many languages contain primitives for the nondeterministic construct with private control, consensus control and/or hybrid control; but none contain the primitive for what we will classify as "preference control." The "by" construct was introduced by Andrews [2] and Concurrent C [7] later implemented the "by" construct and the "such that" construct. These constructs allow the entry to selectively choose an entry call from the entry queue instead of receiving the entry calls from the queue in FIFO order, which is the default. The "by" and the "such that" constructs differ from preference control in that they control choices from within an entry′s queue; "pref" controls the choice of alternatives within the select statement. The "cell" concept [14] allows explicit preference control amongst the entries within the select statement by attaching labels to entries and ordering the labels statically. Some languages can use other primitives to simulate preference control, but we will argue that these implementations are very complicated and unacceptable by software engineering standards. Preferences should allow some choices, within a nondeterministic construct, to be chosen before others. Concurrent C and Ada have implicitly defined preferences built into the language; in Concurrent C, an available accept alternative is chosen before an open immediate alternative. None of these languages contain a primitive to control preferences explicitly; this led us to the implementation of the "pref" primitive, which is necessary for preference control. Take for example, the resource manager that continuously releases and regains resources. Since the manager must have a resource in order to release it, a wise manager should give preference to the regaining of resources. The availability of the resource can be maintained by private control; the requests to release or return a resource can be checked by consensus control; but no primitive exists to express preference control, which is necessary in this case to give preference to the release of a resource. Therefore, we are forced to use other primitives to implement preference control, which we feel should be included as a primitive. These implementations require some programming effort and result in implementations that do not support software engineering principles. Some programming languages implement priorities; priorities will be discussed in a later section, since they are not part of what we have classified as controls for nondeterminism within unique tasks. Preference control can also be used to implement "fairness" and avoid process/task starvation; this will also be covered in section 4.1.

### 3.2 *IMPLEMENTATION OF PREFERENCES WITH EXISTING PRIMITIVES*

Suppose we have a process/task that is required to do one of four services ( service1, service2, service3 and service4), and that we wish to give the services preferences - that is, we wish to service4 if possible, else service3, else service2 and the least preference is to service1. Services 1 - 4 are all different. This cannot be implemented in CSP within the nondeterministic construct. This can be simulated in Ada in a couple of ways: (You might try to come up with some solutions yourself before reading the following known solutions)

1. Using low level system defined queues

Example 4

```
task CONTROLLER is
   entry SERVICE4(D:DATA);   -- very urgent
   entry SERVICE3(D:DATA);   -- urgent
   entry SERVICE2(D:DATA);   -- medium urgency
   entry SERVICE1(D:DATA);   -- low urgency
end CONTROLLER;

task body CONTROLLER is
begin
  select
    when B4 => accept SERVICE4(D:DATA) do
          ACTION4(D);
    end SERVICE4;
    or
    when B3 and (not(B4)
              or SERVICE4′COUNT = 0) =>
      accept SERVICE3(D:DATA) do
            ACTION3(D);
     end SERVICE3;
     or
     when B2 and (not(B4) or SERVICE4′COUNT = 0)
           and (not(B3) or SERVICE3′COUNT = 0)  =>
           accept SERVICE2(D:DATA) do
                 ACTION2(D);
            end SERVICE2;
     or
     when B1 and (not (B4) or SERVICE4′COUNT = 0)
         and (not(B3) or SERVICE3′COUNT = 0) and
         (not(B2) or SERVICE2′COUNT = 0) =>
            accept SERVICE1(D:DATA) do
                 ACTION1(D);
     end SERVICE1;
 end select;
end CONTROLLER;
```

1. This implementation is not very readable; it is not clear why the queues for service4, service3 and service2 are being checked if service1 is to be accepted.

2. All of those checks on the queues are expensive and make the implementation very complex.

3. Using the system defined low level queues forces the programmer to use low level commands, which ideally should be hidden from the user and are not desirable in a high level language like Ada.

4. This implementation requires a lot of modification if the user wishes to change the preferences or add entries with different preferences.

5. This implementation uses a "loop hole" in Ada, (ie. the COUNT attribute) to implement consensus control using private control. The use of the COUNT attribute as a condition is syntactically private control, and yet semantically consensus control. This inconsistency adds ambiguity to this problem.

6. This implementation is dangerous because it can cause the raising of an unnecessary exception. The semantics of the select statement specify that if all conditions ( the private control ) are false and there is no else alternative or terminate alternative included, then an exception should be raised. This rule was probably made assuming that the conditions covered by private control were static and could not change at a later time. But you can see by this example that if the boolean conditions are true, but the queues are empty, an unnecessary exception will be raised; although entry calls may be in progress. This faulty behavior can be caused by the inconsistent use of private control instead of consensus control ( as described in the latter paragraph).

2. Using nested select statements

Example 5

```
task CONTROLLER is
        entry SERVICE4(D:DATA);
        entry SERVICE3(D:DATA);
        entry SERVICE2(D:DATA);
        entry SERVICE1(D:DATA);
end;

task body CONTROLLER is
begin
Done:boolean = false;
while not(DONE) do
  loop
    select
      when not(Done) and B4 =>
      accept SERVICE4(D:DATA) do
           ACTION4(D); end SERVICE4; Done=true;

      else select
         when not(Done) and (not(B4)
              and B3) =>
              accept SERVICE3(D:DATA) do
                   ACTION3      (D); end SERVICE3; Done=true;

         else select
                    when not(Done) and (not(B4)
                    and not(B3) and B2) =>
                       accept SERVICE2(D:DATA) do
                            ACTION2(D); end SERVICE2; Done=true;

                    else select
                               when not(Done) and
                               (not(B4) and not(B3)
                               and not(B2) and B1) =>
                               accept SERVICE1(D:DATA) do
                                      ACTION1(D); end SERVICE1;
                                      Done=true;

                           else NULL;
                       end select;
                end select;
         end select;
    end select;
  end loop;
end CONTROLLER;
```

(NOTE: Could not use array/family of entries since all four entries are different)

1. This implementation is ambiguous; it is not clear why all of the nesting is necessary or how the nondeterminism will work in this case.

2. The nesting is very complex and will require further nesting if entries of different preferences were to be added!

3. This example requires an extra boolean variable (private control) and a loop (although the repetitive behavior of a loop is not desired) structure to make sure one and only one entry is accepted; this is extremely inefficient and confusing to a reader.

4. This example also implements "Busy Waiting", which is very expensive and inefficient.

5. This implementation is also very difficult to modify; changing the preferences of the entries would require renesting the entire select statement.

Both of these simulations are ambiguous and do not support software engineering standards. The need is then evident for a primitive to implement preference control within a nondeterministic construct.

### 3.3 *INTRODUCTION TO THE PREFERENCE CONTROL PRIMITIVE CONSTRUCT*:

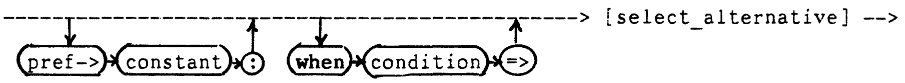
We propose the syntax: "**pref** -> <constant>" to assign a static preference control value within a nondeterministic construct. Dynamic preference control, in which we could pass "pref" the value of an expression, is much more powerful and expensive ( and out of the scope of this paper ). Static preference control is simple, easy to implement, and can be evaluated at compile-time. For the Ada nondeterministic construct, we suggest the following syntax for the select alternative:

Example 6

Syntax for the select alternative:

**pref** -> <constant>: **when** <condition> => select_alternative

SELECT ALTERNATIVE:



Example 7

```
selective_wait ::=
     select
        [pref -> constant : ]  [ when condition => ]
                select_alternative
       { or [pref -> constant : ]  [ when condition => ]
                select_alternative }
       [ else
          sequence_of_statements ]
      end select;

select_alternative ::=
    accept_statement [sequence_of_statements]
  | delay_statement  [sequence_of_statements]
  | terminate;
```

All of the nondeterminism constraints are listed before the entry call: first, the preference control (pref -> constant); followed by the private control (when <boolean expression>; and finally, the consensus control (=> accept <entry>). ( We considered placing the preference control declaration within the task entries declaration, but concluded it belonged within the select statement, with the other nondeterminism controls.) If a preference is not specified, it should default to the lowest value ( ie. if negative values for preferences are not allowed, then default to 0 ). The same value preference can be assigned to different entries within the same select statement to allow a greater amount of nondeterminism.

For example, using the nondeterministic construct "select" in Ada, combined with our proposed preference control construct, the problem described above can be solved by the following:

Example 8

```
task CONTROLLER is
   entry SERVICE4(D:DATA);        *** very urgent
   entry SERVICE3(D:DATA);        *** urgent
   entry SERVICE2(D:DATA);        *** medium urgency
   entry SERVICE1(D:DATA);        *** low urgency
end CONTROLLER;

task body CONTROLLER is
begin
  select
  pref -> 4: when B4 => accept SERVICE4(D:DATA) do
              ACTION4(D); end SERVICE4;
  or
  pref -> 3: when B3 => accept SERVICE3(D:DATA) do
              ACTION3(D); end SERVICE3;
  or
  pref -> 2: when B2 => accept SERVICE2(D:DATA) do
              ACTION2(D); end SERVICE2;
  or
  pref -> 1: when B1 => accept SERVICE1(D:DATA) do
              ACTION1(D); end SERVICE1;
  end select;
end CONTROLLER;
```

Semantics of preference control construct: Select one of the available alternatives with the highest pref value. More than one entry can have the same pref value; this will increase the nondeterminism of the choice.

1. This example is much more readable than the previous two and is much simpler and easier to understand.

2. Since nested select statements, loops and low level queues are not needed, this is also a more efficient implementation that supports software engineering standards.

3. Different entries could have the same preference and possibly differ in the private control or consensus control.

4. This construct adds expressive power to languages, like CSP, that cannot otherwise implement preferences.

5. A smart compiler could save some unnecessary evaluations by first evaluating the entries with the highest preferences.

6. This implementation is easy to modify; changes of priorities or the addition of entries would require minimal change of code.

7. This implementation does not contain busy waiting; nor does it include the danger of causing an exception handler to be raised unnecessarily because it makes a clear distinction between private control, consensus control and preference control.

The preference control primitive can directly be used to give an elegant solution to the resource manager problem by simply giving a higher preference to the releasing of resources. It should be noted that assigning preferences to the entries sequentially as they are ordered within the select statement is not a valid implementation of preference control, since the "pref" value of each entry would be unique; preference control requires that more than one entry can have the same "pref" value.

## 4. *EXTENSIONS & ISSUES OF PREFERENCE CONTROL*:

### 4.1 *FURTHER USE OF PREFERENCE CONTROL TO IMPLEMENT FAIRNESS*:

We propose the extension of the implementation of type tasks in Ada to allow specifying different preferences to the type tasks. A type task could be defined once (possibly with default preferences) and later, when these tasks are declared dynamically, the preferences could be listed as a parameter to the declaration. We could, for example, define :

Example 9

```
        task type CONTROLLERS( prefs -> a,b,c,d ) is
             entry entry1 ...
             entry entry2 ...
             entry entry3 ...
             entry entry4 ...
        end CONTROLLERS;

        task body CONTROLLERS( prefs -> a,b,c,d ) is
             :
             .
             select
                 pref -> a: ... accept entry1 ...
                 or
                 pref -> b: ... accept entry2 ...
                 or
                 pref -> c: ... accept entry3 ...
                 or
                 pref -> d: ... accept entry4 ...
             end select;
         end CONTROLLERS;
```

And then declare:

```
CONTROLLER1 : CONTROLLERS(1,2,3,4);
CONTROLLER2 : CONTROLLERS(4,3,2,1);
CONTROLLER3 : CONTROLLERS(2,3,3,1);
```

CONTROLLER1 is of type CONTROLLERS and was assigned a preference of 1 to entry1, a preference of 2 to entry2, a preference of 3 to entry3 and a preference of 4 to entry4. Oppositely, CONTROLLER2 was assigned a preference of 4 to entry1, a preference of 3 to entry2, a preference of 2 to entry3 and a preference of 1 to entry4. CONTROLLER3 illustrates that more than one entry can have the same pref value. Type tasks with preference control parameterizing would allow the programmer to assign different preferences to different instances of the same task without having to rewrite a copy of the task. The use of preferences can help avoid starvation of processes or tasks and could then implement fairness. Concurrent Prolog [13] implements fairness using the "stable machine", but the stable machine does not appear to implement nondeterminism as needed in our examples.

### 4.2 *PRIORITIES VERSUS PREFERENCE CONTROL*:

We distinguish between preference control and priority control. Priority refers to processes or actions to be chosen at the system level; preferences are defined at the user level. Priorities cannot be considered to be included in our classification of controls restricting nondeterminism within a task. Priority is a function from a set of tasks to a set of values; whereas, preference is a function from a set of entries within a task to a set of values. Priority controls the race among different tasks in the system level. Preferences control the race among entry calls within a task at the user level. Giving a process or task a priority would not solve the example above, since the same process can call the manager for the request or release a resource. Preferences give control to the server, whereas priorities give priority to the clients. Priority control is implemented in both Ada and Concurrent C.

In Ada, for example, the user can explicitly define the priority of a task using the "PRIORITY pragma", which is a suggestion/pragma to the compiler.

"Each task may be assigned a priority that overrides the default priority assigned to a task by the implementation. Tasks can be assigned a priority by using the PRIORITY pragma which is of the form: **pragma PRIORITY(P);** and is included in the specification of the task. P is a static expression of the implementation defined integer subtype PRIORITY. The higher the value of P, the higher the priority of the task."

Like Ada, Concurrent C implements process priority assignment. Concurrent C also implements a different version of priorities, using the "BY" construct, which allows the user to define/prioritize the tasks that could be served by an individual entry. The "BY" construct is considered a priority control because it controls the race among different tasks. Concurrent C controls this at the user level as an additional language within a nondeterministic construct, not at the system level like Ada does. The "BY" construct is not powerful enough to solve the resource manager problem, since we need to prefer one entry over other entries, not one task over another at the entry level.

Concurrent Prolog defines a stable machine as: " A Concurrent Prolog machine is ′stable′ if it always chooses the first unifiable clause for reduction, if several such clauses exist." Concurrent Prolog implements implicit preference control, but it does not do so within a nondeterministic construct. Therefore, we cannot classify Concurrent Prolog′s stable machine as a priority, nor as preference control, because it does not control a nondeterministic construct. Preferences are implicitly defined (and forced) by the ordering of the statements. Similar to preference control, the stable machine in Concurrent Prolog can implement fairness and decrease the chance of process/task starvation.

### 4.3 *NEW ISSUES RAISED BY PREFERENCE CONTROL*:

The additional expressive power of implementing preferences may bring about other difficulties such as: difficulty of implementation; and difficulty of use. Consider the following program in CSP with the addition of preferences:

Example 10

```
P:: P1 || P2

P1:: [
      [] pref->2, P2?x ==> S1;
      [] pref->1, P2!0 ==> S2;
     ]

P2:: [
      [] pref->2, P1?y ==> S3;
      [] pref->1, P1!0 ==> S4;
     ]
```

The above conflict arises when P1 & P2 are executed in parallel and are in essence "deadlocked"; this new type of error can be introduced by preferences. The programming methodologies of Communication Closed Layers [5] of constructing well-structured distributed programs may help avoid such errors, but cannot insure their discovery or elimination before run time. Ada and Concurrent C avoid this conflict by the asymetric use of the accept alternatives and the call alternatives within separate select alternatives.

These issues, and others that may arise from the combination of preference control and different language constructs, are out of the scope of this paper. We simply wish to introduce the concept of "preference control" restricting nondeterminism for concurrent programming languages. The actual implementation of preference control will have to vary for each individual programming language, depending on the language′s programming philosophies and methodologies.

## 5. *CONCLUSION*:

Nondeterminism is a central concept and issue in modern concurrent programming languages that exploits explicit parallelism. Controlling nondeterminism should therefore be an important issue of distributed programming language design. In this paper, we first classified the current available primitives that can be used for controlling nondeterminism : private control, consensus control and hybrid control. We then introduced and suggested the addition of a new language independent primitive to control nondeterminism, which we call preference control. Our examples have illustrated the expressive programming power of controlling nondeterminism with the above mentioned controls. We strongly suggest the use of preference control in real time applications, where it is urgently needed.

# REFINED FORTRAN:
# ANOTHER SEQUENTIAL LANGUAGE FOR PARALLEL PROGRAMMING

*Henry Dietz and David Klappholz*

Center for Distributed Processing
Stevens Institute of Technology
Castle Point
Hoboken, NJ 07030

**Abstract** — This paper presents the application of the refined-language methodology to **ANSI FORTRAN 77**. The resulting language, **RF77**, permits:

- Users to write code which differs from standard **ANSI FORTRAN 77** code only in that *data access* rights are more precisely specified
- Compilers, using well-known flow-analysis techniques, to generate consistently good, highly-parallel, race-free, code for virtually any machine architecture.

In modifying **ANSI FORTRAN 77**, our goal is not merely to find parallelism where none was envisioned by the programmer, but to provide a more general way of expressing algorithms for parallel computers of any type (MIMD, VLIW, SIMD, etc.).

## Introduction

In our paper, "Refined C: A Sequential Language For Parallel Programming," which appeared in the proceedings of ICPP 1985 [Die 85], we presented both a definition of the language **RC**[1] and a discussion of what the refined-language methodology is. We also claimed that the methodology could be applied to other languages — and everyone asked "Can you do it with **FORTRAN**?"

In this paper, we present both a review of the problems encountered when flow analysis is applied to unmodified **ANSI FORTRAN 77** (toward concurrency-detection), and the specification of **RF77**: *refined* **ANSI FORTRAN 77**.

As might be expected, the substantially different natures of **C** and **FORTRAN** are reflected in significantly different-looking refinements being made to **FORTRAN** as compared to **C**. However, the methodology remains intact.

## The Methodology

The *refined*-language approach begins with a conventional HLL — nearly any HLL: in this paper, **ANSI FORTRAN 77**. We have chosen this particular dialect of **FORTRAN** because it is a superset of most dialects in popular use, yet its specification is readily available. Because the **ANSI FORTRAN 8x** specification includes vector operations, it might seem, at first, that we are attempting to "re-invent the wheel" — but vector operations do not make generation of good MIMD code significantly easier [Die 86]. In addition, the refinements made to **ANSI FORTRAN 77** are compatible with the vector notation of **ANSI FORTRAN 8x**; hence, **RF77** can be easily transformed into **RF8x**.

Since **ANSI FORTRAN 77** contains no explicit parallelism or synchronization constructs, it is naturally impossible to write a race condition in the language. Likewise, a flow-analyzing compiler re-structuring code into a parallel form by using only correctness-preserving transformations will be incapable of generating a race condition. Therefore, if such a compiler is given pure **ANSI FORTRAN 77** code, the programmer is guaranteed that the parallelized program will produce the same result as the sequential program — the program will be debuggable. Perhaps even more important, using a compiler with a "back-end" appropriate for each parallel or sequential machine, the program will be completely portable.

Unfortunately, the amount of useful parallelism found by a flow-analyzing compiler examining a typical (unrefined) **ANSI FORTRAN 77** program is not necessarily all (or even a large fraction of all) that is present in the program

[1] The syntax of **RC** has been slightly altered to better conform to the draft specification of **ANSI C**. A revised definition of **RC** is available from the authors upon request.

0190-3918/86/0000/0184 $01.00 © 1986 IEEE

[Kuc 72]. This discrepancy is caused by certain language constructs obscuring (from the compiler's flow analysis) the fact that some operations could be parallelized. In refining **ANSI FORTRAN 77**, constructs which obscure the needed information are removed from the language and are replaced by modified versions which do not inhibit the analysis. These replacements can be made to look much like the original constructs and can provide all, or nearly all, of their expressive power. All the other language constructs remain as they were.

The resulting language, **RF77**, looks and "feels" like **ANSI FORTRAN 77**, but, unlike the latter, can be compiled into *reasonably efficient* race-free code for any kind of machine, parallel or sequential (assuming a compiler has been constructed for the machine in question).

## What's Wrong With FORTRAN?

For the purpose of automatically generating parallel code, it is convenient that typical (unrefined) **FORTRAN** programs are far simpler and more static than programs written in most other languages. Programs are simpler because **FORTRAN** is a relatively spartan language — there are not as many different ways to say the same thing as in most other languages. Programs are more static in that more information than usual about the run-time behavior of a program can be determined at compile-time. For example, the amount of data space required by a typical **FORTRAN** program is known at compile time; in most languages, the ability to perform recursive calls and to dynamically request chunks of memory makes determining the run-time size equivalent to solving the halting problem.

In these respects, **FORTRAN**, in any of its major dialects, is an ideal language for a compiler to analyze. This fact is evidenced by the multitude of parallelizing compilers for *dusty deck* **FORTRAN** [All 82] [Fis] [Kuc 84] [Nic 85] [KAI 85] and the lack of parallelizing compilers for almost any other language.

Although the simple, static, nature of **FORTRAN** programs aids the compiler in its analysis, there are **FORTRAN** constructs which severly impede analysis for automatic parallelism-detection. Any construct which blurs the compiler's picture of which data items might be accessed by any particular reference will result in the compiler making a "safe" assumption. For example, in:

```
C      For this and the following examples, assume
C      that labels 10 and 20 are never referenced;
C      they appear only to relate each example to
C      the discussion in the text.
 10    A =B * C
 20    D =E * F
```

it is obvious that the statements labeled 10 and 20 can be executed either sequentially or in parallel, but if and only if the answers to the following questions are "No":

(1) Is B or C an alias for D? Is E or F an alias for A?

(2) Are A and D aliases for each other?

If any part of (1) was answered "Yes," executing statements 10 and 20 in parallel could produce an incorrect result — a write/read race condition would exist. If (2) was answered "Yes," executing statements 10 and 20 in parallel would produce unreliable results — a write/write race condition would exist.[2] If static analysis could not answer either (1) or (2), or if either answer was "Sometimes Yes," the only "safe" assumption is that parallel code for statements 10 and 20 cannot be generated.

The previous example is somewhat contrived, because it is (usually) trivial for a flow-analyzing compiler to determine the answers to each of the above questions — any of the "dusty-deck" parallelizing compilers mentioned above could answer them. However, we will use minor variations on this example to demonstrate the analysis problems caused by each of the **ANSI FORTRAN 77** constructs which must be *refined.*

## References to Global Data (COMMONs)

Suppose that A, B, and C are all defined as independent variables which reside in a **COMMON** and that the statement labeled 20 is changed so that we now have:

```
10    A =B * C
20    CALL SUBR
```

[2] It is interesting to note that, in general, if an answer is known to be "Yes" then a sequential code optimization is possible. For example, if A and D are aliases for each other, statement 10 is a dead computation and can be eliminated.

Also assume that SUBR is a **SUBROUTINE** which is defined in another file. The questions the compiler must answer are essentially the same:

(1) Does SUBR (or any subprogram invoked by SUBR) contain any stores into B or C or any loads of A?

(2) Does SUBR (or any subprogram invoked by SUBR) contain any stores into A?

In order for the compiler to generate code which can safely execute statements 10 and 20 in parallel, the answers to both questions must be known to be "No."

The time complexity of some flow-analysis techniques used to attempt to answer these questions forces flow-analysis to be localized to small regions of a program (for example, a **SUBROUTINE** or **FUNCTION** at a time) — analysis of larger regions would take an unacceptably long time. Since the above example may require this analysis to be performed on the entire program,[3] the compiler would probably be unable to answer these questions. This, in turn, would force the compiler to make the "safe" assumption that every **SUBROUTINE** or **FUNCTION** call might affect every variable that appears in any **COMMON**. Sequential code results.

A less obvious, but very similar, situation exists relative to the use of I/O channels by subprograms. The I/O channel numbers act like global variables. Consider:

```
10   WRITE (6,*) A
20   CALL SUBR
```

It is impossible to tell if SUBR uses I/O channel 6 without looking, at the very least, at the code for SUBR.

## References using Pointers (Call-by-Address)

Let us now assume that A, B, and C are all defined as independent variables local to the **SUBROUTINE** in which the following code appears:

```
10   A =B * C
20   CALL SUBR(A, B)
```

As before, SUBR is assumed to be defined in another file; but, since we have already considered the problem, we will assume that there are no **COMMONs** in SUBR. Although **FORTRAN** does not explicitly support *pointers*, it does use call-by-address in passing arguments to **FUNCTIONs** and **SUBROUTINEs**. The compiler must now find answers to:

(1) Does SUBR (or any subprogram invoked by SUBR) store into B or load from A?

(2) Does SUBR (or any subprogram invoked by SUBR) store into A?

which, of course, would normally be too expensive for the compiler to answer.

## References to Indexed Data Structures

Let us return to our original example, again, slightly modified:

```
     IMPLICIT INTEGER A-Z
     DIMENSION G(100)
10   G(A) = G(B) * G(C)
20   G(D) = G(E) * G(F)
```

Again, we must answer nearly the same questions as for the original, trivial, example:

(1) Is G(B) or G(C) the same element as G(D)? Is G(E) or G(F) the same element as G(A)?

(2) Is G(A) the same element as G(D)?

However, these questions are much harder to answer. In fact, they cannot be answered at compile time if any of A, B, C, D, E, and F is given a value at run-time which is not related to all the other variables' values in an obvious way. For example, suppose a value is **READ** for A in the statement which is executed just before 10. It is not merely difficult to find answers to these questions by analysis; it is theoretically impossible in such a case. In other cases, answering these questions requires theorem proving.

If the value of any of A, B, C, D, E, and F is affected by a parameter entering the **SUBROUTINE** which contains the above example, then the corresponding argument to *every* **CALL** of that **SUBROUTINE** must be examined. This may be theoretically possible, but it certainly is not practical.

Since it can be very difficult to determine which element(s) of a data structure an indexed reference can access, it is often necessary to

[3] Recently, substantial advances have been made toward limiting the scope of analysis by constructing "programming environments" which incrementally collect the needed information. A good example of this is [Coo 85]. However, this mechanism alone is not capable of solving the problems described in section on **References to Indexed Data Structures.**

assume that such a reference potentially affects any (every) element of the array.

Several attempts have been made to resolve these analysis problems by having the programmer insert assertions. Some of these assertions have been of the form "Trust Me . . . it's safe to do this in parallel," which is very thinly-disguised explicit parallelism — with all the disadvantages thereof. The best approach to adding assertions is described in [Fis] and [Fis 84]. These assertions take the form of equations which can actually be checked for validity at run-time, but solving the equations is a complex task for the compiler and the assertions themselves are quite alien to the average **FORTRAN** programmer.

The **RF77** equivalent to assertions (the concept of *partitioning*) is both efficient and safe, but, most importantly, it makes sense in terms of expressing an algorithm.

### The Refinements

In each of the situations described above, the compiler's inability to resolve exactly which data items might be accessed by a particular reference must result in the "safe" assumption — that all possibly touched items are not "available" across such a reference — which typically forces the generation of sequential code. If we can enable the programmer to specify what really happens in these cases, more computations can be known to the compiler to be available, fewer precedence constraints need be artificially imposed by the compiler, and less of the generated code will be forced to be sequential.

Each refinement can be viewed as simply providing the programmer with a language construct which, while being intuitive and natural to the programmer, allows him to provide exactly the extra information the compiler needs.

### Access Permissions for Globals

As pointed-out in the discussion above, **FORTRAN** supports two basic kinds of global data:

- **COMMON**s, which are used to group sets of variables together by name and to give **FUNCTION**s and **SUBROUTINE**s access to the variables by these group (**COMMON**) names.
- I/O channel (logical unit, logical file) numbers, each of which is used to give the set of data within a file a name (number) and to give **FUNCTION**s and **SUBROUTINE**s access to the variables by that name.

the two are very similar in concept.

The kind of language structure needed to solve the problems associated with global data references closely resembles a **COMMON**. Unfortunately, although **COMMON** statements provide the naming features needed, they are scattered throughout the source program and potentially across a large number of files. To make compilation speed acceptable, the information must be available without having to scan the entire source program.

The required information about use of globals in an **RF77** program is placed in a separate *interface specification* file,[4] which is **#INCLUDE**d by all files that constitute the source program — much as **C** programs **#include** "header files." The *interface specification* file simply contains the definitions of global variables and the access permission each **FUNCTION** and **SUBROUTINE** has for each global.

Borrowing the terminology of Ada [Ada 80], there are two primitive kinds of access permission relevant in performing concurrency detection and generation of efficient parallel code:

**IN** For a variable, permission for the variable's *rvalue* to flow into the **FUNCTION** or **SUBROUTINE**; for a file, permission only to **READ** from the file.

**OUT** For a variable, permission for the *rvalue* of a variable to be different as the variable flows out of the **FUNCTION** or **SUBROUTINE** from what it was at entry; for a file, permission to **WRITE** to the file.

Also, as in Ada, these access permissions may be combined:

**IN OUT** For a variable, permission for the variable's *rvalue* to both flow into the **FUNCTION** or **SUBROUTINE** and to be different as the variable flows out; for a file, permission both to **READ** from and to **WRITE** to the file.

COMMON Permissions. Each individual entry within an **RF77** *interface specification* takes one of the following forms:

[4] A software tool currently under development, called **PREFINE**, will automatically convert a **FORTRAN** program into its **RF77** equivalent — including the creation of an appropriate *interface specification* file.

```
IN /global_name/ subprogram_list
OUT /global_name/ subprogram_list
IN OUT /global_name/ subprogram_list
```

where IN and OUT are as indicated above and IN OUT is equivalent to *both* IN and OUT permission. Note that *global_name* may be either the name of a COMMON or it can be blank, representing the unnamed COMMON.

The following is a skeletal example of the use of IN, OUT, and IN OUT:

```
C      this would be the interface spec., "TEST.H"
       IN /A/ SUBR1,FUNC2
C      SUBR1 and FUNC2 both can examine any var in A
       OUT /A/ SUBR2
C      SUBR2 can change any var in COMMON A
       IN OUT /A/ FUNC1
C      FUNC1 can examine and change any item in A

C      the following appears in TEST1.RF
#INCLUDE TEST.H
       FUNCTION FUNC1(. . .)
       COMMON /A/ X,Y,Z
       . . .
       END

C      the following appears in TEST2.RF
#INCLUDE TEST.H
       FUNCTION FUNC2(. . .)
       COMMON /A/ X,Y,Z
       . . .
       END

C      the following appears in TEST3.RF
#INCLUDE TEST.H
       SUBROUTINE SUBR1(. . .)
       COMMON /A/ X,Y,Z
       . . .
       END

C      the following appears in TEST4.RF
#INCLUDE TEST.H
       SUBROUTINE SUBR2(. . .)
       COMMON /A/ X,Y,Z
       . . .
       END
```

It is important to note that the RF77 compiler will flag any attempt to reference a global for which permission was not explicitly or implicitly granted: if any subprogram attempts to exceed the access rights granted by the *interface specification*, a fatal compile-time error will result. By the *interface specification* given in the previous example, the following definition of SUBR1 is an error because only IN rights were granted for members of the COMMON A:

```
SUBROUTINE SUBR1(B)
COMMON /A/ X,Y,Z
X = 5.0
END
```

By the same principle, any attempt to CALL a SUBROUTINE or FUNCTION which has access privileges beyond those of the caller also constitutes a fatal compile-time error:

```
SUBROUTINE SUBR1(B)
COMMON /A/ X,Y,Z
CALL SUBR2
END
```

I/O Channel Permissions. As we pointed-out at the start of this section, I/O channels are also a form of global, named by the INTEGER channel number (which is considered to be a *pre-defined* COMMON name). For example, the ability to READ from I/O channel 7 would be granted to subroutine SUBR3 by:

```
IN   /7/   SUBR3
```

The parallelization of I/O operations is traditionally one of the most difficult and unreliable language features, as evidenced by the lack of I/O operations in many new parallel-processing languages. In creating RF77, this problem is even more difficult because much of the flavor of FORTRAN is its style of I/O — drastically changing the I/O would have made RF77 drastically different from FORTRAN. We have chosen to maintain the FORTRAN I/O style, at a slight cost in reliability of parallelization.

To function properly, I/O operations would have to be based on naming *files* — but FORTRAN, and hence RF77, I/O is based on naming *channels.* RF77 *compilers assume that operations performed using different I/O channels are always independent of each other.* Strictly speaking, this is not always true — a single file may be associated with several I/O channels: if one is WRITEing, the compiler might accidentally create a race condition by assuming that operations on two different channels can proceed simultaneously. In fact, this can also cause unpredictable results on some single-processor machines, due to I/O buffering problems.

### Argument Passing & Parameter Definition

Each FORTRAN FUNCTION or SUBROUTINE is able to accept any number of call-by-address arguments. Since call-by-address is used, each argument passed to a subprogram could be carrying **IN**, **OUT**, or **IN OUT**, permissions to the *rvalue*: for the same reasons that a parallelism-detecting compiler must know the access permissions that subprograms have to **COMMON**s and I/O channels, the compiler must know which of these permissions each argument carries. As with global information, the same specification must be available to the compiler during compilation of both the **CALL**er and the **CALL**ed subprogram. The **CALL**ed routine cannot require access privileges not granted by the **CALL**er.

The access privileges granted by the caller for each argument should generally match those rights required by the called subprogram of its parameters.[5] By placing this information in the *interface specification*, it need be given only once for each **FUNCTION** or **SUBROUTINE**. **RF77** uses the following syntax to state which access rights are carried by each argument of a subprogram:

```
function_spec ::= ARGUMENT FORTRAN_type arg_spec
subroutine_spec ::= ARGUMENT arg_spec
arg_spec ::= sub_name ( a_p_list )
a_p_list ::= a_p_list , perm type_size
        | perm type_size
perm ::= IN | OUT | IN OUT | null_string
type_size ::= FORTRAN_type ( dim_list )
        | FORTRAN_type
        | null_string
```

where *FORTRAN_type* is any data type available in **ANSI FORTRAN 77**.

Normally, **ARGUMENT** specifications will state the access permission carried by each argument; however, if the access permission carried by an argument is not specified then the permission is assumed to be **IN**. The optional *type_size* specifications, if given, allow the **RF77** translator to perform type checking on arguments — a feature not related to parallel execution, but desirable for other reasons.

As an example of access permission specification, a subroutine to add its first two arguments and store the result in the third might be written as:

```
C       this would be the interface spec., "TEST2.H"
        ARGUMENT ADDSUB(IN, IN, OUT)

C       the following appears in TEST2.RF
#INCLUDE TEST2.H
        SUBROUTINE ADDSUB(A, B, C)
        C = A + B
        RETURN
        END
```

And ADDSUB would be called as, for example:

```
CALL ADDSUB(5, D, E)
```

A more concrete (but still artificial) example of the use of these constructs is the following matrix multiplication code:

```
C       this would be the interface spec., "MATMUL.H"
C       MATMUL and DOTPRO examine COMMON AB
        IN /AB/ MATMUL, DOTPRO
C       DOTPRO can examine,examine,&change its args
        ARGUMENT DOTPRO(IN,IN,OUT)
C       MATMUL can change its arg
        ARGUMENT MATMUL(OUT)

C       the following appears in some other file
#INCLUDE MATMUL.H
        SUBROUTINE MATMUL(C)
        REAL C(100,100)
        COMMON /AB/ A(100,100),B(100,100)
        DO 10 I=1,100
            DO 20 J=1,100
                CALL DOTPRO(I, J, C(I,J))
 20         CONTINUE
 10     CONTINUE
        STOP
        END

C       the following appears in yet another file
#INCLUDE MATMUL.H
        SUBROUTINE DOTPRO(I, J, C)
        COMMON /AB/ A(100,100),B(100,100)
        SUM = 0.0
        DO 10 K=1,100
            SUM = SUM + A(I,K) * B(K,J)
 10     CONTINUE
        C = SUM
        RETURN
        END
```

The constructs presented in this and the previous section enable the **RF77** compiler to determine which subprograms can be executed in parallel with one another *without* requiring expensive global analysis. The constructs presented in the next section permit the programmer to express information beyond that which can be expressed in a "dusty-deck" language, hence greatly increasing parallelism.

[5] In fact, these permissions often do not match. An individual call might pass more restricted rights than the subprogram normally requires, but that are known to be sufficient for that call. Capitalizing on this was deemed too risky.

## Indexing and Partitioning

Partitioning is the technique used by refined languages to create new names for arbitrary portions of a data structure. Once these names exist, it is a trivial matter to independently control the access permissions of each piece (called a *partition-element*).

C-Style Partitions. Partitioning can be viewed as a way of more-precisely specifying what pointers have permission to point at, which may imply a conceptual rearrangement of the object data structure such that elements which are not accessible appear to be removed from the structure. This the primary function of partitions in languages like C [Die 84] [Die 85].

Partitioning a matrix by an arbitrary formula specifying which partition-element each datum belongs to can produce partition-elements which *are not the same size or shape as the original array — perhaps not even rectangular.* For example, each "row" might be of a different length. This style of partitioning is what we call partitioning with *dynamic indexing*; that is, the shape and indexing structure may change dynamically according to the partitioning specification.

FORTRAN Partitions. FORTRAN doesn't support pointers. FORTRAN programmers don't want to think in terms of non-rectangular structures because conventional FORTRAN doesn't provide any way of building such structures.

In RF77, the shape and indexing structure of the *original data structure* must be preserved independently of the partitioning specification — we call this partitioning with *static indexing.*

Static indexing means that, for example, when a matrix is partitioned into partition-elements above and below the diagonal, each partition-element has the same indexing formulas and shape as the original matrix, but some of the data of the original matrix are inaccessible by each partition-element name: a reference to a datum by indexing the "above" partition-element, where the datum is conceptually contained in the "below" partition-element, is an error. In effect, static indexing means that partitioning is a zero-cost operation and each partition-element has a *membership test formula* associated with it.[6]

Partitioning is accomplished by the (apparently executable) PARTITION statement:

```
partstat ::= PARTITION ( structure , partlist part )
partlist ::=part ( condition ) , partlist
         | null_string
```

where *structure* is the name of the structure being partitioned (including dummy variables naming each subscript) and *part* is a name for a partition-element.

The *conditions* within a PARTITION statement are evaluated left-to-right *on only those data which have not yet been placed in a partition-element*, therefore, all partition-elements are guaranteed to be mutually exclusive: each datum can belong to only one at a time.

The following code illustrates the definition and use of a PARTITION which creates partition-elements naming the portions of the array A which are, respectively, above, on, and below, the diagonal:

```
      REAL A(100,100)
      . . .
      PARTITION(A(I,J), AUPPER(J .GT. I),
     1     ADIAG(I .EQ. J), ALOWER)
C     the following reference is valid
      AUPPER(5,7) =3.14159265
C     the following reference is not valid
C     and would cause a fatal compile-time error
      ALOWER(5,7) =3.14159265
```

The user may explicitly test whether a particular datum is a member of a partition-element by using the unary prefix operator .MEMBER., which simply applies the membership test formula for the following subscripted reference and returns a logical value of .TRUE. if that reference is valid. Thus:

```
C     the condition below is obviously .TRUE.
      IF (.MEMBER. AUPPER(1,99)) GOTO 30
C     this might or might not be .TRUE.
      IF (.MEMBER. AUPPER(4*K-1,L)) GOTO 30
C     the condition below is obviously .FALSE.
      IF (.MEMBER. AUPPER(I,I)) GOTO 30
```

## Compilation Techniques

Fundamentally, compilation of RF77 into efficient parallel code *is identical to* compilation of FORTRAN into efficient parallel code. Any

[6] The concept of membership also applies to other data structures. For example, an array membership test formula simply checks that subscripts are within bounds.

of the techniques of [All 82] [Fis] [Kuc 84] [Nic 85] [KAI 85] could be used and the result would be at least as good as — probably much better than — that obtained from "pure" FORTRAN.

Of course, just as we have our own parallel computer design [Par 86] [Die 85/2] in mind for the execution of these programs, we also have our own way of constructing *refined*-language compilers. The most unusual features of our approach are:

- Use of conventional (sequential) optimizing compiler flow-analysis concepts and techniques, as per [Coc 70] and [Aho 79], to build an *access-flow* graph.
- Use of non-deterministic *process-packaging*. The kind of parallel code generated is determined by a pruned search for target-machine-dependent structures within the *access-flow* graph. The basic technique is similar to that used by [Kru 82] for sequential code generation.

## Conclusions

In this paper, we have given a detailed presentation of the application of the *refined*-language methodology to ANSI FORTRAN 77, and we have given a reasonably precise definition of the resulting language, RF77, including many small examples.

Throughout our modifications, we have not changed the FORTRAN flavor of the language nor have we imposed any particular view of parallel processing. We have, however, built the language in such way that it can be easily compiled into efficient code for nearly any kind of parallel computer. Further, since these refinements aid *any* compiler in building a more accurate flow-graph, RF77 is completely compatible with, and efficiently usable by, compilers for single-processor machines. In fact, by applying conventional optimization techniques to the better quality flow graph, RF77 may actually be a more efficient language for SISD machines than ANSI FORTRAN 77.

# A VLSI COMPARISON OF SWITCH-RECURSIVE BANYAN AND CROSSBAR INTERCONNECTION NETWORKS *

*T.H. Szymanski*

Department of Electrical Engineering
University of Toronto
Toronto, Ontario, Canada

Abstract – A class of multistage interconnection networks (MINs) that minimizes the number of wire crossovers is presented. The basic idea is to use a MIN (made with smaller MINs) as the basic switch in the realization of a larger MIN. The resulting *switch-recursive* MIN has far fewer wire crossovers when compared to others MINs, such as the SW-Banyan, Baseline, Delta and Omega networks. More importantly, switch-recursive MINs have very distinct clusters in the topology, with heavy communications within clusters, and little communications between clusters. In a discrete component realization, such clustering makes the partitioning of these networks onto printed circuit boards, in a way to minimize edge connector and board costs, relatively straight forward. The network's physical size is reduced, and hence delays through the network are also reduced. In a VLSI realization, where the entire MIN is realized in a single integrated circuit, such clustering reduces the area requirements of these networks by up to 50%, when compared with the SW-banyan layout.

## 1. Introduction

With the emergence of VLSI technology and wafer-scale integration, the prospect of one day integrating an entire system on one wafer is growing. An important component in many systems, such as multiple processor architectures, is the interconnection network. A large number of interconnection networks have been proposed, the most predominant ones being the crossbar network, numerous multistage interconnection networks (MINs), and the single stage shuffle exchange network (SEN). Optimal layouts for SENs have been presented in [7], and the VLSI aspects of SW-banyans [6] and crossbars have been analysed in [4]. This paper extends the latter by introducing a class of banyan networks, called switch-recursive banyan networks (or SR-banyans), with a topology that tends to minimize the "crossovers" of wires. Such a topology is very useful in the VLSI layout and in the discrete component layout (i.e., with printed circuit boards) of MINs.

An analysis by Franklin on the VLSI requirements of crossbar and SW-banyan networks indicated that "for reasonable values of [network size] the two have roughly comparable space-time performance" [4]. A strong result of Franklin's work is that the area of both networks grows as $O(N^2)$, where $N$ is the number of input or output ports. While there is little that can be done to improve the layout or performance of a crossbar, a large number of parameters may be selected to improve the layout or performance of a banyan network. Switch-recursive banyan networks have such a topology. In addition, other aspects of the system such as the use of multiple metal layers for routing are examined in this paper. We present much simpler and more general models for VLSI area comparisons than presented in [4], and use these to calculate the area requirements of conventional SW-banyan and switch-recursive banyans.

One area of research identified by Franklin was the general question of which MIN, out of many topologically equivalent ones, (i.e., the SW-banyan [6], baseline [2], delta [10], omega [8], indirect binary $n$-cube [11]) to use in a discrete component environment. "The printed circuit boards and the wire interconnecting the boards are much larger contributors to system delays [compared with chip delays], primarily because the distances the signals must travel are orders of magnitude longer" [13]. Our analysis indicates that switch-recursive banyan networks are preferable to other MINs in a discrete component environment by virtue of their minimized wire crossovers, which will result in increased packaging densities and thus fewer boards and connectors to realize the system. Hence, the delays through interconnect in the network will also be reduced.

The use of recursion to realize large switches is not a new concept. However, the topological considerations of switch-recursive networks have gone largely unnoticed. A detailed examination of these issues is presented in this paper.

This paper is organized as follows. Definitions are presented in Section 2. Section 3 presents a simple VLSI area model for crossbars and SW-banyans. This model will be used to calculate the area requirements of the switch-recursive MINs introduced in a later section. Section 4 summarizes Franklin's VLSI delay models for SW-banyan and crossbar networks. Section 5 presents a comparison of SW-banyans and crossbars in a VLSI environment. Our assumptions and analysis are different from Franklin's, and hence our results are significantly different. Section 6 introduces the switch-recursion used to realize MINs with low wire crossover counts. Section 7 presents a VLSI comparison of switch-recursive banyans and crossbars in a VLSI environment. Section 8 contains some concluding remarks.

## 2. Definitions

Many of our definitions have been previously presented by Franklin [4]. We present a brief overview.

An $N \times N$ crossbar connects $N$ processors to $N$ memories, as shown in fig. 1a. The basic switch used in these crossbars has 2 states, which are shown in fig. 1b.

An $N \times N$ *SW-banyan* network, built with $2\times2$ switches, connects $N$ processors to $N$ memories, as shown in fig. 2a [6]. The basic switch used in these networks has 6 states, which are shown in fig. 2b.

*Network Cost:* In a discrete component environment, the cost $C$ of a network is usually the number of switches required to realize it. The cost of the crossbar $C_{cb}$ is $N^2$, and the cost of the banyan $C_{ba}$ is $(N/2)\cdot\log_2 N$.

*Network Delay:* The *average network delay* $D$, experienced by any individual connection request, can be modelled as $1/(1-pb)$ times the average path length through the network, were $pb$ is the *blocking probability* of a network under the assumed operating mode [10].

* This research was partially supported by NSERC (Canada) Grant A-5192.

0190-3918/86/0000/0192 $01.00 © 1986 IEEE

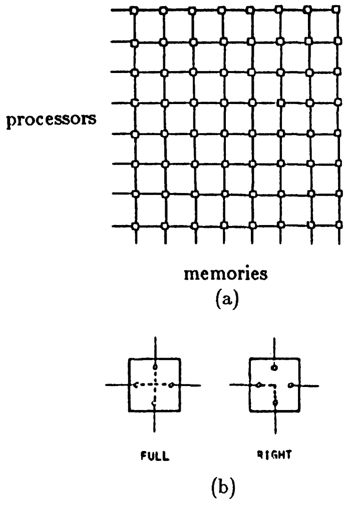

Fig. 1: a) an 8×8 crossbar network. b) the 2 states of a basic switch.

In a crossbar network, a request must travel through $N$ switches on average, hence the delay of a crossbar $D_{cb}$ is given by

$$D_{cb} \approx N \cdot \frac{1}{1-pb_{cb}} \tag{1}$$

where $pb_{cb}$ is the blocking probability of the crossbar network.

In a banyan network, a request must travel through $\log_2 N$ switches, hence the delay of a banyan $D_{ba}$ is given by

$$D_{ba} \approx \log_2 N \cdot \frac{1}{1-pb_{ba}} \tag{2}$$

where $pb_{ba}$ is the blocking probability of the banyan network.

The blocking probabilities of these networks are more difficult to arrive at. For simplicity assume that the network is synchronously circuit switched and all $N$ input ports are occupied in each cycle, (i.e., the network is fully saturated). Franklin used the $pb$ when the set of $N$ requests submitted during each cycle was a randomly selected permutation in the equations above. In this case the $pb$ of a crossbar is 0 and the $pb$ for the banyan was obtained by simulations. However, this permutation model biases the results in favour of the crossbar, since the banyan has large $pb$ 's under this assumption, even for very small $N$.

A more realistic, general performance comparison is to use the blocking probability when the requests are random and independent during each cycle. This model would correspond to general *MIMD* operating environments. In this case, the difference between the $pb$ 's for both networks is reduced considerably.

We assume that the requests submitted during each cycle are random and independent. Under this assumption, the $pb$ of an $N \times N$ crossbar is simply [10]

$$pb_{cb} = 1 - \frac{u_2}{u_1} \tag{3}$$

$$u_2 = 1 - \left(1 - \frac{u_1}{N}\right)^N$$

where $u_1$ is the probability that each processor issues a request in every cycle.

Under these assumptions, the blocking probability of an $N \times N$ banyan, built with 2×2 switches and with $n = \log_2 N$ stages, is simply [10]

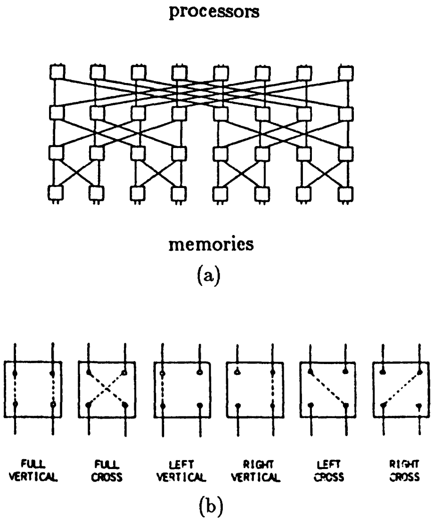

Fig. 2: a) a 16×16 SW-banyan network. b) the 6 states of a basic switch.

$$pb_{ba} = 1 - \frac{u_n}{u_1} \tag{4}$$

$$u_n = 1 - \left(1 - \frac{u_{n-1}}{2}\right)^2$$

and $u_1$ is as above.

*Cost-Delay Products:* A general figure of merit that has been used to compare networks is the ***cost · delay*** product [4]. Using these equations, the cost-delay figure of merit $C \cdot D$ for each of these networks, in a discrete component environment, can be computed:

$$C_{cb} \cdot D_{cb} = N^3/(1-pb_{cb}) \tag{5}$$

$$C_{ba} \cdot D_{ba} = N(\log_2 N)^2/2(1-pb_{ba}) \tag{6}$$

The remainder of this paper examines how this figure of merit changes when the entire network is realized in a single integrated circuit. As will be shown later, the area requirements of the SW-banyan are largely due to routing, and a topology that minimizes the wire crossover count will be introduced.

## 3. VLSI Area Models

We now present a simple and general model for the VLSI area requirements of SW-banyan networks. This model includes the effects of the use of multiple layers of metal for the routing, and is easily extensible to other topologically different MINs. In a later section we introduce the class of switch-recursive banyan networks, which require about 50% less area than the SW-banyan for large network sizes. The area models developed here will be adapted to calculate the area requirements of these recursive MINs.

### 3.1. VLSI Area Model For Crossbar Networks

An accurate model for the crossbar is difficult without undertaking a detailed design in a particular technology. To simplify the analysis, we assume the existence of a basic 2-input 2-output switch, with $w$ bits in each input and output, as shown in fig. 3. We assume that metal lines are 3 λ wide and must be spaced 3 λ apart, where λ is a basic dimension [9]. Assume that the basic switch is square and has dimensions given by Franklin's equation

$$L = 6\sqrt{K(\gamma + w^2)}$$

where $K \approx 1.5$, and $\gamma \approx 20$ [4]. We assume that the switch is

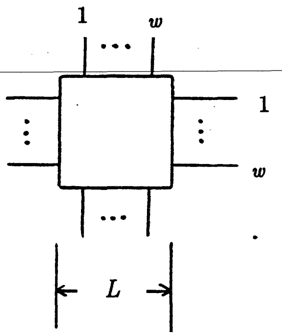

**Fig. 3:** the basic switch with $w$ bits in each input and output

square for simplicity, however, we note that non-square switches would reduce the area of the banyan network considerably.

Assuming the crossbar topology as shown in fig. 1a, the area of a $N \times N$ crossbar is approximately $(N \cdot L_{cb})^2$, where $L_{cb} = L + 3$ (the 3 is due to spacing between switches).

### 3.2. VLSI Area Model for SW-Banyan Networks

We assume that the SW-banyan network is made with basic $2 \times 2$ switches, with $w$ bits in each input and output, as shown in fig. 3, and that these switches have the same area as the basic switches used in the crossbar [4]. This assumption is valid if the control logic associated with each switch is not significant [4], and that the basic switch dimensions are limited by the minimum possible pitch for a transistor in the fabrication technology.

We currently ignore the increased area required by the line drivers used in the switches in the banyan network; this will be examined later. The SW-banyan network topology we are assuming is shown in fig. 2a.

A $2 \times 2$ switch requires height $L_{cb}$, since we assume the basic switches have comparable complexity, as in [4]. The wires into and out of the sides of the basic switch must be bent to go vertically, which will increase the horizontal space required by each switch. We assume, as Franklin did, that each switch can be realized in width $W_{ba} \approx L_{cb} + 6w$, as shown in fig. 4a. Note that $W_{ba}$ may be decreased if more layers of metal are used for routing, and the area of the banyan will be reduced proportionately.

Assume the technology used has at least 2 layers of metal used for routing. By implementing all horizontal inputs in one layer and all horizontal outputs in another, the layout in figures 4a and 4b are realizable. A small area above or below each switch may have to be used to convert from one layer to another (for channel routing).

Consider the $N \times N$ SW-banyan network shown in fig. 2a. This network clearly has a recursive structure; it consists of one stage of $2 \times 2$ switches, connected to two smaller networks of size $N/2$ each. Between the first and second stages (from the top), exactly $N/2$ links, with $w$ bits each, will cross an imaginary line drawn vertically through the middle of the network. Assuming that the vertical components of links are routed on one layer and the horizontal components of links are routed on another, the vertical height required for routing these links is then $(N/2)6w$. Note that this is true regardless of the basic switch size used in the banyan network.

If we have more than 2 layers of metal, then assume any extra layers are used to route the horizontal links between stages. If we let $s$ denote the number of metal layers used for horizontal routing, then the vertical area required is reduced by a factor of $s$.

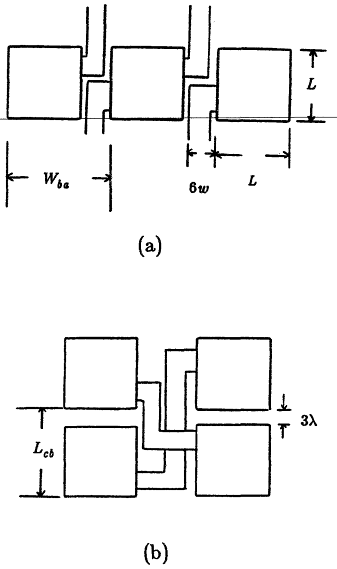

**Fig. 4:** a) minimum horizontal spacing for switches. b) minimum vertical spacing for switches.

(The effects of extra layers on the switches must be reflected in the basic switch size $L$, but it appears that $L_{cb}$ will not change much for a crossbar; In the case of the banyan, $W_{ba}$ may be reduced, and the network's area requirements are reduced proportionally).

The height of the network, $H_{sw}(N)$, is determined by the the height of the first stage of $2 \times 2$ switches, the height required for routing between the first stage and the two smaller networks of size $N/2$, and the height of the smaller network of size $N/2$:

$$H_{sw}(N) = \frac{6wN}{2s} + H_{sw}(2) + H_{sw}(N/2)$$

$$H_{sw}(2) \approx L_{cb}$$

Assuming that a $4 \times 4$ banyan has the layout shown in fig. 4b, then

$$H_{sw}(4) \approx 2L_{cb}$$

### 3.3. Driver Considerations

The preceding development has ignored the area required for drivers in each stage of the banyan network. The propagation delay through a long line is minimized by having a sequence of successively larger drivers driving the line [9]. Franklin has shown that the area of a driver will require between 10 and 30% of the area of the line being driven (assuming NMOS fabrication) [4], and assumed the value 25%, as we will do (i.e., $v = 0.25$). We now must derive an expression for the line length.

Assume the line length must be greater than some minimum value $(2/0.75\alpha)$ in order for a driver to be necessary. The reason for this choice will become apparent in the section on delays.

Consider switches in the first stage of the $N \times N$ SW-banyan. Each switch will have two types of drivers; $w$ drivers that drive a line with a vertical component only, and $w$ drivers that drive a line with both vertical and horizontal components [4]. The vertical component of a line after the first stage is $\approx 6wN/2s$. The sum of the vertical and horizontal components of a line with both components is $\approx (6wN/2s) + (N/2) \cdot (W_{ba}/2)$, of which $\approx W_{ba}/2$ is used to reach the drivers (if any), and the remaider is the length of the line being driven.

We assume these drivers are implemented in a way to increase the vertical dimensions of the switch, rather than the horizontal [4]. Each switch may have $w$ drivers of each type, which must be realized within the width of the switch $W_{ba}$ (note that we differ from Franklin here, and this difference is not insignificant). Assume each line contributes height $dr_{sw}(p)$ to the height of the switch, where $p$ is the line length:

$$dr_{sw}(p) = \frac{v(3 \cdot p)}{W_{ba}} \quad \text{if } p \geq \frac{2}{.75 \cdot \alpha}$$

$$dr_{sw}(p) = 0 \qquad \textit{otherwise}$$

The added height due to drivers after the first stage, $DR_{sw}(N)$, is then

$$DR_{sw}(N) = w \cdot dr_{sw}\left(\frac{6wN}{2s}\right) + w \cdot dr_{sw}\left(\frac{6wN}{2s} - \frac{W_{ba}}{2} + \frac{N}{4}W_{ba}\right)$$

$$DR_{sw}(2) = 0$$

Assume that a 4×4 banyan has the layout shown in fig. 4b and that no drivers are used:

$$DR_{sw}(4) = 0$$

The height of an $N \times N$ SW-banyan network is then

$$H_{sw}(N) = \frac{6wN}{2s} + DR_{sw}(N) + H_{sw}(2) + H_{sw}(N/2)$$

The width of the banyan network is determined by the $(N/2)$ 2×2 switches, and is given by $\approx (N/2)W_{ba}$. Hence, the total area required for a $N \times N$ SW-banyan, made with 2×2 switches, with $w$ bits per input/output, and with $s+1$ metal layers for routing, is given by

$$\approx H_{sw}(N) \cdot \frac{N}{2} W_{ba} \tag{7}$$

## 4. VLSI Delay Models

We use the NMOS delay models developed by Franklin [4], but with a few modifications. Recall that Franklin assumed that the $pb$ used in equations (5) and (6) was the observed blocking probability when the request pattern submitted during each cycle was a randomly selected permutation. We assume that the individual requests are random and independent. Hence, in our delay model the crossbar also has a non-zero blocking probability.

In addition, Franklin assumed that all lines being driven in the banyan required drivers. This is not true in the last few stages where the line lengths are relatively small.

### 4.1. General VLSI Delay Models

A very brief summary of Franklin's NMOS delay models is presented [4]. Assume each switch is implemented with NOR gates in NMOS technology. If each gate has a fanout of $f$, and each switch has $m$ levels of logic, then the switch delay is typically [4]

$$\approx 2.5mf\ \tau$$

where $\tau$ is the transit time through the gate's active region.

If the gate is driving a line of length $p$ whose total capacitance is comparable to the gate capacitance, then the delay associated with driving such lines is [4]

$$\approx \tau(1 + 0.75\alpha p)$$

If the line to be driven has a total capacitance that is much larger than a minimum sized gate's capacitance,then the delay is minimized by having a sequence of successively larger drivers driving the line [4,9]. Assuming each gate is 4 times the size of its predecessor [4], then the delay associated with driving a line of length $p$ is

$$\approx 2\tau \log_2(0.75\alpha p)$$

If the line is very long, then a resistance factor should be taken into account and a transmission line model should be used. We assume that a simple capacitance based model is sufficient.

Franklin assumed a value of $\alpha$=0.1. However, an examination of *SPICE* circuit parameters for NMOS and CMOS indicates that $\alpha$=0.03 is typical today. The value $\alpha$=0.03 will be used throughout this paper. An implication of this assumption is that lines can be much longer before a driver is required.

Let $d(p)$ be the delay due to a line of length $p$:

$$d(p) \approx 2\,\tau \log_2(0.75\alpha p) \quad \text{if } p > \frac{2}{0.75\alpha}$$

$$d(p) \approx \tau(1+0.75\alpha p) \quad \text{if } p \leq \frac{2}{0.75\alpha}$$

$$d(p) = 0 \quad \text{if } p = 0$$

### 4.2. Crossbar Delay Model

The delay of an $N \times N$ crossbar is given by [4]

$$D_{cb} = \frac{\tau}{1-pb_{cb}}\Big(2.5Nmf + (N-1)(1+0.75\alpha 3)\Big) \tag{8}$$

We will use $m=2$, $f=2$, and $\alpha$=0.03 throughout the paper, and $pb_{cb}$ can be calculated from equation (3). The parameter $\tau$ will cancel out later.

### 4.3. SW-Banyan Delay Model

Let $D(N)$ be the average path delay through an $N \times N$ SW-banyan:

$$D(N) \approx \frac{1}{2}\left[ d\left(\frac{6wN}{2s}\right) + (1+0.75\alpha W_{ba}/2)\tau + d\left(\frac{6wN}{2s} - \frac{W_{ba}}{2} + \frac{N}{4}W_{ba}\right) \right] \tag{9}$$

$$D(N/2) + D(2)$$

where $D(2) = 2.5mf\ \tau$. Within the large brackets, the first term is the delay of a line with a vertical component only, the second term is the delay to reach the line drivers for lines leaving the side of the switch, and the third term is the delay over a line with a vertical and horizontal component.

If we assume that 4×4 banyans have the layout shown in fig. 4b and have no drivers, then

$$D(4) \approx (1+0.75\alpha W_{ba})\tau + 5mf\ \tau$$

Hence, the delay of an $N \times N$ SW-banyan is given by

$$D_{ba} = \frac{1}{1-pb_{ba}} D(N) \tag{10}$$

where $pb_{ba}$ can be calculated from eq. (4).

## 5. VLSI Comparisons

### 5.1. SW-Banyan and Crossbar Comparisons

In fig. 5, the area, delay and space-time comparisons of SW-banyan and crossbar networks are presented. The space-time ratios in the VLSI environment are similar to the cost-delay ratios in the discrete component environment.

Our area results for the SW-banyan are lower than Franklin's by about 30% [4], which can be explained as follows. While Franklin's analysis was basically correct, his equation (16) increased the area of the banyan by one extra stage of drivers. (This alone accounted for an error of 25%). Also, Franklin's analysis assumed that the area required by drivers was realized in such a way that the width of the switch did not increase (only its height was allowed to increase). Hence, the vertical contribution to a switch of width $L$ due to a driver requiring area $A$ was given by $A/L$. However, while the true switch width is $L$, switches are

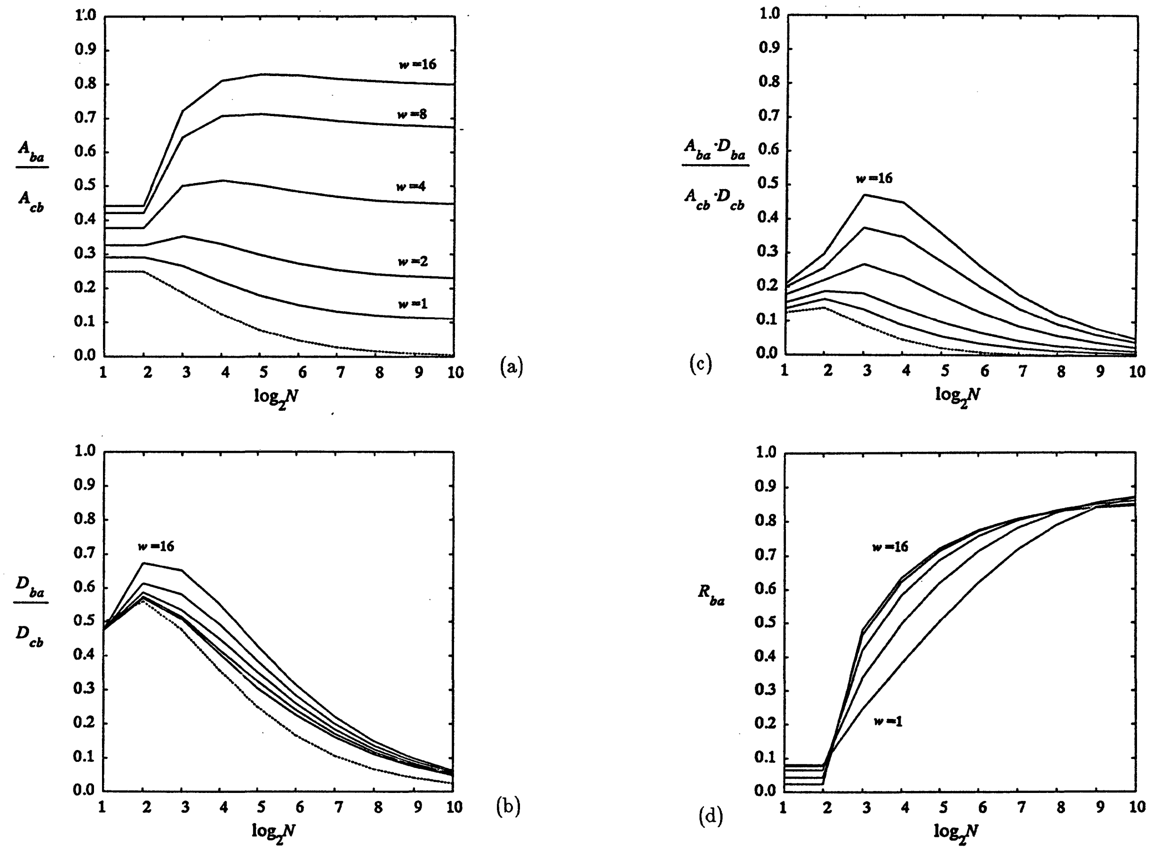

**Fig. 5:** a) ratio of SW-banyan to crossbar areas. b) ratio of SW-banyan to crossbar time delays. c) ratio of SW-banyan to crossbar space-time products. (dashed curves are from traditional analysis); d) fraction of SW-banyan area used for routing.

spaced $6w$ apart, so each switch requires $L + 6w \approx W_{ba}$. Hence, our analysis assumed that the drivers can be realized over the width $W_{ba}$, and the added contribution to a switch's height is then $A / W_{ba}$.

Our delay curves are significantly different from Franklin's since we assumed that the blocking probability of these networks under the assumption of random request distributions was used in equations (8) and (10), and we have used the value of $\alpha$=0.03. The effectiveness of each network is indicated in fig. 5c, the space-time ratios. Our space-time ratio drops off more rapidly than Franklin's, indicating that banyans become more effective as $N$ increases.

Fig. 5d illustrates the area required by routing in the SW-banyan networks. As the network size $N$ increases, this area rapidly approaches an asymptotic limit. This limit can be explained as follows. As $N$ increases, the area required by switches in a banyan approaches 0, and the majority of the area is due to routing and drivers. The area of actual metal routing (not including the spacing between metal lines) is about 50% of the banyan's area, and the drivers require 25% of this area (by assumption). Hence, the drivers require about 12.5% of the area of a banyan, for large $N$.

## 6. Recursive MINs

The preceding graphs indicate that in a VLSI realization, the majority of a large SW-banyan's area is devoted to interconnect between stages. This area can be reduced by selecting a topology that minimizes the wire crossover count. In a discrete component realization, minimizing the wire crossovers will result in increased packaging densities, and hence minimized cost and delays. In this section, we present such topologies.

The SW-banyan network shown in fig. 2a (in section 2) clearly has a recursive structure; a network of size $N$ consists of one row of 2X2 switches that are connected to two smaller networks of size (N/2) each. We introduce another type of recursion, which we call ***switch-recursion***. The basic idea is to use a MIN (made with smaller MINs) as the basic switch in the realization of a larger MIN. We illustrate the concept by examples on various MINs, which we call SR-MINs.

### 6.1. Switch-Recursive Delta Networks

Consider a 64X64 ***delta*** network [10] made with 2X2 switches, as shown fig. 6a. This network can be reorganized into a network where each recursive switch is a 4X4 delta network, as shown in fig. 6b, and into a network where each recursive switch is a 8X8 delta network, as shown in fig. 6c. An advantage in the latter realizations is the decreased wiring complexity. In a printed-circuit board environment, each recursive switch should be realized on the same board. This would translate into an increased component density per board (since less board area is used for routing to edge connectors), fewer boards to realize the network, and decreased interboard communications and delays (through edge connectors and ribbon cables). In a VLSI environment, the clustering and high connectivity within each recursive switch will result in reduced wiring area. (Many automatic placement and routing programs look for such clustering in the "net list" of a circuit, for improved layout [12]).

### 6.2. Switch-Recursive Banyan Networks

The previous figures illustrated the recursive process when

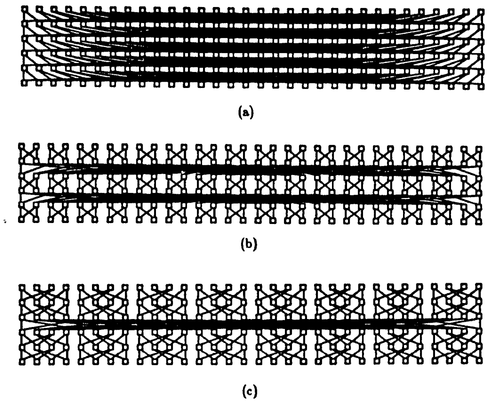

**Fig. 6:** a) a 64×64 delta network. b) a 64×64 delta network with 4×4 recursive switches. c) a 64×64 delta network with 8×8 recursive switches.

applied to delta networks. In a VLSI environment, the SW-banyan network has significantly lower area requirements than the delta. The recursive process can also be applied to SW-banyan networks, as shown in fig. 7. (Note that "delta" networks are actually a subclass of "banyan" networks, as defined in [6]; we use the term "SW-banyan" to denote the topology illustrated in fig. 2a and fig. 7a).

### 6.3. Generalized Switch-Recursive Banyans

A large number of possible topologies exist when switch level recursion is used. A conventional $N \times N$ network can be realized by an $m$ stage network, where each stage is made of $k_i \times k_i$ crossbars [3]. The integers $<k_1,k_2,...,k_m>$ correspond to the factors of $N$, i.e., $k_1 \cdot k_2 \cdot \cdots \cdot k_m = N$. Given a basic switch size, such as a 2×2 crossbar, we can synthesize each $k_i \times k_i$ crossbar with a MIN, provided the crossbar size is a power of 2. After applying switch level recursion corresponding to some factorization of $N$, we are left with a $\log_2 N$ stage network with $N/2$ switches per stage, as before. However, the topology is different and generally has more localized communications.

Clearly, this recursion can be extended to many levels, so that a $k \times k$ switch could be realized by recursive switches, which in turn use recursive switches. We have not yet proven results on an optimal factorization of $N$. However, a heuristic that seems to give optimal results is as follows (let $n = \log_2 N$). To realize an abstract $N \times N$ network, we use a 2 stage recursive SW-banyan, with recursive switches of size $2^{\lfloor n/2 \rfloor}$ in one stage, and recursive switches of size $2^{\lceil n/2 \rceil}$ in the other stage. One recursive banyan network derived from this heuristic is shown in fig. 7b. This particular network requires only one level of recursion.

The recursion process only improves the area requirements when the network size is >8. We have written a ***branch and bound*** routine to try all possible factorizations for a particular $N$, and the heuristic always yields the optimal result.

## 7. VLSI Comparison of SR-Banyans and Crossbars

An analysis of the area requirements of SR-banyans is now presented. Let $H_{sr}(N)$ represent the height required for an $N \times N$ SR-banyan. The SR-banyan consists of 2 stages, with recursive switches of size $2^{\lfloor n/2 \rfloor}$ in one stage, and recursive switches of size $2^{\lceil n/2 \rceil}$ in the other stage, where $n = \log_2 N$.

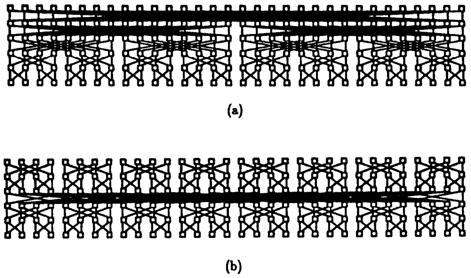

**Fig. 7:** a) 64×64 SW-banyan network, made with 2×2 switches. b) 64×64 SW-banyan network, made with recursive 8×8 switches, in turn made with 2×2 switches.

Our analysis indicates that the area and delays are minimized when the smaller switches are in the first stage, so let each recursive switch in the top stage be of size $2^{\lfloor n/2 \rfloor}$. The recursive switches in the top stage have width $T_{ba} = 2^{\lfloor n/2 \rfloor - 1} * W_{ba}$, and the recursive switches in the bottom stage will have width $B_{ba} = 2^{\lceil n/2 \rceil - 1} * W_{ba}$, where $W_{ba}$ is the width of a 2×2 switch as described in section 3.

Since $N/2$ links, with $w$ bits each, will cross an imaginary line drawn through the middle of this network, the vertical height required for routing between these two stages is $6wN/2s$, where $s$ is the number of metal layers used for horizontal routing.

The height required by drivers for a recursive switch in the top stage must be calculated. Consider a recursive switch nearest the middle of the row in the top stage. At this point, the channel used for routing the wires is most dense and any height required for drivers will contribute to the height of the network (at the ends, the drivers can extend into the channel since very few wires exist there). One line leaving this switch will have ≈ a vertical component of $6wN/2s$ only, two lines will each have this vertical component and a horizontal component of $\approx B_{ba}$, another pair of lines (if any) will have this vertical component and a horizontal component of $\approx 2B_{ba}$, etc. Assuming that the total driver area can be realized over the width of the switch $T_{ba}$, then each line of length $p$ contributes height $dr_{sr}(p)$ to the height of the switch (note that $T_{ba}$ changes according to $N$):

$$dr_{sr}(p) = \frac{v(3p)}{T_{ba}} \quad \text{if } p > \frac{2}{0.75\alpha}$$

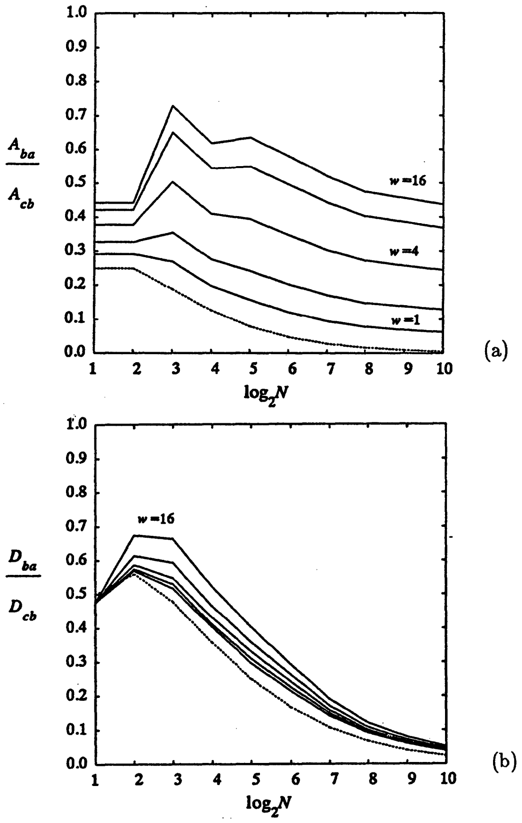
$$dr_{sr}(p) = 0 \quad \textit{otherwise}$$

The total height added to a switch due to drivers is then

$$DR_{sr}(N) \approx \sum_{i=1}^{2^{\lfloor n/2 \rfloor}} w \cdot dr_{sr}\left(\frac{6wN}{2s} + abs\,(2^{\lfloor n/2 \rfloor - 1} - i) \cdot B_{ba}\right)$$

where $n = log_2 N$. Hence, the total height required for the SR-banyan is then

$$H_{sr}(N) = \frac{6wN}{2s} + DR_{sr}(N) +$$
$$H_{sr}(2^{\lceil n/2 \rceil}) + H_{sr}(2^{\lfloor n/2 \rfloor})$$



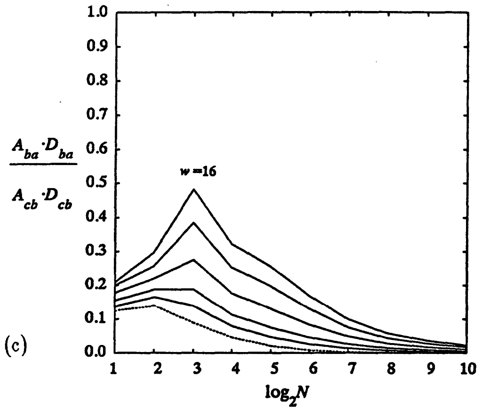


**Fig. 8:** a) ratio of SR-banyan to crossbar areas. b) ratio of SR-banyan to crossbar time delays. c) ratio of SR-banyan to crossbar space-time products. (dashed curves are from traditional analysis);

where $H_{sr}(2)$ and $H_{sr}(4)$ are as before.

The total area of an $N \times N$ SR-banyan is then

$$\approx H_{sr}(N)\cdot\frac{N}{2}W_{ba} \qquad (11)$$

The delay equations from section 4 can be adapted in a similar manner to yield the delay of SR-banyans. (We have used the average delay over a recursive switch at the end of each row and a recursive switch nearest the middle of each row.)

Fig. 8 illustrates the area, delay, and space-time comparisons between SR-banyans (given by the heuristic) and crossbars in a VLSI environment. The area requirements of the SR-banyans are about 50% less than that of SW-banyans for large $N$. For $N=1024$, with $b=16$ and $s=1$, the SR-banyan requires 45% less area than the SW-banyan, and has 19% less delay. For $N=16{,}384$, the savings are 49% and 25% respectively. (Note that Delta [10] and Omega [8] networks require $O(N^2 \cdot \log_2 N)$ area, and are not even considered here.)

Fig. 9 illustrates the area and space-time comparisons when 2 and 4 layers of metal are used for horizontal routing. Clearly, as more layers of metal are used, the banyan network becomes more attractive.

## 8. Conclusions

A class of multistage interconnection networks, called SR-banyans, that minimizes the number of wire crossovers has been presented. The basic idea is to use a MIN (made with smaller MINs) as the basic switch in the realization of a larger MIN. We have presented a heuristic that appears to yield the optimal network, in terms of minimized wire crossovers, for a given network size $N$ and a given basic switch size $k$. The resulting ***switch-recursive*** banyan has far fewer wire crossovers when compared to others MINs, such as the SW-Banyan, Baseline, Delta and Omega networks.

More importantly, switch-recursive MINs have very distinct clusters in the topology, with heavy communications within clusters, and little communications between clusters. It has been estimated that printed circuit boards and wire interconnect are much bigger contributors to system delays than gates, in a discrete component realization [13]. In [2] it is estimated that the round trip network delay is dominated by cable delay, which is irreducible because it is imposed by the physical size of the assemblage. The clustering in switch-recursive MINs makes the partitioning of these networks onto printed circuit boards, in a way to minimize edge connector and board costs, relatively straight forward. The delay through a switch-recursive banyan realized in a discrete component environment should be reduced significantly, since fewer edge connectors and ribbon cables must be traversed, and since the network size should be reduced significantly.

In a VLSI realization, where the entire MIN is realized in a single integrated circuit (as a $\log_2 N$ stage network with $N/2$ switches per stage), such clustering reduces the area requirements of these networks by up to 50% (for large $N$) when compared with the SW-banyan layout. The average delay through the network is reduced by up to 25% (for large $N$) when compared with the SW-banyan layout. (The area required for an 8×8 banyan can be improved further; see [14].)

However, even better layouts for banyans exist if we assume that the links into the network are not necessary. This could be true if a) processors are realized on the same substrate and have negligible area, as in [7], or b) each switch actually contains a processor. Asymptotically up to 50% of the area of the SR-banyan or up to 75% of the area of the SW-banyan can be saved. The savings is achieved by laying out the top row of a SW-banyan as two horizontal rows, one above the other, and each half as long as the original. The two subnetworks (of size $N/2 \times N/2$) are placed one above and one below this "row" (using the SR-banyan layout), for a total area about equal to that for the two subnetworks. (For $N=1024$, $b=16$, and $s=1$, this layout requires 48% less area than that for the SR-banyan, and 70% less than that for the SW-banyan.)

While this paper has focused on SW-banyans and SR-banyans, the results are more general. It has been proved that all "strict-buddy type MINs" (i.e., SR-banyan, SW-banyan, baseline, delta, indirect binary n-cube, and omega networks) are isomorphic [1]. Hence, if we are able to change the labels assigned to the pro-

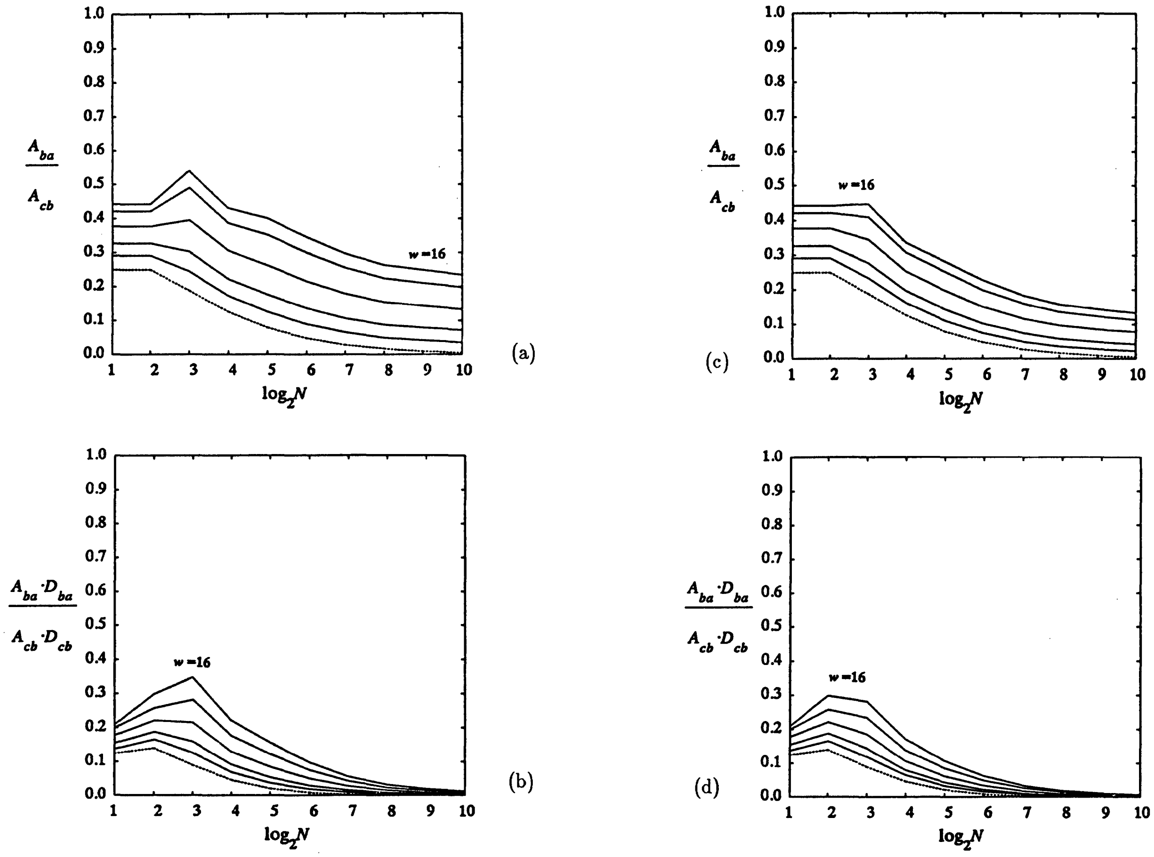

**Fig. 9:** a) ratio of SR-banyan to crossbar areas when 2 layers of metal are used for horizontal routing. b) ratio of SR-banyan to crossbar space-time products when 2 layers of metal are used for horizontal routing. c) ratio of SR-banyan to crossbar areas when 4 layers of metal are used for horizontal routing. d) ratio of SR-banyan to crossbar space-time products when 4 layers of metal are used for horizontal routing.

cessors connected to an SR-banyan, than any strict-buddy type MIN can be realized. This labelling can be accomplished by having a writable register associated with each processor that contains its label. This result has an important implication. The omega network is very useful in array processor architectures [8], but has a very high cost due to the number of link crossovers. However, we can transform the omega network into an SR-banyan, and obtain the exact same behaviour at a much lower cost. Similarly, any other strict-buddy type MIN can be realized simply by changing the processor labels.

## ABSTRACT

This paper envisages to evaluate three types of static interconnection networks for VLSI implementation. At first, a realistic VLSI computational model has been proposed taking into account several aspects of VLSI technology, like chip embedding, interconnection delay, chip yield, device dissipation, device failure, etc. The criteria of evaluation have been selected from three orthogonal aspects - physical (chip area and dissipation), computational speed (message delay and message density) and cost (chip yield, operational reliability and layout cost). The result of the evaluation reveals that the Cellular Networks similar to two dimensional meshes are most suitable for on chip parallel processing in VLSI. The salient feature of this paper is to augment the selection criteria for the interconnection networks from the classical $AT^2$ metric and to provide results pertaining to realistic VLSI implementation.

## 1. INTRODUCTION

Over the past two decades many interconnection networks have been proposed in the literature for SIMD architectures. Extensive accounts of these networks and their performance evaluation have been reported in [1, 2, 3, 4]. Now with the advent of submicron silicon technology, more than ten million devices can be integrated in the VLSI circuit [5] and it has opened a new vista in parallel processing. On-chip multiprocessing by several processors for executing special algorithms is envisioned to be the major application goal of the future generation computers using massive parallelism.

In order to justify the need for re-evaluation of interconnection networks, it should be noted that in the design of earlier networks adapted for non-VLSI environment

a. spatial distribution of the processors is not a constraint on the design,

b. signal propagation time is exclusively determined by the velocity of electromagnetic wave in the resistive medium and is negligibly small compared to the speed of operation. Thus the length of the interconnecting wire is not a constraint on design,

c. cost of the system is directly proportional to the average number of links per node,

d. fault-tolerance capability of such networks is merely a topological property (i.e., whether alternate message transmission routes exist or not)

On the contrary, under a VLSI environment

a. the spatial distribution of the processors play an important role on the total chip area.

b. the interconnecting wire behaves as transmission line having both resistive and capacitive components and signal propagation time is largely dependent on these values which are directly proportional to the length of the interconnection,

c. link per node does not have any direct relevance to design cost. The regularity of the networks topology decides the layout cost and size of chip decides the fabricational cost,

d. fault-tolerance has an additional role to play. To improve the device yield and thereby to reduce the overall cost, it is necessary to introduce redundant processors. The existence of long interconnects increases the chip failure probability, both at the time of fabrication and in normal operation.

This paper which was written as a term project in an architecture course envisages to evaluate the performance of three types of static interconnection networks and to determine how these new constraints modify the performance of these interconnection networks in VLSI implementation. The choice of the networks has been motivated from the facts that these networks have been widely pursued in the literature for designing many algorithms [6, 7] and all of them have optimal VLSI layouts. Also, these provide the insights to three topologically different classes of networks. The networks discussed are: two dimensional meshes, binary trees and Cube Connected Cycles (CCC). These three networks conceptually belong to separate classes in the sense that if the interprocessor link is constrained to have constant length, their distribution in three dimensional space reveals somewhat planar, conical and spherical surfaces, respectively. Thus the results of this evaluation can be easily extended to assess the performance of other networks, because most networks have one of these three topologies in three dimensional space. Networks with wraparound connections like the ILLIAC IV describe a torroidal surface and are not suitable for VLSI implementation because the endaround interconnection introduces large delay and also expands the area by a factor of two. Otherwise, the overall performance of these networks is similar to two dimensional meshes [3].

At first, a computational model for the VLSI technology is proposed and the results of the model is employed to evaluate the performance of the networks. The model is similar to Thompson's [8] model and additionally accounts for device faults and chip yield. The criteria of evaluation are enumerated from three orthogonal viewpoints, viz. area, speed and cost. The results of the analysis are compared and it is concluded that the regular structured Cellular Networks having short interconnects similar to the two dimensional meshes are the most suitable candidates for VLSI implementation with two layered interconnects. It may be pointed out that the conclusion

[1] This research was supported by the *Semiconductor Research Corporation* (SRC) under contract 84-06-049.

made here is on the basis of asymptotic performance and may not hold good for small sized networks. Some of the results discussed here have been reported by other researchers. But the modest objective of this paper is to identify the relevant aspects of VLSI technology and to demonstrate that under the new constraints (like chip yield, layout regularity, failure probability of long interconnects, reliability improvement per redundant processor, etc.), Cellular Networks indicate overall better performance than H-tree, CCC and other fast networks. This is in direct contrast to the results of [3, 9] where it was concluded that fast networks like CCC, PSN, dual bus hypercubes, etc., have better overall performance. The paper is organized as follows: Section 2 discusses the VLSI model, Section 3 discusses the criteria of evaluation, Section 4 provides the performance analysis, Section 5 compares the performance of these three networks and Section 6 concludes the paper.

## 2. VLSI MODEL OF COMPUTATION

The model is based on MOS and C(omplementary)MOS technologies and assumes a two layered model for interconnects. The two layered model uses one layer of polysilicon and one layer of metal for interconnection networks. A two layered model is easy to fabricate and provides a high yield. A composite two layered metal interconnects like Al-Pt-Ti-Au improve the device performance, but is difficult to fabricate and is not assumed in this model. The model makes four types of assumptions as discussed below:

### 2.1. Embedding Assumptions:-

**Assumption 2.1.1:** *All processors are identical in shape and size.*

Since the processors have identical computational power, they need equal computational area and hence can be identical in shape and size.

**Assumption 2.1.2:** *Each processor occupies O(1) area and can be represented as a square of unity area.*

The natural layout of any computational circuit has a rectangular topology. Any rectangular topology can be converted to a square topology by increasing the overall area by at most a factor of three [10, 11].

**Assumption 2.1.3:** *Wires always run either in vertical or in horizontal direction in two different layers.*

This scheme is called the Manhattan interconnection technique [12]. Since the processors are aligned parallel to the Cartesian co-ordinates, interconnection wires being perpendicular to the sides of the processors run along the horizontal and vertical directions.

**Assumption 2.1.4:** *At most two wires may cross over each other at any point in the plane.*

In MOS technology metal wires can cross over either polysilicon or diffusion without making contact. Whenever polysilicon runs over diffusion automatic contact is established resulting in a transistor at the overlapping surface.

**Assumption 2.1.5:** *Wires can bypass the faulty nodes.*

Switches can be placed over the processor to isolate them [13] and built in self test circuit can be incorporated to test whether the processor is faulty.

**Assumption 2.1.6:** *Wire of length $l$ behaves as a transmission line having $O(l)$ resistance and $O(l)$ capacitance.*

Since the interconnection wire has distributed resistance and capacitance all along the length of the wire, $O(l)$ assumption is justified.

### 2.2. Timing Assumptions:-

**Assumption 2.2.1:** *Processors have O(1) computational delay.*

Since the processors are identical in shape and occupy O(1) area, the delay is constant.

**Proposition 1** *Wire of length, $l$ introduces $O(l^2)$ delay and this is the upper bound of propagation delay.*
Proof: see [14].

For metal wire, the delay can be reduced to $O(\log l)$ by introducing a cascade of drivers as stated in the following proposition.

**Proposition 2:** *The metal wire of length, $l$ has a minimum of $O(\log l)$ delay and it needs $O(\log l)$ stages of drivers having a combined area of $O(l)$.*
Proof: see [15].

Mead & Conway [14] have shown that quadratic propagation delay in polysilicon (or diffusion ) wire of length $l$ can be minimized to $O(l)$ by introducing $l/k$ drivers at regular interval such that the driver delay is equal to signal propagation time over polysilicon (or diffusion) of length $k$. Thus

**Proposition 3:** *The poly/difusion wire of length, $l$ has a minimum of $O(l)$ delay and it needs $l/k$ stages of drivers having a combined area of $O(l)$.*
Proof: see [14].

Ramachandran [16] has shown that if many parallel long wires exist and space available externally to the processors is not sufficient to lay down all the drivers, then the delay can be minimized at the cost of increasing the size of the processors. In the worst case, this results in quadrupling the area of the processor.

### 2.3. Energy Dissipation Assumption:-

**Assumption 2.3.1** *Each processor of size $O(1)$ consumes $O(1)$ power in unit time.*

Since the power consumption in CMOS occurs due to charging and discharging of nodal capacitors, the switching power consumption at a node is equal to $0.5CV^2f$, where $f$ is the frequency of operation and C is the nodal capacitance. For a static CMOS circuit, the total switching power dissipation depends on the input to the processor and the internal circuit configuration of the processor. On the average, the dissipation will be a constant fraction of the total processor area and is bounded by $O(1)$. For dynamic CMOS circuit, since each gate will be charged by the refreshing clock, an $O(1)$ power consumption automatically follows.

**Proposition 4:** *Wire of length $l$ consumes at most $O(l)$ power.*
*Proof:* The power consumed by the resistor $R(l)$ in charging the capacitor $C(l)$ is equal to $0.5C(l)V^2f$. The capacitor stores charge only and does not dissipate any energy. Hence the upper bound is $O(l)$. □

### 2.4. Failure Assumptions:-

The failure in VLSI can be classified into two categories - chip related defects which lower the IC yield and the field operational which is a function of time.

**Assumption 2.4.1:** *Defects in the fabrication of an IC (viz., pinhole defects in oxide, defects in photoresist, implant defects, etc.) are randomly distributed and statistically independent.*

Generally, gross imperfections causing large areas of the chip to be bad (i.e., area defects) are detected at slice test and and line defects (like scratches) do not occur in a well-controlled process [17]. The most commonly encountered chip related flaws are random isolated spot defects. Clusters of spot defects also occur, but they can be treated as a single defect since usually the size of the processor is large enough to encompass the whole cluster. Thus the probability of failure of processors is independent and the same for all the processors.

**Assumption 2.4.2:** *The yield of an IC decreases inversely with the size of the chip.*

Since the defects occur randomly as Poisson's process, the yield (i.e., the probability of having no defect in a chip) is given by

$$Y_0 = e^{-AD_0} \qquad (2.4)$$

Practical results show that this under-estimates the yield slightly for larger size chips [18] and Poisson's distribution of random defects represents the yield pessimistically [19]. A better fitting with practical results has been obtained by employing Bose-Einstein statistics and it is shown [20] that the yield of defect-free chips are given by

$$Y_0 = \frac{1}{1+AD_0} \qquad (2.5)$$

where, $AD_0$ is the average number of defects per chip.

The random distribution of defects can be assumed to increase linearly with size for small sized defects like pinholes and to decrease as the cube of defect size for large sized defects like those occurring in diffusion patterns [21]. Using this random defect distribution, it can be shown that the effect of these defects on interconnection is very drastic and the failure rate is related to the aspect ratio of the interconnection wire. Formally,

**Proposition 5:** *Long wire of length, $l$ and width, $\lambda_w$ can fail with a probability proportional to $O(l/\lambda_w)$.*

Proof: Let L be a long wire of length, $l$ and width, $\lambda_w$. Let a circular defect of diameter, $\eta$ occur randomly on the conducting wire resulting in a hole as shown in Figure 1. If the width of the conducting material available for current conduction is sufficient to carry current in normal operation without causing any catastrophic failure, then the pinhole caused by the defect will not have any effect on the wire. Let $\delta$ be the minimum width of the wire required for normal operation at a particular current density, then defects of diameter, $\eta<(\lambda_w-\delta)$ will not cause any failure, while the defects of diameter, $\eta \geqslant (\lambda_w-\delta)$ will cause failures if they occur such that they do not leave $\delta$ width of conducting wire. The locus of the center of defects that lead to failure is called *critical area*, $A(\eta)$ and is given by

$$A(\eta) = \begin{cases} 0 & \text{for } 0 \leqslant \eta < (\lambda_w - \delta), \\ (\eta - \lambda_w) l, & \text{for } (\lambda_w - \delta) \leqslant \eta < \infty. \end{cases}$$

If $f(\eta)$ denotes the distribution of defect density, then the average value of the critical area with respect to defect size distribution is given by

$$\bar{A} = \int_0^\infty A(\eta) f(\eta) d\eta.$$

Very small defects can be assumed to increase linearly with defect size up to a certain value (say $\eta_0$) and large defects can be assumed to vary inversely as the cube of defect size [21]. Thus

$$f(\eta) = \eta/\eta_0^2 \quad \text{for} \quad 0 \leqslant \eta < \eta_0,$$
$$f(\eta) = \eta_0^2/\eta^3 \quad \text{for} \quad \eta_0 \leqslant \eta \leqslant \infty.$$

Hence,

$$\bar{A} = \int_{\lambda_w}^{\infty} (\eta - \lambda_w) l (\eta_0^2/\eta^3)\, d\eta = O(l/\lambda_w), \quad \text{assuming } \delta << \lambda_w.$$

The probability of failure of the wire is directly proportional to its critical area and is $O(l/\lambda_w)$. □

## 3. CRITERIA FOR EVALUATION

The interconnection networks have been modeled to study three aspects - a) the physical aspects, b) the computational aspects and c) the cost aspects. The overall performance of the networks has been estimated from these viewpoints which form three orthogonal classes.

### 3.1. Physical aspects:

The physical aspects relate to the chip area and power consumption by the chip.

### 3.1.1. Chip Area

The chip area refers to the total area required to lay the processors and the communication links. The area occupied by the processors is the computation area. The ratio of the computation area to the total area is the performance metric and is defined as *area efficiency*.

### 3.1.2. Power Consumption

Like the chip area, the total power consumed by the chip can be divided into computational power which is equal to the power dissipated by the processors and the power required to drive the communication links. The ratio of the computational power to the total power consumed by the chip is defined as the *power efficiency*. The average power consumption inside the chip is an important parameter because in VLSI the chip computational limitation is largely due to finite device dissipation. The standard commercial epoxy and ceramic packages allow about 2-5 watts of steady state power dissipation.

### 3.2. Computational Aspects:

The computational aspects refer to the speed of computation and the message flow within the networks. The speed is estimated by computing the delay in interprocessor communications and the message density in the interprocessor links reveals the message flow.

### 3.2.1. Delay

The delay refers to the time needed in interprocessor communication to execute a computational task. This is both the property of the topology of the network and the length of interconnects. The average energy dissipation is measured as a product of the total chip area and the average delay.

### 3.2.2. Message Traffic Density

An important aspect of the computational power of the networks is the distribution of data flow within the networks. An efficient network should avoid the message traffic congestions at the links and should distribute the data (message) flow uniformly across all the available links. The message traffic density of at the links with respect to the networks size is a good measure of the computational power of the network. The average rate at which each node originates messages is assumed to be fixed at one message per time unit regardless of network size $N$. Also it has been assumed that the average rate at which any node, $i$ within the network transmits messages to another node $j \neq i$ in the network, is constant. The average message traffic density is defined as the product of number of processors ($N$) and the ratio of average number of nodes visited by a message to the total number of links in the network and is denoted by $\bar{M}$.

### 3.3. Cost Aspects:

The cost aspects consider the fabrication cost and the replacement cost due to poor reliability of the networks. The manufacturing cost of the IC is related to the total chip area (Assumption 2.4.2) and the regularity of the layout [22]. The reliability of the networks largely depends on the presence of long interconnects (Proposition 4) in the embedding and the topology of the networks. Depending on the existence of alternate message routes within the networks, the networks can fail completely or partially.

### 3.3.1. Yield

The yield of the IC is largely dependent on the total chip area. The occurrence of random spot defects will reduce the yield by a factor inversely proportional to the area, $A$ of the chip. This $O(1/A)$ factor is called the ***yield factor*** and is a measure of manufacturing cost of the IC. The defective processors can be replaced by redundant processors, but the chips with defects on the interconnects cannot be salvaged. The size of the interconnect is highly relevant for the chip yield (Proposition 4) and the presence of long wires will be enumerated for evaluation of the manufacturing cost.

### 3.3.2. Regularity

The regularity of the network largely decides the layout cost. Since all processors are identical, an $O(1)$ layout cost can be assumed for laying out a processor. Each link between the processors also can be made hierarchically, the actual cost to layout the links may be much less than the actual number of links. The ***regularity factor*** is a measure of layout cost and is defined as the ratio of total number of interconnections to the number of interconnections actually laid.

### 3.3.3. Fault-tolerance

The fault-tolerance capability largely decides the reliability of a working chip. Due to a host of causes, like electromigration, Kirkendall's effects, hot electron effects, etc., a processor or a link may fail during the normal use of the chip. Depending on the topology of the networks, the effect of failure of a single processor or a link will adversely affect the operation of the network. Normally the level of masking and processing associated with the interconnect is far more simpler than the processors and the reliability of the interconnect is higher than the reliability of the processor. So the reliability due to the processor failure and the interconnect failure are separated and different measures are used here. Since by Proposition 4, the probability of interconnect failure is directly proportional to its length, total length of the interconnects in the network is used as the measure of fault-tolerance due to interconnect failure and is denoted by $R_l$. The failure of a single processor will result in performance degradation because it may isolate one or more processors. The degradation in computing will be determined by the maximum number of connected processors (say $N'$) in the network due to the occurrence of a single processor failure. The value of $N'$ depends on the topology and the location of failed processor. The ratio of maximum value of $N'$ to the original size of the network is defined as the degradation factor, $\delta$ and is used as a measure of fault-tolerance. The reliability of the network can be improved by introducing redundant processors. The ratio of the reliability of redundant network to that of the non-redundant (original) network is defined as reliability improvement factor ($RIF$). Since the addition of redundant processors increases the chip area, the ratio of $RIF$ to the number of redundant processors (denoted by $\rho$) is also used here as a measure of fault tolerance. Overall fault-tolerance capability of three networks will be graded as **High, Medium** and **Low** by making a relative comparison of these three measures.

## 4. EVALUATION OF NETWORKS

### 4.1. Two Dimensional Meshes

The two dimensional mesh is shown in Figure 2. By Assumption 2.1.2, each processor is represented as a unit square and the interconnect length can be ignored. Thus both the area efficiency and the power efficiency of two dimensional meshes are approximately equal to 1.

In order to compute the delay in a $\sqrt{N} \times \sqrt{N}$ mesh, it should be noted that the message path length between two arbitrarily located processors at $(i, j)$ and $(k, l)$ within the square grids is given by the *city block distance* $d = |i-k| + |j-l|$. Thus the average message path length from a source processor is a function of its location $(i, j)$, assuming the lower leftmost processor is at $(0, 0)$. If the source processor is at any of the locations $(0, 0)$, $(n, 0)$, $(0, n)$ or $(n, n)$, ( where $n = \sqrt{N}$ ), then the average message path length is $\bar{d}_1 = n^{-2}[2*1+3*2+\cdots+n*(n-1)+(n-1)*n+\cdots+(2n-2)] = O(n) = O(\sqrt{N})$. If the source processor is at $(n/2, n/2)$, then the average message path length is $\bar{d}_2 = 4n^{-2}[2*1+3*2+\cdots+\frac{n}{2}*(\frac{n}{2}-1)+(\frac{n}{2}-1)*\frac{n}{2}+\cdots+(n-1)] = O(n) = O(\sqrt{N})$. For the source processor in any other position it can be shown that the average message path, $\bar{d}$, is $O(\sqrt{N})$ and satisfies the inequality $\bar{d}_2 < \bar{d} < \bar{d}_1$.

Assuming an $O(1)$ delay time (Assumption 2.2.1) associated with each processor, the average delay between the processors is $\bar{D} = O(\sqrt{N})$.

The total number of links in the square mesh is equal to $2\sqrt{N}(\sqrt{N}-1) = O(N)$ and the average message path is $O(\sqrt{N})$. Assuming all the $N$ nodes issue messages simultaneously, the average message traffic density is then $\bar{M} = NO(\sqrt{N})/O(N) = O(\sqrt{N})$.

Since the average delay is $O(\sqrt{N})$ and the chip size is $O(N)$, the average chip dissipation is $O(N^{3/2})$. Also the area efficiency is 1 and by Assumption 2.4.2, the yield is $O(1/N)$.

The layout can be constructed hierarchically and a block of $4^k$ processors can be laid in $k$-th step paying $2^{k+1}$ cost. Thus a network of size $N$ needs $\sum_{k=1}^{\log_4 N} 2^{k+1} = 2^{\log_4 N+2}-4 = O(\sqrt{N})$ cost. The regularity factor is thus $O(N)/O(\sqrt{N}) = O(\sqrt{N})$.

Since the network consists of nearest neighbor type connections, interconnect reliability is $R_l \approx 1$. The failure of a single processor does not impair the performance of the networks drastically. Due to the presence of many parallel paths in the square grids, the failure of a single processor results into isolation of the failed processor only and does not impair the performance of the networks drastically. The degradation factor is thus $\delta = 1/N$. If $R_p = e^{-\lambda_p t}$ is the functional reliability of each processor in the meshes, then the overall reliability of the network is $R_M(t) = R_p{}^N$. This reliability can be sufficiently ameliorated by adding a redundant row and the overall network can be made to be $(\sqrt{N}-1)$ fault-tolerant. The reliability of the redundant mesh network is $R_{rM}(t) = (R_p{}^n + n(1-R_p)R_p{}^{n-1})^n$ , where $n^2=N$. The reliability improvement factor, $RIF_M$ due to the redundant processors is given by $RIF_M = R_{rM}/R_M$ such that $\rho = (1/(2n-1))(1+n(R_p{}^{-1}-1))^n$.

The delay can be improved for mesh networks if the processors belonging to each column and each row are connected hierarchically as binary trees. Such networks are known in the literature as orthogonal tree networks [23], mesh of trees [24, 25] and orthogonal forests [26]. The average delay for such networks reduces to $O(\log N)$ but the chip area increases to $O(N\log^2 N)$. The overall performance thus does not improve. On the contrary, the presence of long interconnects of length $O(\sqrt{N})$ actually increases the average delay to $O(\log^2 N)$ (by Proposition 2). Moreover, these networks suffer from many practical limitations as poor yield (due to large chip size), poor regularity (due to presence of mesh and trees combined), $O(N\log N)$ cross-overs, long interconnects, etc.

### 4.2. Binary Tree Networks:

The complete binary tree networks of $N$ processors is shown in Figure 3 which needs at most $O(N \log N)$ layout area corresponding to $O(N)$ leaves and $O(\mathit{log}N)$ height of the tree. A better layout which needs optimal $O(N)$ area can be constructed using the concept of an H-diagram, originally proposed by Marihugh and Anderson [27] as a graphical approach to logic design. Horowitz and Zorat [28] have constructed the algorithms for the generation of such a layout and the modified network is henceforth referred as an **H-tree**. The H-tree layout of the binary tree is shown in Figure 4. The total area for a complete binary tree of $N$ processors can be computed from the following recursive relationship

$$A(N) = [2\sqrt{A(\lceil N/4 \rceil)} + 1]^2 \qquad \text{with } A(1) = 1.$$

Assuming $N = 2.4^k - 1$, it can be shown that $A(N) = 4^{k+1} - 2^{k+2} + 1 = 2N - 2.82\sqrt{N+1} + 3$.

Thus, the area efficiency is better than 0.5. The longest wire in the layout is of size $\sqrt{N}/2$ and the total length of wires in the layout is given by the recurrence relation:

$$L(N) = 4L(\lceil N/4 \rceil) + \sqrt{N} \qquad \text{with } L(7) = 1$$

which gives a solution $L(N) = O(\sqrt{N} \log N)$.

The power efficiency depends on $L(N)$ and the width of the wires and is more than 0.5.

The worst case delay occurs when a message is propagated between the leaves through the root of the tree. Assuming $O(l)$ delay for both metal wire (without driver) and polysilicon wire (with interspersed driver), the worst case delay can be given by $D_{max}(N) = 2^*[2\sum_{j=1}^{k}(2^{k-j}-1)+2k+1] = 2\sqrt{2(N+1)} - \log(N+1) - 2 = O(\sqrt{N})$. But this delay is smaller than in mesh network, since only $2\log N$ intermediate processors are visited as opposed to $2\sqrt{N}-1$ in mesh network. The average message delay between root and other processors can be given by $\bar{D} = \sum_{j=0}^{2k-1}\sum_{i=1}^{\lfloor j/2 \rfloor} 2^{j-2k}(2(2^{k-i}-1)+(j \bmod 2)(2^{k-\lfloor j/2 \rfloor -1}-1)+\mathit{log}\ j) = O(\sqrt{N})$.

To calculate the message traffic density on a link, consider $N-1$ time units during which $N(N-1)$ messages are generated and each node on the average will have sent a message to each of the others. Let $h = \log(N+1)$ be the height of the tree network, denoted as $T_h$, such that $|T_h| = N$. A subtree of $T_h$ at level $k$ from leaves is shown as $T_k$ such that $|T_k| = 2^k - 1$. A link between level $k$ and level $k+1 \leqslant h$ will be used to transmit messages between i) all the nodes of the left and the right subtrees each of size $|T_k|$ and ii) one subtree of size $T_k$ connected by the link and $(N - 2T_k)$ nodes of the tree, $T_h$ (Figure 5). Thus, the message density per unit time at a link between level $k$ and level $k+1$ is $M(k) = \frac{2}{N-1}[|T_k|^2 + (N - 2|T_k|).|T_k|)] \approx (2^h - 2^k)\left(\frac{2^k - 1}{2^{h-1} - 1}\right)$. Since M(k) is a monotonically increasing function of $k$, the maximum congestion occurs at the link between the root and its sons (i.e., $k = h-1$) which can be obtained by solving $\frac{\partial M(k)}{\partial k} = 0$. The total number of messages that pass through these links is $M(h-1) = 2^{h-1} \approx N/2 = O(N)$.

Since the area efficiency is less than 1, the yield is not likely as high as the meshes, but it is asymptotically equal to $O(1/N)$. The average energy dissipation of the chip is $O(N^{3/2})$.

The layout can be constructed hierarchically and each level of embedding needs $7 \times O(1)$ cost and the overall connection cost for a network of $N$ processors is equal to $O(\log_4 N)$. The total number of links in a binary tree is equal to $N-1$. Thus the regularity factor is $O(N/\log N)$.

The fault-tolerance capability of the network due to the failure of a single processor depends on the location of the processor. If the external communication is done solely through the root, its failure will have total disastrous effect invalidating the usability of the IC. Since there is no parallel path for message flow, failure of any links will truncate the operability of the chip. If any processor other than the root fails, will also reduce the performance of the IC by an amount depending on its location in the tree. The computational degradation that occurs due to a faulty processor or an interconnect at level $i$ from the leaf nodes can be defined as the number of processors which are eliminated due to the fault at level $i$ and is equal to $2^i-1$. If the external communication is made through leaf nodes, then $\delta = (N-1)/(2N)$. The network can be restored to function normally by replacing the defective processor by redundant processor. Redundant processors can be placed in the extra space available within the chip and re-routing can be done by electrically programmable routing technique. Since only $N - 2.8\sqrt{N+1} + 3$ space is available for laying out the redundant processors redundancy can be added for nodes till level 2 from the leaf nodes, i.e., level $h-2$ from the root. Thus the leaf processors and their fathers are not replicated and all other nodes in the tree are replicated at locations shown by * in Figure 4. If $R_p$ is the reliability of each processor then the overall reliability of the tree network without any redundancy is $R_T = R_p{}^N$. Clearly, $R_l = O(\sqrt{N} \log N)$. If the redundancy is added as described above, then the reliability of the redundant network is $R_{rT} = R_p{}^{3N/4} \times (2R_p - R_p{}^2)^{N/4}$. The reliability improvement factor, $RIF_T$, is given by $RIF_T = R_{rT}/R_T = (2-R_p)^{N/4}$ and $\rho = (4/N)(2-R_p)^{N/4}$. Thus the reliability of the tree network is poorer compared to the meshes.

### 4.3. Cube Connected Cycles:

An $m$ dimensional Cube Connected Cycle (CCC) is a network which can be derived from a boolean hypercube of $2^m$ vertices by replacing each vertex with a cycle of $m$ vertices. This was originally proposed by Preparata and Vuíllemin [7] to ensure that the degree of each vertex is bounded to 3 and not to $m$ as in an $m$-cube network. The topology of a 3-dimensional CCC with $3.2^3 = 24$ processors is shown in Figure 6 and its optimal VLSI layout has been given in Figure 7. It should be noted from Figure 7 that the layout of an $m$ dimensional CCC can be made by laying out $m$ $C_i$ routes in an $m$-cube [29] on a grid graph and replacing the vertices of $m$-cube by $2^m$ cycles of size $m$. Clearly, the maximum height of the cycle is $\sum_{i=0}^{m-1} 2^i = 2^m$ and there are totally $2^m$ cycles. Thus the total area required by an $m$ dimensional CCC is $2^{2m+1}$ assuming that the width of the edge is equal to the square root of processor area. Since $N = m2^m$, then $2^m = N / (\mathit{log}N - \log m)$, i.e., $m \approx \log(N/\mathit{log}N)$. Thus the total chip area is approximately $O(N^2/\log N^2)$. Thus both the area efficiency and the power efficiency are $O((\log^2 N)/N)$.

Let the interprocessor link in the cycle be called ring link (vertical lines in Figure 7) and the interprocessor link between two adjacent cycles be called vertex link (horizontal lines in Figure 7). Using Wittie's algorithm for message routing, it can be shown that on the average a message traverses $m/2$ vertex links and $(5m/4)-2+2^{1-m}$ ring links if $m$ is even (and an additional $1/(4m)$ ring links if $m$ is odd). It may be noted that Wittie's average path length analysis by his routing algorithm was incorrect and the correct result is stated above. Wires are either horizontal or vertical and cannot be both metal (Assumption 2.1.4). Thus in order to reduce the propagation delay, it is needed that the cycle links should be made of metal and the vertex link should be made of polysilicon (or diffusion). It may be noted that in an $m$ dimensional CCC, there are $m\,2^{m-1}$ vertex links having a total interconnection length of $2^{m-1}\sum_{i=1}^{m} 2^i$ so that average vertex length is $(2^{m+1}-2)/m$. Thus the average vertex delay is $4(2^m-1)$ i.e., $O(N/\log N)$. The asymptotic average delay over metal ring link is $O(\log N)$. The worst case delay is due to message transmission between two processors at the opposite edges of the chip and is proportional to the perimeter of the chip, i.e. $O(N/\log N)$. Since each node has degree 3, the total number of links is equal to $3N$. If $N$ messages are generated on the average in unit time, then the average message density is equal to $\overline{\mathrm{M}} = (N/3N) \times O(m) = O(\mathit{log}N)$.

Since the chip area is very large, the yield is $O(\log^2 N/N^2)$, which is very poor compared to the mesh and the tree networks. The average energy dissipation of the chip is $O(N^3/\log^3 N)$.

The layout can be partially constructed hierarchically. An $N(=m\,2^m)$-node CCC composes of two $(m-1)2^{m-1}$-node CCC and $2^{m-1}$ connections as is evident from Figure 7. Thus the layout cost to construct an $N$-node CCC is $2^m+m-1 = O(N/\log N)$. Since the total number of connections in the layout is equal to $1.5N$, the regularity factor is $O(\log N)$ and is poor compared to the mesh and the tree networks.

The fault tolerance capability of CCC is good because there is always an alternate path to re-route the message like in the mesh. Thus the failure of a single processor will not have any drastic effects on the performance of the network and $\delta = 1/N$. But due to presence of many long interconnects and large chip area, the reliability is not as good as the meshes. Total length of interconnect within the chip is $O(N^2/\log^2 N)$ due to the presence of $N/\log N$ cycles of average height $N/\log N$. Thus $R_l = O(N^2/\log^2 N)$. The reliability of the network due to processor failure can be given by $R_{CCC} = R_p{}^N$. If one redundant processor is added to each cycle, then the reliability improves to $R_{rCCC} = (R_p{}^m + m(1-R_p)R_p{}^{m-1})^{N/\log N}$. The reliability improvement factor, $RIF_{CCC}$, is given by $RIF_{CCC} = R_{rCCC}/R_{CCC}$ and $\rho = (1/m)(1+m(1/R_p-1))^{N/\log N}$.

## 5. COMPARISON OF THREE CLASSES OF NETWORKS

From the analyses done in the previous section, it is evident that each network has certain strong aspects and certain weak aspects. It is difficult to relate all these aspects by a compact formula which can be utilized as a performance metric. A weak effort in this respect was originally done by Mead and Rem [14] relating the area ($A$) and the speed ($T^{-1}$) and proposing the *rental time* of the chip $AT$ as a metric. Thompson [8] has extended the concept for any arbitrary network by showing that $AT^2$ indicates a better performance metric. He has related the area and the speed of computation in a network through its *minimal bipartition width*, $\omega$ and have shown that a computational problem can be solved by exchanging information over $\omega$ such that the speed of computation is directly proportional to the cardinality of $\omega$ while the area of planar implementation of the network is directly proportional to the square of the size of $\omega$. But this metric accounts for the lower bound of the chip area. Savage [30] has contended that $A^2T$ reflects a better evaluation for certain computational problems like binary sorting. From all these contradictory claims, it is evident that it is virtually not possible to correlate all the criteria discussed in section 3. An alternative strategy has been adopted here. The networks have been given credit points for each criterion depending on their relative merits and the total points have been used as a performance index for the network. The results of the evaluation with respect to different criteria have been shown in Table 1. The credit points have been assigned on the basis of relative merits of the networks. From the values of total points, it can be seen that the two dimensional mesh networks indicate overall better performance than the H-tree and the CCC. This is in direct contrast to the results of Wittie [3], Siegel [31, 9], etc., who have concluded that fast networks like CCC, PSN, spanning bus hypercubes, etc., have better overall performance. It may be argued whether it is appropriate to give same weight to all the criteria. But it can be easily seen that the conclusion remains true even if different weights are ascribed to three orthogonal aspects (i.e. criteria having same aspect only has same weight).

## 6. CONCLUSION

The basic conclusion from this paper is that the Cellular Networks which have a similar structure to the mesh can be cost effectively implemented for VLSI implementation and are highly suitable for VLSI parallel processing. The penalty in delay can be offset by the gains of several criteria discussed in this paper. The faster topologies like CCC, PSN, tree, etc., do not provide an overall good performance because of long interconnects which introduce high delay and large chip area which reduces the chip efficiency and the chip yield. A multilayered model with more than one layer of metal will improve the performance of these topologies and a judicial laying out is necessary to reduce the chip area under the multilayered model.

## ABSTRACT

This paper considers various physical constraints which influence the design of VLSI based interconnection networks used in multiprocessor systems. Design expressions are presented for implementing an $N \log N$ packet passing interconnection network composed of circuit switched crossbar chip modules. Expressions reflecting chip level and board level pin and area constraints are derived and used to determine the network delay expected at a given clock frequency. Logic and memory delay, signal path delay, clock skew and clock tree delay parameters are defined and used to determine the maximum frequency which can be obtained with a given design. An example 2048x2048 network design is considered.

## 1. Introduction and Overview

The design of effective multiprocessor systems involves numerous interacting elements ranging from parallel algorithms to programming languages to computer architecture. This paper focuses on the computer architecture question and, in particular, on the design of VLSI based electrical interconnection networks for use in multiprocessor systems. Due to their potentially critical effect on overall multiprocessor performance, interconnection networks have been widely studied. Various studies have focused on their functional properties (permutations, control algorithms) [2,9,14,18], their complexity and performance [5,16,17,23], and their actual design [7,20].

One way of characterizing interconnection networks relates to the style of multiprocessor system in which they are used. At one end of the spectrum are systems where the interconnection network is the central communications component between the processors (as in a message passing system) or between processors and the main memory (as in a shared memory system). The NYU Ultra computer [10], the related IBM RP3 [19] computer and the BBN Butterfly [3] are examples of this style of design. It is convenient to refer to these systems as NETWORK CENTERED multiprocessors since the network is a central resource which has a major effect on overall system performance. This system style encourages viewing memory access and communications interchange in a uniform manner with costs associated with access and communications being roughly independent of physical location. (We ignore questions of cache and processor local memory here. If most accesses are local, then the need for a large and complex interconnection network is questionable). Algorithm development in this environment tends to encourage the use of large data structures which span the memory space and develop processor access patterns which are relatively uniform in nature.

At the other end of the spectrum are systems where the processors are embedded within the network itself with direct communications taking place primarily on a physically local basis. The Intel Cosmic Cube [22], the Blue Chip computer and various tree machines [24,4,11] are examples of this style. These systems are PROCESSOR CENTERED in that processor performance is a main determining factor in overall performance. This system style encourages viewing the world as being made up of local processing niches with data exchange between processors becoming more costly as one reaches further from the local niche. Algorithms which can take advantage of memory access and communications locality associated with a given interconnection structure can operate effectively in this environment.

In the middle of these two ends of the multiprocessor spectrum are machines where some (typically small) portion of the processing task is allocated to the interconnection network. The idea here is that since data must pass through the interconnection network (and be delayed) anyway on its way to and from memory, why not do some processing on the way.

This paper considers the design of large (several thousand inputs and outputs) VLSI based interconnection networks for the case of NETWORK CENTERED multiprocessor systems. The emphasis is on the physical design aspects of the network, and the implications of design constraints on network implementation and performance. A simple modified packet switched $N \log N$ multistage interconnection network topology is assumed, with each node being implemented as a crossbar switch having a limited amount of packet buffering at its input. Interconnection network designs using optical techniques are not considered though they may well serve as the basis for networks of the next generation.

The next section presents overall network topology and operation. Section 3 considers pin and area limitations at both the chip and board levels. Section 4 presents simple models of overall network delay as a function of clock frequency. Section 5 derives data rate equations for the network in terms of various design parameters such as logic, memory, and data path delays. Clock skew and distribution factors are included in the model. The model presented can be used to determine the maximum clock rate achievable and hence the expected delay through the network. Section 6 explores an example design of a 2048 input/output switch. The conclusion indicates that, in the current design environment, a large NETWORK CENTERED shared memory multiprocessor is likely to encounter a large performance penalty when accessing memory on the other side of the switch.

## 2. The Overall Network

The overall network topology considered is of the Boolean hypercube variety as shown in Figure 1. All switch modules are the same and are designed to be crossbar (CB) switches sized so that each one fits entirely on a single chip. Earlier studies have indicated that from an area-time performance viewpoint there is little difference between using an $N \log N$ versus a CB network within a chip [7]. Across the network as a whole, however, use of a Boolean hypercube structure is significantly less costly in terms of the total number of chips required [8].

While each switch module (being a CB) is nonblocking, the network as a whole is a blocking network. The number of stages in the network is $\log_N N'$ where $N'$ is the size of the overall network and $N$ is the size of the CB on a chip (see Table 1 for various definitions). Since the blocking probabilities of the network decrease as the number of stages decrease, it is advantagous to place as large a CB as possible in each switch module. This is shown in Figure 2 which contains a plot of blocking probability versus number of stages for a network of size 4096 (based on the formula derived in [17]). Note that reducing the number of stages from 5 to 3 decreases the blocking probability by about 10%.

0190-3918/86/0000/0208 $01.00 © 1986 IEEE

Note also that the length of off-chip signal lines generally increases as the number of stages increases. Thus, for example, the maximum line lengths between the first and second stages in the network of Figure 1 are shorter than those between the second and third stages. This is important because of the delays associated with driving these lines. Thus, in general, reducing the number of stages reduces the off-chip delays.

Overall network throughput can be increased by using a modified packet switched rather than a pure circuit switched design. A modified packet switched design places a limited number of packet buffers at the input to each of the switch modules. However, within the module circuit switching occurs. Thus, a packet holds an entire path within each switch module as it passes through that module. On leaving the module the path is released for use by some other packet. Increases in throughput which result from a packet switching approach have been discussed elsewhere [5]. These studies also indicate that most of the potential gain from buffering is achieved with a limited number of buffers (about 4) on each switch module input. For simplicity, in our discussion here we assume a single packet buffer. However, this is not critical to the analysis which follows. We also assume fixed size packets of length 100 bits which is about what is needed to include sufficient bits for data, memory module address, intra-memory module address, and return processor address.

Figure 3 shows an example path through a three stage network. In addition to the input packet buffer, a single bit buffer has been placed at each CB output to allow for a limited pipelining capability. Notice that a dotted line is present in the diagram around the input buffers. This indicates the presence of a cut-through mechanism which permits packets to stream through the switch module without going through a buffer filling process if the down stream switch module it requires has an empty input buffer. Under light loading conditions this will allow packets to pass from one switch module to another without being slowed down by buffer fill times [12].

| VARIABLE NAME | TYPICAL VALUE | DEFINITION |
|---|---|---|
| $N'$ | 2048 | Size overall network |
| $N$ | 16x16 | Size crossbar module (NxN) |
| $N_p$ | 250 | # pins on module chip |
| $N_k$ | 40 | # pins on module chip for ctrl, clk, power |
| $W$ | 1,2,4,8 | # of lines in a data path |
| $P$ | 100 | Packet size in bits |
| $F$ | 20,40,60,80 | Clock frequency (MHz) |
| $T$ | 2 | Packet time through ntwk ($\mu$sec) |
| $M_{su}$ | 2 | # clock cycles to perform chip setup functions (DMUX/MUX) |
| $V_{dd}$ | 5 | Power supply voltage (volts) |
| $\Delta V_{\max}$ | 0.50 | Max. variation in power supply voltage (volts) |
| $Z_0$ | 50 | Line driver impedance (ohms) |
| $L$ | 5 | Pin inductance (*nano* henries) |

Table 1: Variable Name Definitions

The broad design philosophy taken is to keep the switch as simple as possible since simplicity generally leads to speed. In this spirit, combining networks and network information processing other than routing is omitted. Hot spots [20] and other problems are assumed either to be dealt with by the operating system, or are accepted and result in performance penalities which hopefully are partially overcome by having a fast network. The network is thus of the RISC (Reduce Interconnection System and Complexity) style of design.

## 2.1. Network Control

The general design methodology employed utilizes clocked as opposed to asynchronous control. Other studies have shown that given today's design environment, system sizes and data rates, clocked designs adequately meet most performance requirements [6,25]. At very high clock rates, multiple clocked approaches will need to be considered, however they are not treated here [1]. We assume that a two phase clock is used and that two pins on each chip are allocated for this purpose.

A complete interconnection network requires control provision for:

- path establishment and data transfer
- detection of a blocked path
- indication of end of transmission
- path clearing

Packets are self routing, moving from CB chip to CB chip according to address bits in the header portion of the packet. Within each CB the entire path is held from chip input to output. Feeding back from each input buffer to the associated output of the preceding chip is a buffer full line. This indicates whether the buffer is full and thus the path is blocked at that point. Packets are backed up and held in prior buffers until the buffer full line indicates transfer can proceed. For each $N$x$N$ CB chip there are thus $2N$ buffer full control lines, $N$ of these indicating whether its buffers are full, and $N$ indicating whether the buffers downstream are full. All packets proceed in lock step from stage to stage in the network.

Given fixed length packets, an on-chip counter can determine when packets have completed transmission. Path clearing will occasionally be necessary when certain error conditions occur. We assume that such clearing operations constitute a type of network reset and that such a drastic action will be initiated by some master processor for the network as a whole. One pin per chip is allocated for this purpose. Thus, ignoring power and ground for the moment, $2N+3$ control lines are needed per chip.

## 2.2. Crossbar (CB) Design

There are many ways of designing CB switches. In this paper we consider two approaches (see Figures 4a and 4b). The first is referred to as the MESH CONNECTED CROSSBAR (MCC) design [16]. In this design, $N^2$ two by two crosspoint switches are placed on the chip, with each switch having a packet routing capability and one bit of buffering to allow for limited pipelining. Packet routing is thus completely local, the layout is planar and the distance between adjacent switches constant. The design is modular and as technology improves larger on-chip CBs can be easily implemented by replicating the basic switch crosspoints. The area of the entire CB grows as $O(N^2)$ while the time delay grows as $O(N)$ .

The second design approach is referred to as the DMUX/MUX CROSSBAR (DMC) design [13]. In this case, after $\log_2 N$ bits have arrived at an input port, an input port controller (IPC) (i.e. a demultiplexer) determines on which output line to route the arriving message. The IPC also signals an output port controller (OPC) (i.e. multiplexer) which selects between multiple input packets that request the same output port. An $N$x$N$ DMUX/MUX crossbar would require $O(N^2)$ two input gates and have a time delay of $O(logN)$ gate delays. In addition to gate delays, however, there are the line delays associated with the potentially long on-chip lines between the input and output ports and controllers. This is due to the fact that path topology from input to output represents a complete bipartite graph whose layout area grows as $O(N^4)$. Certain results show that the overall delay with this type of CB grows as $O(N^2)$ [16].

## 3. Pin and Area Constraints

A serious constraint in the physical design of large networks is imposed by the limited number of signal pins available both at the chip and board levels. In this section these pin limitations are explored assuming a Pin Grid Array (PGA) packaging technology that is aggressive, but currently realizable, and board edge connectors of standard high performance design.

### 3.1. Chip Pin Constraints

Pin usage can be broadly grouped into three categories: data pins ($N_{p.d}$), control pins ($N_{p.c}$), and ground and power pins ($N_{p.g}$). The total number of pins on a chip, $N_p$, is thus given by:

$$N_p = N_{p.d} + N_{p.c} + N_{p.g} \tag{3.1}$$

Since the size of the subnetwork on a chip is $N$x$N$ and $W$ is the data path width, the number of data pins is:

$$N_{p.d} = 2WN \tag{3.2}$$

The control information required for setting up paths in the network is obtained as part of the data and hence requires no extra signal pins. However, for each input or output port, a control signal indicating the state of the buffer (full or not) is required. This necessitates $2N$ pins for the buffer full signals. In addition, we allocate two pins for a two phase non-overlapping clock and a pin for system reset. Hence:

$$N_{p.c} = 2N + 3 \tag{3.3}$$

Normally, when small circuits are considered, especially those that have a small number of signal pins, the use of a single pin for power and a single pin for ground is sufficient. However, for large chips, especially those that have a large number of signals all of which can switch at the same time, it may be necessary to allocate more pins for power and ground in order to maintain ground and power voltage variations to within acceptable limits.

Each signal pin has an associated inductance. When a signal switches between its high and low voltage states, the change in current through this inductance causes a voltage to appear across the pin. As the number of signal pins increases, in the worst case, all of them can switch in the same clock cycle, thus causing a large voltage change of either the ground or the power net. Given the impedance of the pin driver circuit and assuming that this circuit itself is driven by an exponential driver, the rate of change of supply current with respect to time for a single pin can be obtained (by analytic or simulation methods). For a 50 ohm driver driving a 30 inch metal pc board line with typical characteristics, the rate of change of current with respect to time, $di/dt$, is about $7*10^6$ amps/second. The following expression can be used to determine the number of power and ground pins, $N_{p.g}$, needed for a given number of output signal pins, $N(W+1)$, maximum permissible voltage variation, $\Delta V_{\max}$, and pin inductance, $L$.

$$N_{p.g} = \frac{2N(W+1)L}{\Delta V_{\max}} \left( \frac{di}{dt} \right)_{avg} \tag{3.4}$$

The expressions 3.2, 3.3 and 3.4 can now be substituted into 3.1 and the overall number of pins, $N_p$ determined. Using the parameter values indicated in Table 1, Table 2 indicates $N_p$ as a function of subnetwork size and path width. Assuming that the maximum number of pins available on a chip is 240, the portion of the table to the left and top of the heavy lines indicate designs that satisfy the pin constraints.

### 3.2. Chip Area Constraints

We now consider constraints on chip area and obtain the size of the largest network that can be implemented in a single chip. As mentioned earlier, maximizing the size of the CB subnetwork (residing entirely on a single chip) reduces blocking and hence is desirable. The two designs introduced earlier (i.e. the mesh connected CB, MCC, and the demultiplexer/multiplexer CB, DMC) are explored. The development follows that of Padmanabhan [16].

For the case of the MCC design the key element in estimating the area lies in estimating the area occupied by a two input, two output switch. These switches can then be connected in a mesh to form the CB network. Padmanabhan gives a PLA implementation of this switch with a one bit wide data path. He shows that the implementation would occupy a rectangular area of dimensions approximately 100 lambda by 100 lambda. Assume that the above implementation gives the area of the control logic of a switch with a $W$ bit data path. The area occupied by the data path must now be estimated. The data path consists of $W$ lines traversing the switch from left to right and from top to bottom. In addition, $W$ control lines for each set of data lines must be routed. Assuming that separation between lines, including area for driving and control buffers, is 10 lambda, the dimensions of the rectangular area occupied by the switch becomes $100 + 20W$. Hence the area of the MCC realization consisting of $N^2$ switches is:

| | N - Crossbar Subnetwork Size | | | | |
|---|---|---|---|---|---|
| W | 16 | 18 | 20 | 22 | 24 |
| 1 | 72 | 80 | 89 | 97 | 106 |
| 2 | 106 | 119 | 132 | 144 | 157 |
| 4 | 174 | 196 | 217 | 239 | 260 |
| 8 | 311 | 350 | 388 | 427 | 465 |

Table 2: The number of pins per chip necessary, $N_p$, for different values of subnetwork size $N$ and data path width $W$.

$$A_{\text{MCC}} = N^2(100 + 20W)^2 \tag{3.5}$$

Next consider the area occupied by the MUX/DMUX realization. The area occupied by such an implementation can be broadly divided into the area occupied by the $N$ 1-to-$N$ demultiplexers and $N$ $N$-to-1 multiplexers, and the area occupied by the $WN^2$ wires which must be routed from the multiplexers to the demultiplexers. The routing of the wires from the demultiplexers to the multiplexers will be done according to the routing presented by Wise [26] which results in identical wire lengths. Let the minimum separation between wires be $d$ and the vertical separation between consecutive wire origins and endings be $h$. The area occupied by such a routing can be shown to be given by:

$$A_{\text{wire}} = (N-1)^4 \frac{h^2W^2d}{\sqrt{4h^2 - d^2}} \tag{3.6}$$

The minimum area is occupied when $h = d$ which results in:

$$A_{\text{wire}} = (N-1)^4 \frac{(Wd)^2}{\sqrt{3}} \tag{3.7}$$

Next estimate the area occupied by the $N$ demultiplexers and $N$ multiplexers. Assume that the demultiplexers are implemented as a binary tree of 1-to-2 demultiplexers. A 1-to-2 demultiplexer with $W$ data bits occupies a rectangular area of dimensions $30W$ by 24 [16]. A tree realization will have a maximum of $N/2$ demultiplexers in the first stage with $\log_2 N$ stages. Thus, the bounding box of this tree is given by $360WN\log N$. The area occupied by $N$ demultiplexers and $N$ multiplexers (assuming a multiplexer occupies the same area as a demultiplexer) is given by:

$$A_{\text{dmux/mux}} = 360WN^2\log N \tag{3.8}$$

The total area of the MUX/DMUX design is given by:

$$A_{\text{DMC}} = (N - 1)^4 \frac{(Wd)^2}{\sqrt{3}} + 360\,WN^2 \log N \qquad (3.9)$$

The area expressions of (3.5) and (3.9) are lower bound estimates. Table 3 gives the maximum size network that can be implemented in a chip satisfying the above area constraints assuming that these estimates are increased by a third (to handle line drivers, etc.). The maximum chip dimensions assumed are 1cm by 1cm with a $\lambda = 1.5\ \mu m$.

Examination of Table 2 shows that the largest network that can be implemented in a chip satisfying the pin constraints is 22x22 with a 4 bit data path. Table 3 indicates that the area constraints limit the network size to about an 18x18 network with the DMC design and a 25x25 network with the MCC design (assume a 4 bit data path). However, we choose a convenient power of 2 network size of 16x16 with a 4 bit data path as our basic subnetwork to be implemented in a chip, satisfying both pin and chip area constraints. Though not detailed here, a CMOS power analysis of such a chip indicates that about 2.5 watts will be dissipated at 50 Megahertz. We next investigate the layout of the network at the board level.

|   | Sub network size $N$ |   |
|---|---|---|
| W | MCC | DMC |
| 1 | 37 | 34 |
| 2 | 32 | 25 |
| 4 | 25 | 18 |
| 8 | 17 | 13 |

Table 3: The largest subnetwork that can be implemented on a 1cmx1cm chip.

### 3.3. Board Area Constraints

Assume that the pin layout on the chip package uses a pin grid array with three rows of pins having a separation between adjacent pins of 100 mils. The size of a package with at least 175 pins is about 2 inches on a side. The use of a 16x16 subnetwork makes a 256x256 network reasonable for implementation on a single board. This network has two stages, each stage consisting of 16 chips. If a stage of 16 chips is lined up on a single side along a board edge then the board length will be about 32 inches. The routing of wires between these two stages will determine the width of the board occupied by the 256x256 network.

To estimate the area occupied by the routing assume that the routing strategy is similar to that adopted for the chip level DMC implementation. The routing in this case is identical to the DMC implementation of a 16x16 crossbar network. The parameters $h$ and $d$ must, however, be estimated differently. $d$ still remains the minimum separation between wire at the board level with a typical value of 50 mils. Assume the board has two signal layers. The total number of wires to be routed is $N^2(W + 1) = 1280$. Each layer then has to route half the total number of wires, that is, 640 wires. Hence the vertical separation between wires is $h = 32000/640 = 50$ mil, the minimum. The area occupied by the wires is then obtained by evaluating (3.7) as 73 square inches. Thus, the width of the layout of the wires is about 3 inches and the longest path on the board is then no more than $32 + 3 = 35$ inches. This layout will be used in Section 6 in examining the design of a 2048x2048 network.

### 3.4. Board Pin Constraints

At the board level, consideration must be given to the routing of signal wires from one board to the next. Implementing a 256x256 network with a 4 bit data path requires the routing of 1280 wires on the input and output sides. In the last section it was shown that the layout of the chips required each edge of the board to be about 32 inches long. If the wires were brought out to the edge of the board on two layers, it was shown that the separation between wires would have to be 50 mil. This is about the minimum separation between wires on the board that keeps crosstalk among wire to acceptable levels. Commercially available connectors are able to connect up to 100 lines from one side of a board and are no more than 4 inches long. Thus with connectors using both sides of the board, eight connectors can be used for the entire 1280 lines which can be lined up on one edge of the board. Thus the pin constraints at the board level can be satisfied.

## 4. Network Delay

In this section expressions are presented for the time to transfer a packet through the network ($T$). This is a one way network delay time and doesn't include memory access time. A best case model is presented in which a lightly loaded network is assumed with no blocking of packets. Packets, in this situation, can thus stream through the entire network from the input to the output being delayed only by chip module setup and pipeline fill times.

For the case of the MCC design, network delay is composed of two components. The first is the time to fill the pipe of crosspoint switches from input to output of the network. The second is the time it takes to transfer the packet once it has arrived at the end of the network. Thus:

$$T_{MCC} = \textit{pipeline fill time} + \textit{packet transfer time} \qquad (4.1)$$

In this design the average number of crosspoint switches per chip that a packet passes through is $N$. The number of stages the packet traverses is $\lceil \log_N N' \rceil$. Thus, the pipeline fill time is $N \lceil \log_N N' \rceil$. The number of bit times associated with a packet transfer is the packet size ($P$) divided by the path width ($W$). Thus, the packet delay time is:

$$T_{MCC} = (N \lceil \log_N N' \rceil + P/W)(1/F_{MCC}) \qquad (4.2)$$

In the DMC design, associated with routing the packet within each chip is a setup time. This time is dependent on the size of the on-chip CB in that at least $\lceil \log_2 N \rceil$ bits must be received by the chip before the path can be established. Given a path width of $W$, the number of clock periods, $M_{ss}$, associated with this setup time for a single chip (or stage) through which the message passes is thus:

$$M_{ss} = \lceil \log_2 N / W \rceil \qquad (4.3)$$

To break up long path delays, this design also assumes that a 1-bit buffer is present at the output of each chip. This acts as a $\lceil \log_N N' \rceil$ pipeline through the network. As in the MCC case, a packet transfer time is also present to account for the time it takes the packet to leave the network when its first bit starts to leave an output port. The resulting overall time is given by:

$$T_{DMC} = \textit{setup time} + \textit{pipe fill time} + \textit{packet transfer time} \qquad (4.4)$$

$$T_{DMC} = (\ [M_{ss} + 1] \lceil \log_N N' \rceil + P/W\ )(1/F_{DMC}) \qquad (4.5)$$

These network delay expressions have been evaluated and are presented in Table 2. Notice that the results indicate that, even at fairly high clock frequencies, the one way delay through the network is substantial when compared to typical memory cycle times. For example, in the DMC model operating at 40 MHz with a path width of 2, the one way network delay is 1.48 $\mu$seconds. Round trip delay, including 200 nanoseconds for memory access, would be 3.16 $\mu$sec. . That is, the remote (through the network) memory access is more than an order of magnitude greater than local memory access. Note also that the delay expressions and associated tables do not indicate whether or not the frequencies suggested are achievable. This is dependent on the logic and path delays, and on clock distribution characteristics (e.g. clock skew). These design parameters are explored in the next section.

## 5. Clock Frequency and Data Rate Expressions

The clock frequency at which a given system can run is determined by a host of factors ranging from effectiveness of the logic design, to chip layout and signal delay consequences of using a particular packaging technology. The final result of these factors are a set of delay parameters which determine the rate at which data can pass from chip to chip. This maximum data rate corresponds to the maximum clock frequency which can be used without errors occurring.

| | CLOCK FREQUENCY (MHZ) | | | | |
|---|---|---|---|---|---|
| W | 10 | 20 | 30 | 40 | 80 |
| 1 | 14.8 | 7.4 | 4.9 | 3.7 | 1.9 |
| 2 | 9.8 | 4.9 | 3.3 | 2.5 | 1.2 |
| 4 | 7.3 | 3.7 | 2.4 | 1.8 | .91 |
| 8 | 6.1 | 3.1 | 2.0 | 1.5 | .76 |

MCC (Mesh Connected Crossbar) MODEL

| | CLOCK FREQUENCY (MHZ) | | | | |
|---|---|---|---|---|---|
| W | 10 | 20 | 30 | 40 | 80 |
| 1 | 11.5 | 5.75 | 3.8 | 2.88 | 1.44 |
| 2 | 5.9 | 2.95 | 1.9 | 1.48 | .74 |
| 4 | 3.1 | 1.55 | 1.03 | .78 | .39 |
| 8 | 1.9 | .95 | .63 | .48 | .24 |

DMC (Demux/Mux Crossbar) MODEL
Table 2: Time Through Network ($\mu$sec)
($P$=100, 512$\leq N' \leq$4096, $N$=16)

The data rate can be expressed in a general form as follows:

$$DR = \frac{1}{max[\textit{information signal delay, clock signal delay}]} \qquad (5.1)$$

Information signal delays consist of logic and memory delays ($D_L$), information signal path delays ($D_p$) and delays due to clock skew ($\delta$). The sum of these delays can be associated with the time for a signal to pass between communicating modules (chips or crosspoint switches). Since this must occur within a single clock cycle, a constraint is placed on minimum clock cycle duration (and thus maximum frequency). Taking the worst case (largest) sum of these delays overall communicating modules leads an overall constraint on data rate and clock frequency [25].

In a similar manner, delays associated with propagation of the clock signal form another basic limitation on clock frequency. Two types of clock distribution schemes are considered here. In the first (the STANDARD CLOCK SCHEME), the entire clock tree is viewed as an equipotential surface which must achieve a single final voltage in each half of the clock cycle. That is, the entire clock tree must be charged and discharged during the clock cycle. Given that such clock trees may present a large capacitive load, and that this load grows as systems become larger, this constraint can be a limiting factor in achieving high frequencies in physically large systems. If $\tau$ is the time required to charge or discharge the clock tree, then the data rate for this clocking scheme is constrained to be less than $1/2\tau$. Based on the above, the data rate for the case of a Standard Clocked Scheme is as follows:

$$DR_{sc} = \frac{1}{max[D_L + D_p + \delta,\ 2\tau]} \qquad (5.2)$$

Notice also that a relationship exists between $\tau$ and $\delta$. That is, as the clock line increases in length, both $\tau$ and $\delta$ increase with $\tau$ being an upper bound on $\delta$. One model that relates $\tau$ and $\delta$ was developed by Wann and Franklin [25]. The model assumes simple exponential rise times to and from the power supply voltage, $V_{dd}$. Variations in material properties can result in variations in rise time which can be expressed in terms of maximum and minimum $\tau$ values, $\tau_{\max}$ and $\tau_{\min}$. Variations in processing can result in variations in FET threshold voltages which can also be expressed in terms of maximum and minimum threshold voltage values, $V_{Tmax}$ and $V_{Tmin}$. The resultant expression is:

$$\delta = \tau_{\min}\, ln(1 - \frac{V_{Tmin}}{V_{dd}}) - \tau_{\max}\, ln(1 - \frac{V_{Tmax}}{V_{dd}}) \qquad (5.3)$$

When dealing with long clock lines, the charge/discharge time constraint and the clock skew can severely limit performance. The charge/discharge time constraint can be partially overcome by treating the clock lines as transmission lines and, using the memory properties of the line, placing multiple pulses on the line at the same time instant thus reducing the delay between clock pulses (MULTIPLE PULSE SCHEME). Clock skew can be reduced by using a global clock and employing phase locked loop techniques (called "dynamic delay adjustment" in reference 1) to perform phase synchronization. These techniques, however, add complexity to the design and are not pursued here.

## 6. An Example

### 6.1. Physical Design

Based on the design constraint and data rate expressions developed in prior sections, we now consider the design of an interconnection network with 2048 inputs and outputs. As stated in section 3, pin constraints on the chip limit the maximum size of the crossbar that can be implemented in a chip. A 16x16 network having path widths of 4 bits appears to be reasonable and is used in this example.

The implementation of a 256x256 network on a single board was shown to be possible, satisfying area and pin constraints on the board. Larger size networks can then be implemented from these boards by racking the boards in three dimensional space to reduce the distances over which wires must be routed. A 2048 input, 2048 output network implementation is shown in Figure 5. The first two stages of the network are implemented from eight 256x256 network boards; the last stage consists of eight boards with each board implementing one eighth of the last stage. If the boards are stacked as shown in Figure 5, the longest wire between any two chips is one that traverses the diagonal of a board. In section 3 we showed that this distance is 35 inches.

### 6.2. Clock Frequency

Expressions for the clock frequency (data rate) were derived in Section 5 based on the logic and memory delays and signal path delays and skews in clock distribution. In this section we estimate the information signal delays and clock delays from a knowledge of the physical layout of the network. A STANDARD CLOCK SCHEME is used.

Information signal delays consist of delay in the logic and in the memory of a finite state machine implementaion. Estimates given in [16] indicate that the logic delay would be about 12 nano seconds whereas the memory delay can be restricted to about 2 nano seconds. This results in $D_L$ = 14 nsec.

Consider the path delay. Since the network is pipelined, only the largest path delay is of significance. This corresponds to the path that has to go off-chip and traverse the longest distance (35 inches) on the board. This results in off-chip delays much larger than the signal rise times, thus off-chip paths must be viewed as transmission lines with on-chip drivers matched to their impedance (50 ohms). The off-chip path delay is determined largely by the speed of signals on the board and this is typically 0.15 nsec/inch. The delay in driving the driver is about 6 nsec. Hence $D_p = 6 + 0.15*35 = 11.3$ nsec.

The clock distribution essentially consists of two parts: one totally internal to a chip, consisting of a tree distributing the clock to the 16x16 network, and the second external to the chips consisting of the clock distribution on the board. Using a H-tree distribution to minimize clock skew for the clock distribution internal to a chip, the clock delay is given by [27]:

$$\tau_{\text{chip}} = (10N^3 - 3)(3 - 2/N)R_0C_0/7 \qquad (6.1)$$

where $R_0$ and $C_0$ represent the resistance and capacitance of the last branch of the tree distributing the clock to a switch. In this design (a 16x16 network occupying a 1cmx1cm chip) we have $R_0C_0 = 0.244$ pico sec. and we get $\tau_{\text{chip}} = 4.1$ nano sec. The delay in the clock distribution on the board is determined in a similar manner as the path delay. It consists of the delay in driving a driver with a 50 ohm output impedance and the delay in driving a line of maximum length of 35 inches. Thus $\tau_{\text{board}} = 11.3$ nanoseconds. Thus, the total clock delay is $\tau = 15.4$ nanoseconds. An expression for the clock skew is given in Section 5. Assuming a 20% variation over the nominal value in both the clock delay and transistor threshold voltages, the clock skew is obtained as:

$$\delta = .8\tau\log(1-2/5) - 1.2\tau\log(1-3/5) = .7\tau = 10.8 \text{ nano sec.} \qquad (6.2)$$

We can now estimate the clock frequencies. Note that due to the pipeline design of the network, only the largest delays are significant and both the MCC and DMC designs resulted in equal clock frequencies. Since, $D_L + D_p + \delta > 2\tau$ the clock frequency is:

$$F = \frac{1}{D_L + D_p + \delta} = 27.7 \ MHz \qquad (6.3)$$

### 7. Summary and Conclusions

This paper has presented design expressions for implementing an $N \log N$ packet passing interconnection network composed of circuit switched CB chip modules. The expressions considered are derived from various physical constraints and network models. Chip level and board level pin and area constraints are considered and expressions are derived which indicate the sort of delay which can be expected through a network at a given frequency, and the design constraints on achieving that frequency.

An example 2048x2048 network design is considered. This example indicates that using aggressive packaging and MOS technology, a rate of about 28 Mhz is achieveable. However, this frequency, with this network design, would result in a one way delay (ignoring blocking and hot spot delays) of about 1 $\mu$second. A read operation from memory requiring a round trip would thus require more then 2 $\mu$seconds. This represents more then an order of magnitude slowdown when compared with accessing strictly local memory and appears to be a major problem in the design of VLSI based, network centered multiprocessor architectures which utilize standard clock destribution designs.

ACKNOWLEDGMENT

We would like to thank Bill Thomas for his help in developing a number of the models presented in the paper.

### *ABSTRACT*

Symmetric graphs, such as the ring, the $n$-dimensional Boolean hyper-cube and the cube-connected cycles, have been widely used as processor/communication interconnection networks. The performance of such networks is often measured through an analysis of their degree, diameter, connectivity, fault tolerance, routing algorithms, etc. In this paper we develop a formal group theoretic model, called the *Cayley graph* model, for designing, analyzing and improving such networks. We show that this model is universal and demonstrate how the networks mentioned above can be concisely represented in this model.

More importantly, we show that this model enables us to design new networks based on representations of finite groups. We can then analyze these networks by interpreting the group theoretic structure graph theoretically. Using these ideas, and motivated by certain well known combinatorial problems, we develop two new classes of networks, called the *star graphs* and the *pancake graphs*. These networks are shown to have better performance, as measured by the parameters mentioned above, than the popular n-cubes.

## 1. INTRODUCTION

A processor/communication interconnection network is often modeled as an undirected graph, in which the nodes correspond to processor/communication ports, and the edges correspond to communication channels. Communication over such a network is achieved by a message passing protocol, and the delay in communication is measured by the number of edges traversed. Some of the key features of interest in such an interconnection network are its degree, diameter, congestion, symmetry, connectivity, routing algorithms, structure, etc.

A number of interconnection network topologies have been suggested in the literature which address one or more of the above features ([1-7]). These range from simple graphs, such as cycles, complete graphs and stars to more sophisticated graphs such as shuffle-exchange graphs, n-dimensional Boolean cubes and cube-connected cycles. Since there is no single measure to compare these networks, each of the above examples have been justified for one application or another.

A special class of networks, called *symmetric interconnection networks*, have the property that the network viewed from any vertex of the network looks the same. In such a network congestion problems are minimized since the load will be distributed uniformly through all the vertices. Moreover, this symmetry allows for identical processors at every node with identical routing algorithms. It is also very useful in designing algorithms that exploit the structure of the network. it is this class of networks that we address in this paper. With the exception of the star network and the shuffle exchange graphs, all of the networks mentioned above are symmetric networks.

In designing symmetric interconnection networks, the overall objective has been to construct large vertex symmetric graphs with small degree and diameter, high connectivity and offering simple routing algorithms.[1] One attractive network that offers all these properties together with a good degree and diameter is the n-cube, which is a network of $2^n$ vertices, with degree $n$ and diameter $n$. Thus, the n-cube will be used as a standard against which to compare many of the networks constructed in this paper.

Specifically, we shall present a group theoretic model for designing, analyzing and improving symmetric interconnection networks. We show that most symmetric interconnection networks can be represented using this model, and that *every* symmetric interconnection network can be represented by a simple extension of this model. This allows us to provide an algebraic representation of each of the symmetric networks mentioned above. More importantly, this group theoretic model enables us to start with an arbitrary finite group and construct a symmetric network using that group as the algebraic model. This, in conjunction with the vast literature, on finite groups allows us to construct a variety of new interconnection networks.

Another advantage of analyzing such networks in this algebraic setting is that many properties of these networks can be proved for the class as a whole, instead of proving that property for each network independently. For example, all networks derived from a finite group are necessarily vertex symmetric, i.e., the network viewed from any vertex in the network looks the same. We prove a number of other such properties of these networks. Further, even for specific networks constructed using this algebraic model we can often derive properties algebraically and interpret the properties graph theoretically. We will repeatedly use this technique in this paper.

Apart from the algebraic model suggested in this paper we also offer two specific classes of networks that are especially attractive for distributed processing. We call these the *star graphs* and the *pancake graphs*. We describe these networks in some detail and compare them to the $n$-cubes.

The paper is organized into 8 sections. In the second section we define the algebraic model, called the *Cayley graph* model and provide a number of examples as well as some new networks. In Section 3 we prove certain general properties of Cayley graphs. In Section 4 we define *transposition trees* which is a level of abstraction beyond Cayley graphs. A specific Cayley graph resulting from a specific transposition tree, called the *star graph*, is investigated in Section 5. In Section 6 we present some preliminary ideas on designing algorithms on another class of such graphs, called *pancake graphs*. In Section 7 we compose Cayley graphs using a variety of group theoretic operations and study the resulting graphs. The concluding Section 8 reiterates the fertile source of new networks offered by this group theoretic model.

[1] We point out that the problem of constructing large graphs of a given degree and diameter - known as the (d,k) graph problem - is a well studied extremal graph theory problem. However, solutions to the (d,k) graph problem often ignore the more subjective parameters of this problem, such as symmetry, ease of routing and the structure of the graph, which are essential for the design of efficient algorithms on these networks.

In the remainder of this section we will state the group theoretic and graph theoretic terminology that we will use in this paper. We will assume basic knowledge of elementary group theory and graph theory. The reader is referred to [14 and 15] for an elementary exposition of the relevant terminology in group theory and graph theory, respectively. Since we will only be considering finite groups we will represent our groups as permutation groups. We will be using a one-row representation for permutations. Thus, the permutation whose cycle representation is (12)(345) will be represented by us as 21453. Recall that transpositions are permutations with exactly one cycle of length 2 and all other cycles of length 1. Our descriptions of permutations will be quite informal. Thus, we will view a transposition as *swapping* a pair of symbols.

As we mentioned in the beginning of the section, we will view interconnection networks as an undirected[2] graph. Thus in the remainder of the paper we will use the term *graph* in place of *interconnection network.* Our graphs will be finite, undirected, loop-free and devoid of multiple edges. We will make special use of cycles, complete graphs, trees, and stars.

## 2. THE CAYLEY GRAPH MODEL

Given a set of generators for a finite group G, we can draw a graph, called the *Cayley graph,* in which the nodes correspond to the elements of the group G and the edges correspond to the action of the generators. That is, there is an edge from an element $a$ to an element $b$ iff there is a generator $g$ such that $ag=b$ in the group G. We require that the set of generators be closed under inverses so that the resulting graph can be viewed as being undirected.

Let us illustrate Cayley graphs with a few examples which will make these ideas clearer. First, we point out that since we will be considering permutation groups the generators are themselves permutations. We will be representing permutations using the symbols 1, 2, 3,..., $n$. For example, consider the generators 1324, 2143 and 4321. Since these generators are permutations of four symbols they must generate either $S_4$ (which itself consists of 24 permutations) or a subgroup[3] of $S_4$. In this case the subgroup generated by these three generators consists of the 8 permutations: 1234, 2143, 2413, 4231, 4321, 3412, 3142 and 1324. The corresponding Cayley graph arising from the above generators is shown in Figure 1. The reader can easily convince himself that the edges of this graph correspond to the action of the generators.

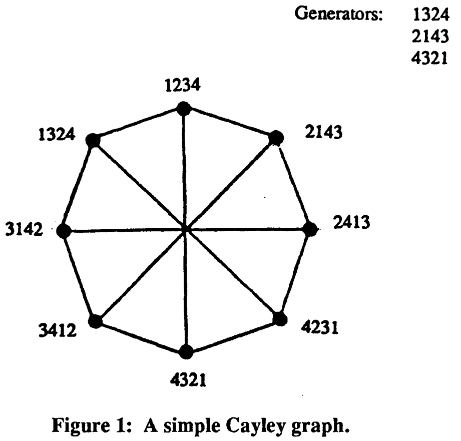

**Figure 1: A simple Cayley graph.**

As another example, consider the generators 213456, 124356 and 123465. The group generated by these generators again contains 8 permutations. These permutations and the corresponding Cayley graph are shown in Figure 2. We might point out that this is, of course, the familiar 3-dimensional cube. Figures 3 and 4 show two additional examples of Cayley graphs, where we have only shown the permutations at a few selected nodes. In Figure 4 we have also shown the generators as labels on the edges. Again we might simply mention that Figure 3 is a 3-dimensional cube-connected cycle, i.e., a 3-dimensional cube with its corners chopped. Figure 4 is an example of a star graph that we will discuss later in this paper.

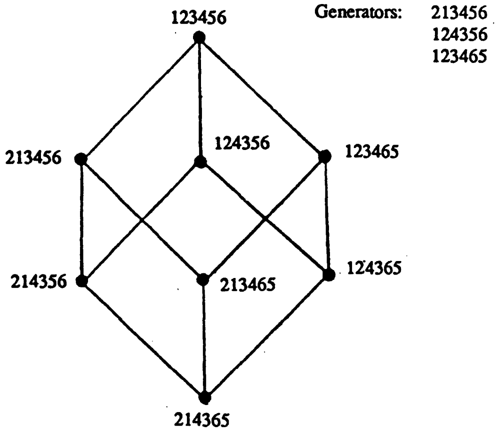

**Figure 2: 3-Cube as a Cayley graph.**

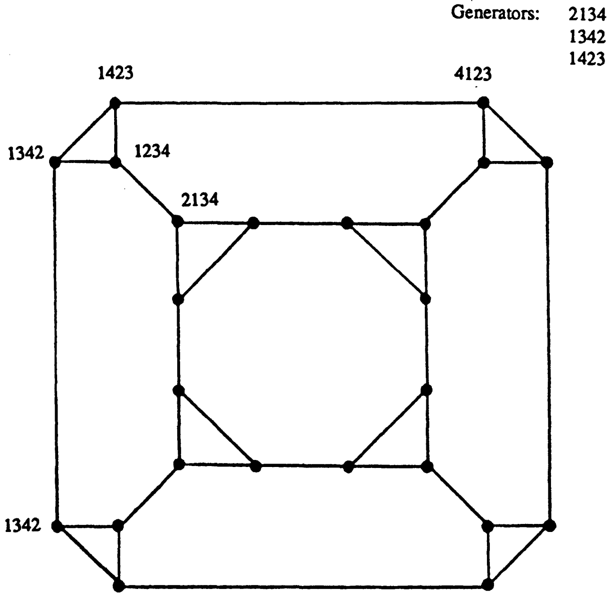

**Figure 3: 3-Dimensional cube-connected cycles as a Cayley graph.**

[2] The techniques of this paper can also be used for directed graphs. However, we will limit our attention to undirected graphs.

[3] The reader unfamiliar with LeGrange's theorem would find it useful to know that in a finite group the order of any subgroup (the number of elements in it) always divides the order of the group.

The reader might have observed that all the Cayley graphs shown so far are vertex symmetric. In fact,

*Theorem 1*: Every Cayley graph is vertex symmetric.

*Proof*: We need to show that given any two vertices in the Cayley graph there exists an automorphism of the graph that maps one vertex into the other. Let $a$ and $b$ be the permutations corresponding to the two vertices. Consider the transformation on the group that maps an arbitrary permutation $x$ into $ba^{-1}x$. Clearly, this maps $a$ into $b$. Further, this transformation is an automorphism of the graph. For, if two permutations $x$ and $y$ were connected by an edge in the graph then there is a generator $g$ such that $xg=y$. Then the images of the two permutations, $ba^{-1}x$ and $ba^{-1}y$, are connected by an edge since $ba^{-1}xg=ba^{-1}y$. Hence the proof. □

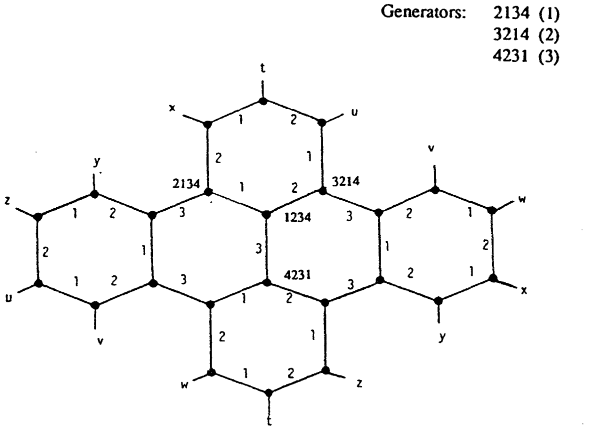

**Figure 4: An example of a star graph.**

As mentioned in Section 1, an attractive feature of vertex symmetric graphs is that routing between two arbitrary nodes reduces to routing from an arbitrary node to a special node. We can now state this more formally. First, observe that in a Cayley graph a path from one vertex to another can be represented by a sequence of generators $g_1,g_2,\ldots,g_p$, where each $g_i$ is a generator of the Cayley graph. Now if $g_1,g_2,\ldots,g_p$ is a path from $x$ to $y$ then it is also a path from $y^{-1}x$ to $I$, the identity permutation. Thus if we want to find a route from $x$ to $y$ we can instead find a route from $y^{-1}x$ to $I$. Consequently the problem of routing reduces to the problem of sorting!

We can now describe a class of Cayley graphs, which we will call the *bubble sort graphs*. Recall that a Cayley graph is completely specified by providing the set of generators. The generators for the $n^{th}$ bubble sort graph is the set of $n-1$ transpositions of the $n$ symbols $1,2,\ldots,n$ that transpose adjacent symbols. Thus, for $n=4$ the generators are: 2134, 1324 and 1243. Notice that a path in this graph is a sequence of adjacent transpositions. Thus, finding a route from a given permutation to the identity permutation is equivalent to sorting the given permutation using the familiar bubble sort algorithm. The reader can verify that the group generated by this set of generators is the symmetric group $S_n$. Consequently, the corresponding Cayley graph has $n!$ vertices. Further, it is easily shown that the corresponding Cayley graph has degree $n-1$ and diameter $\binom{n}{2}$.

As a second example of a family of Cayley graphs we consider an old combinatorial problem, called the *pancake flipping problem* [8]. The problem is to sort a stack of $n$ pancakes of different sizes by repeatedly flipping top sub-stacks with a spatula. For example, consider an arrangement of 5 pancakes represented by the permutation 23514. Let us adopt the convention that the left end of the permutation is the top of the stack. Thus the sorted stack would look like the identity permutation 12345. If we apply a 3-flip, i.e., flip the top (left) three pancakes with the spatula, the 23514 permutation will be transformed into 53214. Notice that such a 3-flip is equivalent to multiplying on the right by 32145. We give below a sequence of flips to sort the given permutation:

$$23514 \rightarrow 53214 \rightarrow 12354 \rightarrow 45321 \rightarrow 54321 \rightarrow 12345$$

We model the pancake flipping problem as a class of Cayley graphs using generators representing the pancake flips. Thus, flipping the top $i$ of $n$ pancakes with a spatula gives rise to the generator $i(i-1)...321(i+1)(i+2)...n$. Clearly, there are (n-1) generators, one for each value of $i$, $1<i\leq n$. It is easy to show that the corresponding Cayley graph has $n!$ vertices with degree $(n-1)$. Finding the diameter of the *pancake graph* is equivalent to finding the maximum number of pancake flips one would need to sort an arbitrary stack of pancakes. This problem is still open, and the best know results can be found in [13].

For this paper we will give a simple routing algorithm that routes in at most (2n-3) steps. Recall that instead of finding a path between two arbitrary permutations, it suffices to find a path from one permutation to the identity, i.e., sort a given permutation. In one step we can bring the symbol $n$ to the left most position using an appropriate flip (generator). In one more step, we can bring $n$ to the $n^{th}$ position using the $n$-flip. Thereafter, we can ignore the symbol $n$ and sort the remainder of the permutation, recursively. This yields a route of $2n$ steps. We can slightly improve this by observing that the last two symbols, i.e., the symbols 1 and 2, do not require two steps each. In fact, when we have moved all the other symbols to their place, 1 and 2 would require at most one more flip. Hence the (2n-3) result. Note that we have in effect proved a (2n-3) upper bound on the diameter of this Cayley graph. We will point out that in contrast to the $n$-cubes, whose diameter and degree grow logarithmically as a function of the number of vertices, the $n$-pancake graphs have degree and diameter that grow slower than logarithmically as a function of its size.

Before we offer a picture of the pancake graph for a small value of $n$, we will first mention some elementary properties of Cayley graphs. This will allow us to use the underlying group theoretic structure of these graphs in analyzing them.

## 3. PROPERTIES OF CAYLEY GRAPHS

Since a Cayley graph is completely specified by a set of $d$ permutations as generators. The degree of the graph will, of course, be $d$. We have already shown in Theorem 1 that every Cayley graph is vertex symmetric. As we had mentioned in Section 1, a vertex symmetric graph has the desirable property that the communication load is uniformly distributed on all the vertices so that there is no point of congestion. A stronger notion of symmetry, called *edge symmetry* requires that every edge in the graph look the same. That is, given two edges of the graph there is an automorphism of the graph that maps one edge into the other. Such a symmetry would ensure that the communication load is uniformly distributed over all the communication links, so that there is no congestion at any one link. It is easy to prove the following necessary condition for a Cayley graph to be edge symmetric. We state it without proof:

*Theorem 2*: Consider a Cayley graph defined by a set of $d$ generators on $n$ symbols $\{1,2,3,...,n\}$. If for every pair of generators there exists a permutation of the symbols that maps one generator into the other then the Cayley graph is edge symmetric.

As a consequence of the above theorem we can conclude that the bubble sort graphs are edge symmetric.

Apart from the symmetry properties of these Cayley graphs there is a very useful decomposition of these graphs that can be seen using elementary group theory. First, we observe that one of the attractive features of the $n$-cube is its recursive decomposition into smaller cubes. Thus, an $n$-cube can be viewed as consisting of two $(n-1)$-cubes, interconnected by edges that are said to lie in the $n^{th}$ dimension. We will now show that this property can be abstracted as a group theoretic property and is possessed by a number of different Cayley graphs.

Consider the 4-pancake graph defined by the 3 generators 2134, 3214 and 4321 on 4 symbols. Let us examine the subgraph of the 4-pancake graph consisting of those vertices (i.e., permutations) that fix the symbol 4 in the $4^{th}$ position. Clearly, there are 3! such permutations and thus six vertices in this subgraph. Further the only edges that connect these vertices in this subgraph are those that correspond to the first two generators, since the last generator will move the symbol 4 from the $4^{th}$ position. Consequently, this subgraph is identical to a 3-pancake graph (on the symbols $\{1,2,3\}$), with the symbol 4 being affixed at the end of each permutation.

More interestingly, let us now examine the subgraph of the 4-pancake graph consisting of the 6 permutations that fix the symbol 3 in the last position. Once again we will find that the subgraph is identical to the 3-pancake graph, but this time on the symbols $\{1,2,4\}$, with the symbol 3 being affixed at the end of each permutation. In this manner we can identify 4 mutually disjoint subgraphs of the 4-pancake graph, each of size $3!=6$, with each subgraph being a copy of the 3-pancake graph. These 4 copies of the 3-pancake graph are then interconnected by edges that correspond to the $4^{th}$ generator, i.e., the generator corresponding to a flip of all four pancakes. We can now offer the informative picture of Figure 5 illustrating the 4-pancake graph.

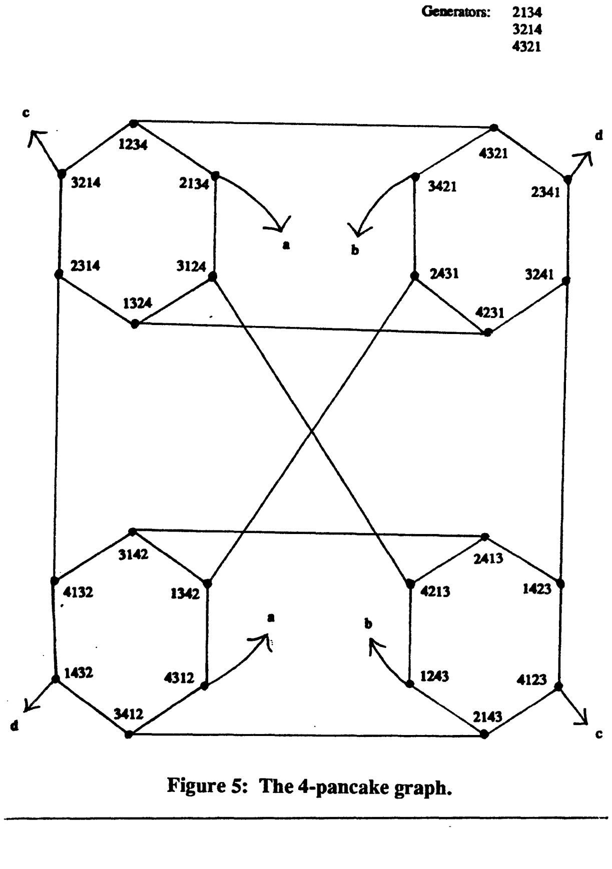

**Figure 5: The 4-pancake graph.**

Finally we make the trivial observation that the 3-pancake graph itself (i.e., the hexagon) is made up of 3 copies of the 2-pancake graph which is itself a line. More generally, an $n$-pancake graph can be viewed as $n$ copies of $(n-1)$-pancake graphs that are interconnected by edges corresponding to the $n$-flip. Further, this decomposition can be carried out recursively, so that each of the $(n-1)$-pancake graphs in turn are made up of $n-1$ copies of $(n-2)$-pancake graphs, and so on.

We can now ask which Cayley graphs have this recursive decomposition property. Notice that in the 4-pancake graph we used the property that the 4-flip cannot be obtained through any combination of 2- and 3-flips. That is, the permutation corresponding to the 4-flip, i.e, 4321, is outside the subgroup generated by the 2- and 3-flips. In fact, that is the only requirement that is needed for such a decomposition. Thus, for convenience we will define a Cayley graph to be *hierarchical*, if its generators can be ordered as $g_1,g_2,\ldots,g_d$, such that for each $i$, $1<i\leq d$, $g_i$ is outside the subgroup generated by the first $i-1$ generators. Under this definition, every hierarchical Cayley graph has such a recursive decomposition structure.

Another important property of interconnection networks is their fault tolerance. The *fault tolerance* of a graph is better defined through the graph theoretic property, called *connectivity*. The *connectivity* of a graph is the minimum number of vertices that need to be removed to disconnect the graph. The fault tolerance is then one less than the connectivity and indicates the maximum number of vertices that can be removed and still have the graph remain connected. Clearly, any graph can be disconnected by removing all the vertices adjacent to a given vertex. Thus its connectivity can be at most its degree.. It has been shown that hierarchical Cayley graphs (with an additional size requirement) are *maximally fault tolerant*. That is, their fault tolerance is exactly one less than their degree.

The last property we will mention in this section is the universality of this model for symmetric graphs. Can every vertex symmetric graph be represented as a Cayley graph? For example, the $n$-cube can be represented as a Cayley graph by generalizing the example shown in Figure 2. We will offer a more formal representation of the $n$-cube in Section 7. We will also provide in that section a representation of the cube-connected cycles as Cayley graphs. While, most symmetric networks considered in the literature can be viewed as Cayley graphs, it remains that there are certain vertex symmetric graphs that cannot be represented as Cayley graphs. A prime example is the Petersen graph, shown in Figure 6.

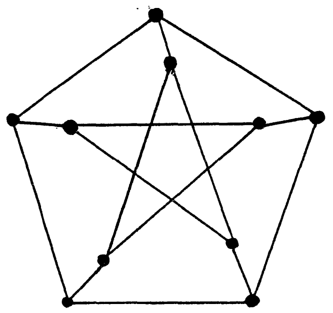

**Figure 6: Petersen graph — An example of a vertex symmetric graph that is not a Cayley graph.**

However, one can extend the Cayley graph model to the *quotient graph* of two Cayley graphs. In this paper we will merely give a rough definition of the quotient and state (without proof) a theorem that establishes the universality of this model. To define the quotient graph of two Cayley graphs we select a subgroup of the group generated by the given set of generators. We then identify the subgroup and all its cosets as subgraphs of the Cayley graph. The quotient graph is obtained by reducing these subgraphs to vertices and connecting two such vertices iff there existed an edge between elements of the corresponding subgraphs.

*Theorem 3*: Every vertex symmetric graph can be represented as the quotient of two Cayley graphs.

Finally, we mention an interesting open conjecture. Recall that a *Hamiltonian path* is a path that visits every vertex exactly once. A *Hamiltonian cycle* is a cycle that forms a Hamiltonian path.

*Conjecture*: Every Cayley graph is Hamiltonian, i.e., has a Hamiltonian cycle. Further, every vertex symmetric graph has a Hamiltonian path.

This conjecture has remained open in the sense that neither has it been proven nor has a Cayley graph been shown to violate it. For specific Cayley graphs it is often easy to establish that it is Hamiltonian. For example, the Hamiltonian property of the $n$-cubes is demonstrated by Gray codes. The Hamiltonian property of the $n$-pancake graphs have been shown in [16].

As we have mentioned, most symmetric interconnection networks that have been suggested in the literature can be represented as Cayley graphs. However, we offer this group theoretic model not only to capture existing networks, but also to design new networks. It is in this vein that we suggest the pancake graphs. We have already pointed out how their degree and diameter (as a function of its size) are more attractive than the $n$-cubes. Later, in Section 6 we will show how we can design some fundamental computational algorithms on the pancake graphs. But first, we will show how even better graphs can be designed using the Cayley graph model.

## 4. TRANSPOSITION TREES

Again we recall that a Cayley graph is completely specified by providing a set of $d$ permutations as generators. We do point out a requirement that this set of permutations be closed under inverses. In the examples of Cayley graphs given above we have not explicitly shown to have met this condition since the generators that we have used have often been involutions, i.e., self-inverses. A special class of involutions are the transpositions — permutations that swap two symbols. For example, 12435 is a transposition that swaps the symbols 3 and 4. All the generators of the bubble sort graphs are transpositions. In this section we provide a model for representing a set of (n-1) transpositions as generators.

Consider a tree on $n$ vertices. We can label the vertices of this tree with the symbols $\{1,2,3,...,n\}$ and interpret the edges as transpositions. For example, the tree on 6 vertices shown in Figure 7, gives rise to 5 transpositions: 321456, 132456, 124356, 123546 and 123654. Thus, we can interpret a tree as a set of transpositions, which in turn give rise to a Cayley graph. We call such a tree, a *transposition tree*. As another example, the path on $n$ vertices gives rise to the bubble sort graph. The following general theorem about Cayley graphs of transposition trees is an indication of the symmetry and structure underlying these graphs that can be readily uncovered by a simple group theoretic analysis:

*Theorem 4*: Let $\Gamma$ be a Cayley graph of a transposition tree of order n. Then,

1. $\Gamma$ has $n!$ vertices. (A well known result attributed to Polya)
2. Both the edge and vertex connectivity of $\Gamma$ are maximal, i.e., equal to its degree.
3. The chromatic index of $\Gamma$ is equal to its degree.
4. $\Gamma$ can be represented as an interconnection of n identical copies of a Cayley graph of a transposition tree of order $n-1$, and hence is hierarchical.

We can view the Cayley graph of a transposition tree as the state diagram of a puzzle. Consider the vertices of the transposition tree to be labeled as suggested above. Now place $n$ markers, each labeled with a symbol from $\{1,2,3,...,n\}$, at the vertices of the tree in any arbitrary way. The puzzle is to move the markers to their appropriate positions by moves consisting of interchanging the markers at the ends of an edge in the transposition tree. The Cayley graph is then the state diagram of such a puzzle. That is, the vertices of the Cayley graph are the possible arrangement of markers at the vertices of the tree. The edges of the Cayley graph correspond to the permissible moves in this puzzle. Finding a path in the Cayley graph corresponds to sorting a permutation, which in turn corresponds to solving this puzzle. It can be shown:

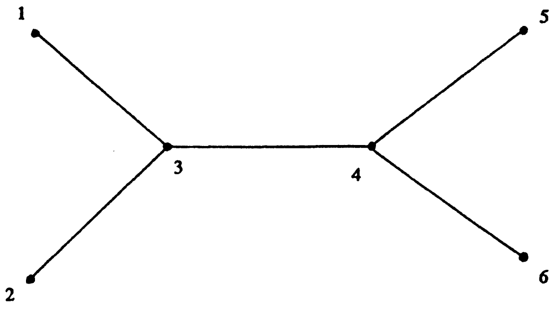

**Figure 7: An example of a transposition tree.**

*Theorem 5*: Let $T$ be a transposition tree on $n$ nodes. Given an assignment of markers as a permutation, $\pi$, of the nodes of $T$, $\pi$ can be sorted in

$$\textit{\# of cycles in } \pi + n + \sum_{i=1}^{n} \delta(i,\pi(i))$$

where, $\delta(i,j)$ is the distance between nodes $i$ and $j$ in $T$.

We remark that the above bound on the diameter of the Cayley graph conforms to the diameter of the bubble sort graph. In fact,

*Theorem 6*: Of all trees on n nodes, the path yields a Cayley graph (i.e., the bubble sort graph) of maximum diameter.

We omit proofs of the above theorems for brevity. Instead we now focus our attention on a specific transposition tree.

## 5. THE STAR GRAPH.

Motivated by Theorem 6, we consider the other extreme tree, namely the star, as a transposition tree. The resulting Cayley graph is called the the *star graph*. Since this is an especially attractive alternative to the n-cube, we provide an informal description of this graph. The nodes of the graph are labeled by permutations of 1 through $n$. A permutation is connected to every other permutation that can be obtained from it by interchanging the first symbol with any of the other symbols. Thus, clearly the degree of the graph is $n-1$. An illustration of the 4-star graph was given in Figure 4.

Let us examine how we might route within this graph. Recall that routing between two vertices in a Cayley graph is equivalent to sorting a permutation. So we need to ask how we might sort a given permutation by exchanging the first symbol with any of the other symbols. For example, consider the permutation 64725831. Let us employ a greedy algorithm where we observe that the symbol in the first position, namely 6, can be moved to its correct position by exchanging 6 and 8. This gives us the permutation 84725631. Again, a greedy move gives us 14725638.

Now we are stuck, since 1 is already at its own position. We now waste one step and move 1 into any position not occupied by the correct symbol. In this case we could interchange 1 and 4 yielding the permutation 41725638. Now following the greedy approach gives us 21745638 and subsequently 12745638. Again we need to waste a step and insert 1 into a position not occupied by the correct symbol. Thus, interchanging 1 with 7 gives 72145638. Resorting back to the greedy step gives 32145678 and the final move to 12345678. Notice that we took 8 moves to sort this permutation. That means that in the Cayley graph we have shown a path of length 8 between 64725831 and the identity.

Of course, this does not establish the diameter of the Cayley graph. For that we must find the permutation that requires the maximum number of steps to sort. Instead, we will derive the exact number of steps required to sort an arbitrary permutation in the following Lemma:

*Lemma 1*: The number of steps required to sort a permutation $\pi$ using the generators of the star graph is given by [4]:

$$n + \#\ \mathit{of\ cycles\ in}\ \pi - 2(\#\ \mathit{of\ invariances\ in}\ \pi) - \begin{cases} 2 & \text{if } \pi(1) \neq 1 \\ 0 & \mathit{otherwise} \end{cases}$$

*Proof*: Follows from the routing algorithm described above. □

*Theorem 7*: The diameter of the $n$-star graph is $\left\lfloor \frac{3}{2}(n-1) \right\rfloor$, and its average diameter is $n+\frac{2}{n}+H_n-4$, where $H_n$ is the $n$th Harmonic number.

*Proof*: The diameter follows by maximizing the formula given in Lemma 1. To establish the average diameter we total the quantity given in Lemma 1 for each $\pi$ and divide by $n!$. It is well known (see [17, p.176]) that the average number of cycles in a permutation of $n$ symbols is $H_n$, the $n^{th}$ harmonic number. Thus, the total number of cycles, over all $n!$ permutations is $n!H_n$. It is also easy to establish that the total number of invariances over all permutations of $n$ symbols is $n!$. Finally, the total number of permutations $\pi$, such that $\pi(1)=1$ is $(n-1)!$. Thus, the average diameter is:

$$\frac{1}{n!} \left[ n(n!) + n!H_n - 2 \cdot n! - 2(n! - (n-1)!) \right]$$

$$= n + H_n - 4 + \frac{2}{n}. \ \square$$

Let us compare this network against the $n$-cube. Recall that the $n$-cube interconnects $2^n$ vertices with degree $n$ and diameter $n$. In contrast, the $n$-star graph interconnects $n!$ vertices with degree $n-1$ and diameter $\left\lfloor \frac{3}{2}(n-1) \right\rfloor$. Notice that both the degree and diameter of the star graph grows slower than a logarithmic function of its size. Thus, asymptotically, the star graphs offer a network with less interconnecting edges and smaller communication delays than the $n$-cubes. Even from a practical point of view, it is evident from Table 1 that purely based on the degree and diameter requirements the star graph is superior. Table 1 provides a comparison of various $n$-cubes against comparable $n$-star graphs.

| A Comparison | | | | | | | |
|---|---|---|---|---|---|---|---|
| *n-cube* | | | | *n-star graph* | | | |
| *n* | *Size*<br>$2^n$ | *Degree*<br>*n* | *Diameter*<br>*n* | *n* | *Size*<br>*n!* | *Degree*<br>*n-1* | *Diameter*<br>$\left\lfloor \frac{3}{2}(n-1) \right\rfloor$ |
| 7 | 128 | 7 | 7 | 5 | 120 | 4 | 6 |
| 8 | 256 | 8 | 8 | 6 | 720 | 5 | 8 |
| 9 | 512 | 9 | 9 | 6 | 720 | 5 | 8 |
| 10 | 1024 | 10 | 10 | 7 | 5040 | 6 | 9 |
| 11 | 2048 | 11 | 11 | 7 | 5040 | 6 | 9 |
| 12 | 4096 | 12 | 12 | 7 | 5040 | 6 | 9 |

Table 1.

Of course, the degree and the diameter are not the only consideration for choosing a specific network. Let us examine some of the other relevant properties. The connectivity of the $n$-cube is $n$, indicating that up to $n-1$ vertices can fail without disrupting the network. Recall that the connectivity is at most equal to the degree of the graph. In the case of the $n$-star graph the degree is $n-1$, And, indeed, its connectivity is also $n-1$. So it is maximally fault tolerant. This is a result from [10]. Actually, such a worst-case fault tolerance measure does not really reflect the practical fault tolerance of the network. Even though the $n$-cube has a connectivity of $n$, the only way to remove $n$ vertices and disconnect the graph is by removing all the $n$ neighbors of any one vertex — a very unlikely event. Likewise, even though the connectivity of the $n$-star graph is $n-1$ the only way to remove $n-1$ vertices and disconnect the graph is to remove all the $n-1$ neighbors of any one vertex. In general both these networks can tolerate a much higher failure.

With regard to symmetry considerations, we recall that the $n$-cube is both vertex and edge symmetric. This alleviates any congestion problems. We know that the star graphs, being Cayley graphs, are vertex symmetric. Further, it is easy to show that the Cayley graph of an edge symmetric transposition tree is itself edge symmetric. Thus, the star graphs, arising from the star as a transposition tree, are also edge symmetric.

We have already noted the recursive decomposition structure of the $n$-cube? Does the star graph possess that property? It is easy to see from the generators that the star graphs are hierarchical. We can infer from that that they can be recursively decomposed. But, better yet, they can be recursively decomposed into $n$ copies of $(n-1)$-star graphs, each of which is in turn further decomposable into smaller star graphs. Such a recursive decomposition can be identified in the diagram of the 4-star graph given in Figure 4. Since the 3-star graph is a hexagon, the 4-star graph consists of 4 copies of the hexagon interconnected by edges corresponding to the $3^{rd}$ generator. Even though a preliminary inspection of Figure 4 suggests 6 hexagons, we should isolate those hexagons whose edges are labeled with 1 and 2 only. The reader will notice 4 such hexagons. These are then interconnected by the edges labeled 3.

Additionally, like the $n$-cube which can be decomposed along any one of its $n$ dimensions, the star graphs can be decomposed along any one of its "$n$ dimensions." Let us explain this further. Observe that an $n$-cube is made up of two copies of an $(n-1)$-cube connected by edges in the $n^{th}$ dimension. However, any one of the edges of the $n$-cube can be viewed as the $n^{th}$ dimension. Similarly, any one of the edges in the star graph can be viewed as the last dimension. So we can break it up into $n$ copies of $(n-1)$-star graphs along that dimension. We do this by observing that if we consider the subgraph consisting of all the permutations that fix the symbol $i$ $(1<i\leq n)$ in the $i^{th}$ position then we are left with $(n-1)!$ vertices that are interconnected by edges that correspond to swapping the first symbol with any one of the other symbols — except the symbol in the $i^{th}$ position.

[4] The number of cycles in a permutation includes the number of invariances.

We have tried to make a case for the star graphs by comparing them to the $n$-cubes. We believe that the Cayley model extracts the attractive properties of the $n$-cubes and formulates it in an abstract setting. This allows us to design other networks that possess similar properties, the star graphs being a prime example. An issue that we have not addressed in this section is how one uses the interconnection structure of these Cayley graphs to develop specific computational algorithms that can be executed on these networks. We address that in the next section using the pancake graphs as our example.

## 6. ALGORITHMS ON THE PANCAKE GRAPHS

Recall that the $n$-pancake graphs are obtained using the $n-1$ possible pancake flips, which we will denote by $f_2, f_3, ..., f_n$, as generators. The $i^{th}$ pancake flip, $f_i$, is a permutation that reverses the prefix of $i$ symbols in the identity permutation. In Section 2 we analyzed the degree and diameter of these graphs and also its recursive decomposition structure.

In this section we show how we might implement certain fundamental algorithms on such a network. First, we should recount similar algorithms on the $n$-cube. Suppose we wish to find the maximal element amongst $2^n$ elements distributed among $2^n$ processors located at the vertices of an $n$-cube. A straightforward algorithm involves $n$ time steps. At the $i^{th}$ step every processor communicates with the processor connected to it along the $i^{th}$ dimension and compares notes on the maximal element that it has encountered so far. We then claim that at the end of the $n$ steps every processor knows the value of the maximal element. The proof of the claim goes as follows: Let $d_i$ represent an edge along the $i^{th}$ dimension and let a word of the form $d_2 d_4 d_3$ represent a path in the $n$-cube starting from a specified vertex. Using these conventions, consider the word $d_1, d_2, \ldots, d_n$. It is easy to see that given any two vertices on the cube, there is a subsequence [5] of the above word that forms a path from the first to the second. Consequently, for every vertex $a$ of the $n$-cube there is a subsequence of the above word that forms a path from the vertex containing the maximal element to $a$. This establishes the claim that the processor at every vertex knows the maximal element.

The reason for detailing the above algorithm is to establish the background necessary to implement a similar algorithm on the pancake graphs. What we need is a word on the alphabet of the generators $\{f_i\}$, such that given any two vertices in the pancake graph there exists a subsequence of the suggested word that forms a path between the two vertices. Actually, it is sufficient to show that we can sort an arbitrary permutation. We provide precisely that. First, we point out that in an algorithm such as the one suggested above for the $n$-cube each processor communicates with only one other processor at each time step. Consequently, the number of processors that know the value of the maximal element can only double at each step. Thus, any such algorithm must take at least as many steps as the logarithm [6] of the number of vertices. In the case of the $n$-pancake graphs, which contain $n!$ vertices, this lower bound is $O(n \log n)$.

Consider the following word (a single word of 21 symbols broken up into many lines) on the generators of an 8-pancake graph:

$$\begin{array}{rl} f_7 f_4 f_2 & f_8 \\ f_6 f_4 f_2 & f_7 \\ f_5 f_4 f_2 & f_6 \\ f_4 f_2 & f_5 \\ f_3 f_2 & f_4 \\ f_2 & f_3 \\ & f_2 \end{array}$$

The above word has been broken up into many lines to emphasize the block structure of the word, and the groupings within each block have been appropriately indicated.

We claim that for every permutation there is a subsequence of the above word that forms a path to the identity, i.e., sorts the given permutation. To sort the permutation we first bring the largest symbol, namely 8, to the first position. This is done using a subsequence of the first three letters in the word (grouped together to indicate that). It should be clear that we can bring 8 to the first position no matter where 8 starts out. Having done that we take 8 to the last position using $f_8$. Thus, the first block of the word is sufficient to position 8 in the correct place. As the reader might have guessed the subsequent blocks of the word are each sufficient to position each of the remaining symbols in their correct places. We have proved the following general theorem:

*Theorem 8*: There is an $O(n \log n)$ algorithm to find the maximal element amongst $n!$ elements distributed among $n!$ processors located at the vertices of an $n$-pancake graph.

*Proof*: It should be clear how to generalize the word suggested above for the 8-pancake graph into a general word for the $n$-pancake graph. Further, we can also similarly prove that every permutation of $n$ symbols can be sorted by a subsequence of that word. The algorithm, then, is merely to execute one letter of that word at each time step. Executing a letter requires that every vertex communicate with the vertex connected to it along the edge corresponding to that generator and compare notes on the maximal element that it has encountered so far. Thus the (parallel) time taken by this algorithm is exactly the length of the word. It is easy to see that the length of the word is $O(n \log n)$. □

In fact, we can use the above technique to construct a binary tree of depth $O(n \log n)$ over the $n!$ vertices of the pancake graph. Every edge of this tree is an edge of the pancake graph. Thus, we can simulate a binary tree. Once we do that we can perform any computation for which the solution on the $n$-cube employs the construction of a binary tree. For example, as the following theorem states, we can compute prefixes over an arbitrary associative binary operation.

*Theorem 9*: Given any associative binary operation $*$ and an assignment of values $x_i$ to each of the $n!$ processors located at the vertices of an $n$-pancake graph, there is an $O(n \log n)$ algorithm that computes (in parallel) the prefix $x_1 * x_2 * \cdots * x_i$ at processor $i$. (The $n!$ vertices must be numbered appropriately.)

*Proof*: Omitted. □

The prefix computation problem is interesting because it is a general formulation of a class of problems. For example, the problem of computing the maximal element can be viewed as the prefix computation problem over the associative binary operation *MAX*. Other trivial applications include computing an $n$-ary associative operation, such as summation. Non-trivial applications include addition of binary numbers, (particularly, computing the carry bits), simultaneous evaluation of polynomials, etc (see [18]). The prefix computation is merely an example of how we might design algorithms on the pancake graphs. Clearly, there is considerable scope for further work in this area.

In the last two sections we have made a strong case for two new interconnection networks: the star graphs and the pancake graphs. We have shown how they compare against the $n$-cubes. We have used the $n$-cubes as our basis for comparison since (we believe) it is the most popular non-trivial interconnection network. However, the $n$-cubes themselves are Cayley graphs, as we mentioned in Section 1. Even some of the variants of the $n$-cubes, such as the cube-connected cycles, can be abstracted as Cayley graphs. However, this requires that we develop an interesting connection between group theoretic products and graph theoretic products. Unfortunately, space limitations prohibit development of that connection in this paper. Instead, we refer the curious reader to the more detailed report [19].

## 7. CONCLUSION

The main conclusion of this paper is that this group theoretic view of symmetric interconnection networks not only abstracts the structure and symmetry properties that make the n-cubes so attractive, but also offers a fertile source of other promising topologies. We can now bring to bear the algebraic tools in analyzing such symmetric networks[7]. The universality of this model, indicated by Theorem 3, allows us to present all symmetric networks in a uniform and comparable framework.

[5] A subsequence need not necessarily be a contiguous subsequence.

[6] All logarithms are in base 2.

[7] An extensive survey of the literature on the use of group theoretic techniques in analyzing symmetries in graphs can be found in [20].

Some of the immediate advantages of using Cayley graphs as a tool for modeling interconnection networks is the conciseness with which a symmetric network can be specified, i.e., by providing the set of generators for the Cayley graph. Furthermore, casting such a network as a Cayley graph immediately allows one to infer all the generic properties of Cayley graphs.

Aside from representing known interconnection networks as Cayley graphs, we have pointed out how this model offers an inexhaustible source of new topologies. In particular, the ability to start from a finite group and construct a Cayley graph is particularly attractive. We believe that we have hardly made a dent in the possible topologies that one could investigate. And even with such a limited investigation we have uncovered many topologies that compare favorably against the $n$-cubes.

The $n$-cubes have a number of attractive features. But many of these features can be interpreted as symmetry properties that many other Cayley graphs could well possess. We have indicated this at many places during the course of our presentation. A case in point is the recursive decomposition structure of Cayley graphs. That is really an analysis of the cosets of the group with respect to a given subgroup.

Finally, we have made an initial attempt at showing how we might design certain fundamental algorithms on such networks as the pancake graphs. We believe that the design of algorithms on such networks could conceivably use the algebraic properties of these graphs. There are definitely many open problems along these lines.

There are also many other features of an interconnection network that we have not at all addressed in this paper. For example, what are the issues involved in laying out these graphs? Can the $n$-star graphs be laid out at least as efficiently as the comparable $n$-cubes? We do conjecture that the $n$-star graphs can be laid out on a surface of genus (n-2).

In summary, we have offered a unified view of symmetric interconnection networks and suggested some new networks — the star graphs and the pancake graphs. We believe that we have done little more than scratch the surface of an obviously fertile field.

*ABSTRACT*

Parallel communication algorithms are central to large scale parallel computing. This paper identifies worst-case source-destination traffic patterns, and proposes a scheme for obtaining relief by means of randomized routing of packets on simple extensions of the well-known omega networks. The communication problem is considered in two separate contexts: the non-renewal, synchronous and the renewal, asynchronous. In the non-renewal context we show that our scheme performs as well as Valiant's. The algorithm extends naturally from the non-renewal to the renewal. First, we explicitly identify the worst-case traffic intensities in the internal links of the extended omega networks over all source-destination traffic specifications which satisfy loose bounds. Second, the benefits of randomization on the stability of the network are identified. Third, exact results, for certain restricted models for sources and transmission, and approximate analytic results, for quite general models, are derived for the mean delays.

## 1. INTRODUCTION

This paper addresses the concern that particular, not rare, source-destination traffic patterns may cause unbalanced usage of the internal links of an interconnection network and thereby severely degrade performance in large parallel computers [1,2]. Worst-case traffic patterns and their effects are identified, and a scheme for obtaining relief by means of randomized routing on simple extensions of the omega network is proposed and analyzed. Another feature of this work is that the main performance results are given as they depend on a parameter $r$ which measures both the degree of extension of the omega network and the degree of randomization. The omega network [3] corresponds to $r = 0$ and the maximum value of $r$ corresponds to the *fully extended omega network* which has one less than twice as many stages as the omega network.

The communication problem with $N$ sources and $N$ destinations is considered in two separate contexts, the *non-renewal* and the *renewal*. The non-renewal context was introduced by Valiant [4-6] and is a model for synchronous communications. Here the task is to complete a *partial h-relation* [4] in which initially each of the sources have at most $h$ packets, with no destination occurring on more than $h$ packets. The assumption is that all link queues are initially empty and that no packets are allowed into the network while the task is in progress. Valiant exhibited an algorithm on a $\log N$-dimensional hypercube which completed the task in time $O(\log N)$ with overwhelming probability. Now, the hypercube requires switches of degree $\log N$ which is unbounded. The algorithm that we give uses switches of fixed degree and also it requires no scheduling [6] — the queue discipline is throughout first-come-first-served. For the fully extended omega network and for the same non-renewal context, we prove that the scheme has as good delay characteristics as has been proven for Valiant's scheme.

The main results of this paper are on the non-renewal context in which packets are generated, and allowed into the network, continually and asynchronously. Here the main interest is in the stationary throughput-delay characteristics [7] for various traffic patterns. The packets at each source are assumed to form stationary renewal processes. The scheme carries over naturally from the non-renewal context. (Valiant's scheme is not defined for this context.) It is not tied to the omega network with 2×2 switches, which we have chosen to be specific, and other pipelined networks with switches of fixed degree can serve just as well. The randomized routing algorithm requires each packet to be given a statistically independent *scattering ticket*. A *distributed switching rule* implements the routing.

The analysis in the non-renewal context considers *partial* $\lambda$*-relations* in which the intensity, or average rate, at each source is no more than $\lambda$ and the intensity at each destination is no more than $\lambda$. We first give an explicit characterization of the extremal traffic on the internal links of the extended omega

networks. The mean delay is nonlinear in $\lambda$ and rapidly goes to $\infty$ as $\lambda$ approaches a stability boundary. Randomization has the effect of extending the region of stability. The stationary mean time from source to destination is characterized for various stochastic models of the source, link transmission time and the degree of randomization. In particular, on the fully extended omega network this mean time is asymptotically proportional to $\log N$ in the region of stability.

In conclusion, the results of the present worst-case analysis argue strongly for maximum randomization. This paper reports partial results; other results and proofs may be found in [13].

## 2. THE EXTENDED OMEGA NETWORK AND RANDOMIZED ROUTING

The *extended omega network* is obtained by preceding an omega network of $n$ stages ($N = 2^n$) by a *scattering network* with $r$ stages, $1 \leqslant r \leqslant n-1$. See Figure 1 for an example with $n=3$ and $r=1$. At each stage of the scattering network, traffic entering a switch is, on the average, routed to each output port evenly. Scattering is accomplished by assigning a *scattering ticket* to each packet at the source. Each scattering ticket is a binary $r$-tuple $c_r, \ldots, c_1$ in which each element is obtained from the result of a completely independent trial with equiprobable outcomes. A packet with scattering ticket $c_r, \ldots, c_1$ is routed to the output port with the least significant bit of its address given by $c_i$ at the $i^{\text{th}}$ stage of the scattering network. Thereafter the packet is routed through the omega network as usual.

We describe an indexing system for the stages and links in the extended omega network. Of the $n+r$ stages, the one closest to the sources is called the first stage. The ports on both sides of each switch are indexed identically, with all port addresses being $n$-bit binary sequences $a_n, \ldots, a_1$ with zero at the top.

Each link is given an address with the format $(i; a_n, \ldots, a_1)$, where $i$ denotes the stage at which it originates and $a_n, \ldots, a_1$ is the address of the port in the switch at the $(i+1)^{\text{th}}$ stage where the link terminates. The wiring connects output ports $a_n, \ldots, a_1$ at the $i^{\text{th}}$ stage to the input port $a_1, a_n, \ldots, a_2$ at the $(i+1)^{\text{th}}$ stage. The link that makes this connection is, by our previously stated rule, $(i; a_1, a_n, \ldots, a_2)$. The net effect is that a packet on link $(i; a_n, \ldots, a_1)$ on entering a switch in the $(i+1)^{\text{th}}$ stage is switched to output port $b \in \{0,1\}$, and leaves on the link $(i+1; b, a_n, \ldots, a_2)$. Each link is equipped with a queue at its originating port, which for the purposes of this paper is of unlimited capacity.

For each packet originating at source $s_n, \ldots, s_1$ with destination $d_n, \ldots, d_1$ and scattering ticket $c_r, \ldots, c_1$ let

$$\mathbf{R} \triangleq d_n, \ldots, d_1, c_r, \ldots, c_1, s_n, \ldots, s_1 .$$

Now consider a window of width $n$, i.e. it exposes $n$ consecutive numbers of $\mathbf{R}$. The window therefore has $n+r+1$ positions. Number these positions 0 to $n+r$, where position 0 is right most and an increment in position corresponds to sliding the window by one unit to the left. *Fact*: the link used by the packet at the $i^{\text{th}}$ stage, $1 \leqslant i \leqslant n+r$, has address given by the values in $\mathbf{R}$ which are exposed by the window at the $i^{\text{th}}$ position. This Fact is very useful in inferring the traffic carried by a particular link.

The above is consistent with the following distributed switching rule: while the packet is at the switch in the $i^{\text{th}}$ stage, route it to the output port whose address has for its least significant bit

$$\begin{array}{ll} c_i & 1 \leqslant i \leqslant r, \\ d_{i-r} & r+1 \leqslant i \leqslant n+r. \end{array}$$

## 3. TRAFFIC ANALYSIS: THE NON-RENEWAL CASE

The probabilistic bound given here holds for *partial h-relations* [7], see Section 1. The assumption is made in this section that each link transmits one packet in unit time.

The extended omega networks are *not* non-repeating [4] and *not* non-overtaking [8]. That is, it is possible for two packets to use a common link at stage $i_1$, different links at stage $i_2$ and a common link at stage $i_3$, for some $i_1$, $i_2$, $i_3$ where $1 \leqslant i_1 < i_2 < i_3$. Note however that there is partial non-overtaking. To see this split the extended omega network with $(n+r)$ stages into two halves. From the Fact in Section 2 it is easy to see that each isolated half is non-overtaking.

Specifically, with

$$\hat{\imath} \triangleq \left\lfloor (n+r)/2 \right\rfloor, \tag{3.1}$$

each packet's transit through links in stages 1 to $\hat{\imath}$ is called its Phase 1 and its transit from stage $(\hat{\imath}+1)$ to $(n+r)$ is called its Phase 2. The time to complete each phase by all packets in a partial $h$-relation is, in turn, bounded below with the help of the non-overtaking property in each phase.

Consider first Phase 1; Phase 2 is similar. The routes of two packets are said to intersect in Phase 1 if at least one link in stages 1 to $\hat{\imath}$ is common to both routes. Let $X$ be a marked packet. The following facts are proven in [13] to hold regardless of the value of $r$: if for each distinct packet other than $X$ we consider a corresponding trial in which success denotes that the packet intersects the route of $X$ in Phase 1, then these trials are statistically *independent*; the expected number of packets which intersect $X$ in Phase 1 is at most $\sigma h/2$, where

$$\sigma = r - 1 + 2^{1+\left\lfloor (n-r)/2 \right\rfloor}.$$

Note that in the fully extended omega network $\sigma = n$. Then by using standard techniques [4] we prove the following in [13]:

*Theorem 1:* (i) For any $\Delta \geqslant \sigma h/2$,

$$Pr[\text{time to complete Phase 1} \geqslant (n+r)/2 + \Delta] \leqslant Nh \left( \frac{e\sigma h}{2\Delta} \right)^{\Delta} e^{-\sigma h/2}.$$

$$Pr\left[\text{time to complete Phase 2} \geqslant \frac{n+r+1}{2} + h + \Delta\right] \leqslant Nh \left( \frac{e\sigma h}{2\Delta} \right)^{\Delta} e^{-\sigma h/2}.$$

(ii) *Asymptotics:* for $r = n-1$, each phase in any partial $h$-relation is completed in time $O(\log N)$ with overwhelming probability. In particular, for any $K \geqslant e$,

$$Pr[\{\text{time to complete each phase}\} \geqslant (n+r+1)/2+h+Khn]$$

$$\leqslant hN^{-(Kh-1)}$$

For $r = \gamma n$, $\gamma$ fixed and less than unity, each phase in any partial $h$-relation is completed in time $O\left[N^{(1-\gamma)/2}\right]$ with overwhelming probability.

## 4. TRAFFIC ANALYSIS: THE RENEWAL CASE

In the renewal context, at each source $s_n, \ldots, s_1$ the packets to be delivered to destination $d_n, \ldots, d_1$ form a stationary stochastic process with mean rate, or intensity, $\lambda(s_n, \ldots, s_1; d_n, \ldots, d_1)$. A particular case is Poisson processes at the sources. The matrix of these traffic intensities over all sources and destinations constitute the *source-destination traffic specification.* Unlike the treatment in Section 3, here we allow for statistical fluctuations in the time required by each link to transmit a packet, although special consideration is given to the case of constant link transmission time. We assume that when the link transmission times are random, they are, for all links and packets, mutually independent, independent of the traffic and picked from a common distribution with mean 1.

In a partial $\lambda$-relation,

$$\sum_{d_n, \ldots, d_1} \lambda(s_n, \ldots, s_1; d_n, \ldots, d_1) \leqslant \lambda, \quad \forall\, s_n, \ldots, s_1 .$$

$$\sum_{s_n, \ldots, s_1} \lambda(s_n, \ldots, s_1; d_n, \ldots, d_1) \leqslant \lambda, \quad \forall\, d_n, \ldots, d_1 .$$

In full $\lambda$-relations, the above holds with equality. Hereafter, in this section, we exclusively consider full $\lambda$-relations since the results on delay statistics for it are obvious bounds for the partial $\lambda$-relations.

### *4.1 Link Traffic Intensities*

Here $t(i; a_n, \ldots, a_1)$ denotes the traffic intensity, i.e. the mean number of carried packets per unit time, on link $(i; a_n, \ldots, a_1)$. Also, $T(\lambda,n,r)$ denotes the extremal traffic intensity over all links and all traffic specifications satisfying the full $\lambda$-relations, i.e.

$$T(\lambda,n,r) \triangleq \max_{\text{full}\lambda\text{-relation}} \; \max_{i; 1 \leqslant i \leqslant (n+r)} \; \max_{a_n, \ldots, a_1} \; t(i; a_n, \ldots, a_1) .$$

We say that the traffic is *symmetric* if the traffic intensity is identical in all links of the network.

We will find useful the notion of traffic class. Each traffic class is indexed by source, destination and scattering ticket. Each traffic class has an associated traffic intensity and quite obviously the traffic intensity of the class indexed by $s_n, \ldots, s_1; d_n, \ldots, d_1; \quad c_r, \ldots, c_1$ is $\lambda(s_n, \ldots, s_1; d_n, \ldots, d_1)/2^r$.

The traffic intensity $t(i; a_n, \ldots, a_1)$ is obtained by summing the traffic intensity of all classes with routes which include the link $(i; a_n, \ldots, a_1)$. The Fact in Section 2 may be used to calculate this quantity.

The following theorem and its corollary is a summary of our results on the extremal link traffic intensities, both as seen by a packet following a specific route and as seen by an independent observer of traffic in the extended omega network. The proof is in [13].

*Theorem 2:* (i) for full $\lambda$-relations and for all binary $n$-tuples $(a_n, \ldots, a_1)$,

$$t(i; a_n, \ldots, a_1) = \lambda, \quad 1 \leqslant i \leqslant r \text{ and } n \leqslant i \leqslant n+r \text{-(4.1)}$$

If $r = n-1$ then the above specifies the traffic intensities on all links of the extended omega network. If $r < n-1$,

$$t(i; a_n, \ldots, a_1) \leqslant \lambda 2^{\min(i-r,\, n-i)}, \quad r+1 \leqslant i \leqslant n-1 \text{(4.2)}$$

(ii) If $r < n-1$ then there are source-destination traffic specifications satisfying the full $\lambda$-relations such that the traffic intensity on each of the links used in the route followed by a particular class is given by (4.1) and (4.2), with equality holding in (4.2).

*Corollary:* (i)

$$T(\lambda,n,r) = \lambda 2^{\lfloor (n-r)/2 \rfloor} .$$

(ii) The traffic is symmetric for all source-destination traffic specifications satisfying the full $\lambda$-relations if and only if $r = n-1$.

In [13] we construct source-destination traffic specifications for which the traffic intensity on links is as bad as asserted in statement (ii) of the Theorem. The point of the construction is to show that they are not rare.

*Example:* Consider the extended omega network in Figure 1 in which $n=3$, $r=1$. Suppose each source transmits at the average rate of $\lambda$ packets per unit time, and, on the average, source $s_3, s_2, s_1$ sends a fraction $\alpha(s_3,s_2)$ of its packets to destination $s_1, s_2, s_3$ and the remainder to $\bar{s}_1, s_2, s_3$, where the bar denotes bit reversal. The numbers $\alpha(0,0)$, $\alpha(0,1)$, $\alpha(1,0)$, $\alpha(1,1)$ are arbitrary in $[0,1]$.

Note that each destination receives packets at the average rate of $\lambda$ packets per unit time. The resulting traffic intensities on the internal links of the network are as shown on the links in Figure 1. The links of stage 2 either have traffic intensity $2\lambda$ or carry no traffic. For general $n$ and $r$, with $(n+r)$ even, there are many source-destination traffic specifications for which $2^{(n+r)/2}$ links at stage $(n+r)/2$ carry traffic of intensity $\lambda 2^{(n-r)/2}$, and the remaining links of the stage carry no traffic at all.

### *4.2 Stability With Respect to Full $\lambda$-Relations*

The stability condition of interest here is that at each link the traffic intensity is less than the mean link transmission time of packets. Our primary interest is in *stability with respect to full $\lambda$-relations*, i.e. stability for all source-destination traffic specifications which satisfy the full $\lambda$-relation. From the Corollary to Theorem 2, the condition for stability with respect to full $\lambda$-relations is

$$\lambda\, 2^{\lfloor (n-r)/2 \rfloor} < 1 .$$

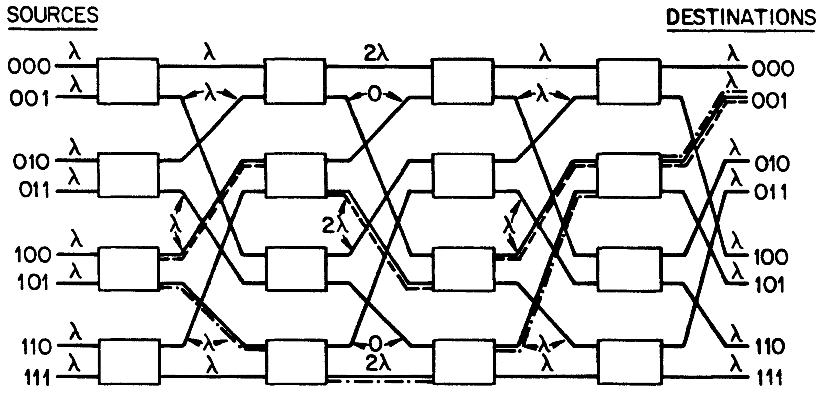

Figure 1: An extended omega network with n=3, r=1. The path from source 101 to destination 001 of packets with scattering ticket $c_1$=1 is shown by chained line, and of packets with $c_1$=0 by dashed line. The inscriptions on links are traffic intensities for Example in Section 4.1.

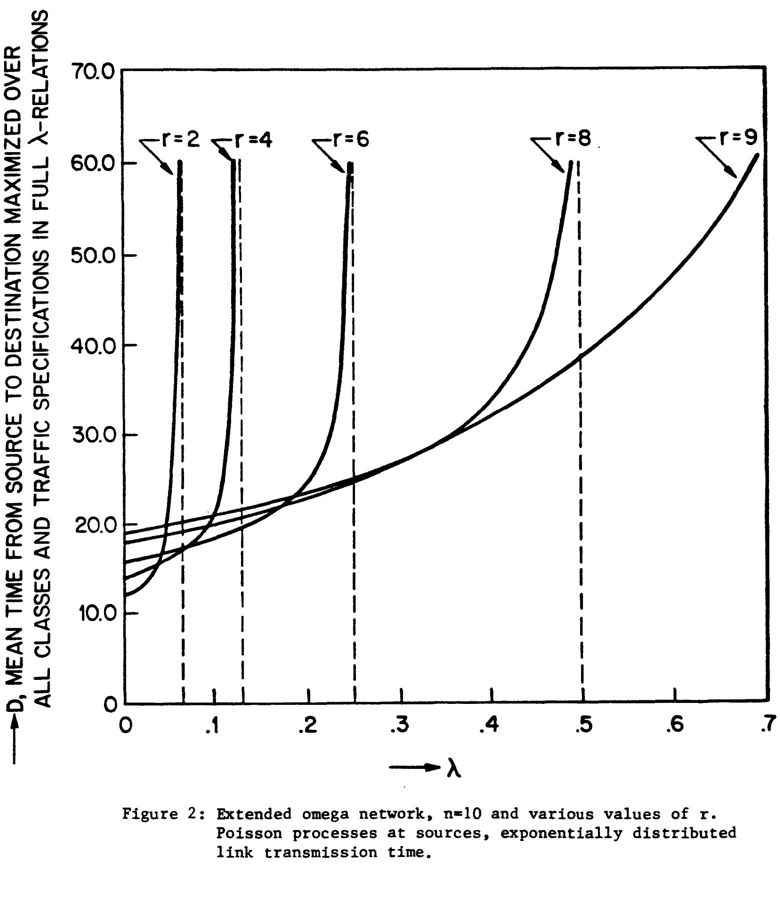

Figure 2: Extended omega network, n=10 and various values of r. Poisson processes at sources, exponentially distributed link transmission time.

For the omega network $r = 0$, and the stability condition is $\lambda < 1/\sqrt{N}$ if $\log_2 N$ is even, and $\lambda < \sqrt{2/N}$ if $\log_2 N$ is odd. For the fully extended omega network $r = n-1$, and the stability condition is $\lambda < 1$.

### *4.3 Mean Delay for Various Degrees of Extensions of the Omega Network.*

Here we make the restrictive assumption that the packets at the sources form Poisson processes and that the link transmission times are random variables with exponential distributions. The exponential has the advantage that exact delay statistics are simple to obtain. The well-known result which makes the problem tractable is that, in equilibrium, the joint distribution of packets of all classes and in all links is of the same form as if the arrival processes to the links are Poisson. Therefore,

$$W(i; a_n, \ldots, a_1) = \text{mean queueing delay at link } (i; a_n, \ldots, a_1)$$

$$= \frac{1}{1 - t(i; a_n, \ldots, a_1)} - 1, \qquad (4.3)$$

where $t(\ )$ is the traffic intensity on the link.

For each class, let

$$D(\text{class}) \triangleq \text{mean time from source to destination for class packets,}$$

$$= \sum_{\text{link} \in \text{class route}} \{W(\text{link}) + 1\}.$$

Finally, let

$$D \triangleq \max_{\text{full}\lambda\text{-relations}} \ \max_{\text{class}} D(\text{class}).$$

From statement (ii) of Theorem 2 we obtain

*Proposition:* With randomized routing in the extended omega network with $n+r$ stages, $1 \leqslant r \leqslant n-1$,

$$D = \frac{2r+1}{1-\lambda} + 2 \sum_{i=1}^{(n-r-1)/2} \frac{1}{1-\lambda 2^i}, \quad \text{if } (n+r) \text{ is odd}$$

$$= \frac{2r+1}{1-\lambda} + \frac{1}{1-\lambda 2^{(n-r)/2}} + 2 \sum_{i=1}^{(n-r-2)/2} \frac{1}{1-\lambda 2^i}, \quad \text{if } (n+r) \text{ is even}$$

Figure 2 plots $D$ against $\lambda$ for various values of $r$ when $n = 10$. This figure indicates that, unless $\lambda$ can be *a priori* restricted to be quite small, the worst-case analysis of this paper argues in favour of maximum randomization.

### *4.4 Approximate Analysis for General Renewal Sources and General Transmission Time Distributions in the Fully Extended Omega Network.*

Here we depart from the preceding treatment of the renewal case by assuming that the packets at the sources form general stationary renewal processes, and the distribution of the link transmission time to be general. Poisson sources and constant link transmission time are, in particular, allowed. However, the analysis is approximate. The program that we follow is based on a proposal of Kuehn [9]. The program decomposes the network into GI/G/1 queues and relates the descriptors of the processes associated with each queue by using prior results [10,11] on GI/G/1 queues. The program undertakes (i) the approximation of the departure process from each link queue as a stationary renewal process, and (ii) the description of each stationary renewal process by two moments, the mean i.e. traffic intensity, and the coefficient of variation of the underlying interarrival distribution. In particular, the distribution of the link transmission time is specified by its mean, which is 1, and its coefficient of variation,

$$c_\ell^2 \triangleq \text{variance of link transmission time.}$$

For constant transmission time $c_\ell = 0$ and for exponential distributions $c_\ell = 1$. Also, the stationary renewal processes at the sources are described by their mean $\lambda$, and the common coefficient of variation $c_s$,

$$c_s^2 \triangleq \frac{\text{variance of interarrival time of packets at source.}}{\lambda^2}$$

For Poisson sources $c_s = 1$. We mention that a large body of validations and corroborations with analytic solutions and simulations have been reported [9-12].

We only consider the fully extended omega network, i.e. $r = n-1$; extensions to $r < n-1$ are easy. In this case traffic is symmetric and we are able to obtain simple, explicit relations, in the form of recursions, for all traffic descriptors in the network. Specifically: (i) the departing process from a link queue in stage $i$ is approximated by a stationary renewal process with coefficient of variation $c_{d,i}$; (ii) this process is split into two stationary renewal processes with means $\lambda/2$ and coefficient of variation $c_{i,i+1}$; (iii) two processes described by $(\lambda/2, c_{i-1,i})$ are superimposed to form the arrival process described by $(\lambda, c_{a,i})$ at a link queue in stage $i$.

We now give three relations to correspond to the above. From [10] we have the approximation

$$c_{d,i}^2 = c_{a,i}^2 + 2\lambda^2 c_\ell^2 - \lambda^2 (c_{a,i}^2 + c_\ell^2)\, g(\lambda, c_{a,i}^2, c_\ell^2),\ i \geqslant 1 \qquad (4.4)$$

where,

$$g(\lambda, c_{a,i}^2, c_\ell^2) = \exp\left\{\frac{-2(1-\lambda)}{3\lambda}\ \frac{(1-c_{a,i}^2)^2}{(c_{a,i}^2 + c_\ell^2)}\right\} \text{ if } c_{a,i} \leqslant 1,$$

$$= \exp\left\{-(1-\lambda)\ \frac{(c_{a,i}^2 - 1)}{(c_{a,i}^2 + 4c_\ell^2)}\right\} \text{ if } c_{a,i} > 1.$$

Decomposition, or splitting, of renewal processes yields [9],

$$c_{i-1,i}^2 - 1 = \frac{1}{2}(c_{d,i-1}^2 - 1),\ i \geqslant 2. \qquad (4.5)$$

Finally, for superposition we use the following approximation [12],

$$c_{a,i}^2 - 1 = \frac{(c_{i-1,i}^2 - 1)}{1 + 4(1-\lambda)^2},\ i \geqslant 2. \qquad (4.6,\text{i})$$

Also, there is the initial condition,

$$c_{a,i}^2 = c_s^2,\ i = 1. \qquad (4.6,\text{ii})$$

Equations (4.4)-(4.6) define a complete recursive system which yields $\{c_{a,i}, c_{d,i}, c_{i,i+1}; i \geqslant 1\}$. Note that the dimension of the network given by $n$ does not appear in the system.

The *mean queueing delay*, $W_i$ for a link queue at stage $i$ (queueing delay excludes transmission time) is given by the following exact relation for GI/G/1 [11]:

$$W_i = \frac{c_{a,i}^2 + 2\lambda^2 c_\ell^2 - c_{d,i}^2}{2\lambda(1-\lambda)}, \quad i \geqslant 1. \tag{4.7}$$

The above together with Little's Law gives the mean queue lengths at each link. Finally, the *mean time from source to destination*, *D*, is given by

$$D = (2n-1) + \sum_{i=1}^{2n-1} W_i\,. \tag{4.8}$$

The first term is from the transmission time and the second is from the cumulative queueing delay. Note that (4.8) is the only point in the procedure where $n$ is used.

Tables 1 and 2 give numerical values for the case of Poisson sources and constant link transmission time. The important observation is that for each $\lambda$, the queueing delay shrinks at the early stages before rather quickly reaching an asymptotic value. For any fixed, positive $\lambda$, $c_s^2$ and $c_\ell^2$, the asymptotic values of $c_{a,i}^2$, $c_{d,i}^2$ and $c_{i-1,i}^2$, as $i \to \infty$, are obtained simply as fixed points of the recursions in (4.4)-(4.6). These may be substituted in (4.7) to obtain the asymptotic value $\overline{W}(\lambda, c_s^2, c_\ell^2)$, where $W_i \to \overline{W}(\lambda, c_s^2, c_\ell^2)$. From (4.8), as $n \to \infty$, we obtain the noteworthy relation

$$\boxed{D \sim 2\{1 + \overline{W}(\lambda, c_s^2, c_\ell^2)\}\, n\,.}$$

The last row of Table 1 gives the computed values of $\overline{W}(\lambda, 1, 0)$ for various values of $\lambda$.

| | Mean Queueing Delay ($W_i$) | | | |
|---|---|---|---|---|
| | $\lambda = 0.2$ | $\lambda = 0.4$ | $\lambda = 0.6$ | $\lambda = 0.8$ |
| Stage 1 | 0.125 | 0.333 | 0.750 | 2.000 |
| Stage 2 | 0.124 | 0.322 | 0.667 | 1.448 |
| Stage 3 | 0.124 | 0.320 | 0.648 | 1.345 |
| Stage 4 | 0.124 | 0.319 | 0.643 | 1.327 |
| Stage $i$, $i > 4$ | 0.124 | 0.319 | 0.642 | 1.324 |

*Table 1*: For $r = n-1$, and full $\lambda$-relations; Poisson processes at sources and unit time for transmission across each link. Calculated from (4.4)-(4.7).

| n | Mean Time from Source to Destination (*D*) | | | |
|---|---|---|---|---|
| | $\lambda = 0.2$ | $\lambda = 0.4$ | $\lambda = 0.6$ | $\lambda = 0.8$ |
| 4 | 7.870 | 9.254 | 11.637 | 17.093 |
| 6 | 12.366 | 14.533 | 18.207 | 26.390 |
| 8 | 16.863 | 19.811 | 24.777 | 35.686 |
| 10 | 21.360 | 25.090 | 31.346 | 44.983 |
| 12 | 25.857 | 30.368 | 37.916 | 54.279 |
| 14 | 30.353 | 35.647 | 44.486 | 63.575 |

*Table 2*: Specification as in Table 1. Calculated from (4.4)-(4.8).

The procedure based on (4.4)-(4.8) with $c_s = c_\ell = 1$ gives correct values for Poisson sources and exponentially distributed link transmission time. In this case, $\overline{W} \equiv W_i = \lambda/(1-\lambda)$. Also, the numerical results for $c_\ell$ in the range [0,1] are bounded by the results for $c_\ell = 0$ and $c_\ell = 1$ in the case of Poisson sources.

### 4.4.1 *Accuracy of Approximation, Simulations*

Comparison with simulations has shown that for constant link transmission time and light traffic, i.e. small $\lambda$, the decomposition overestimates the queueing delay in all stages beyond the first. On the other hand, the approximation is good in heavy traffic. The net effect of the inaccuracies on the mean time from source to destination in the fully extended omega network is small. This is, of course, because in light traffic this time is dominated by the transmission time. Also as expected, the largest errors occur at about $\lambda = 0.6$. Generally, the errors are smaller as we depart from constant link transmission time and add more variability to it.

As previously observed, the procedure in (4.4)-(4.8) yields mean queueing delays which converge quickly, with increasing stages, to asymptotic values. This important fact may be used to simplify simulations. Thus, an omega network of small dimension, say with four stages, may be simulated, and the mean delay observed for the final stage may be taken to apply to all subsequent stages in calculations for large extended omega networks. We have undertaken the program just outlined. The results of the simulation of the four-stage omega network for Poisson sources and unit link transmission time are given in Table 3. The results of the extrapolation to large, fully extended omega networks are given in Table 4, which should be considered a refinement of Table 2.

| | Mean Queueing Delay | | | |
|---|---|---|---|---|
| | $\lambda = 0.2$ | $\lambda = 0.4$ | $\lambda = 0.6$ | $\lambda = 0.8$ |
| Stage 1 | 0.123 | 0.335 | 0.751 | 2.002 |
| Stage 2 | 0.067 | 0.199 | 0.478 | 1.339 |
| Stage 3 | 0.066 | 0.196 | 0.468 | 1.318 |
| Stage 4 | 0.067 | 0.195 | 0.461 | 1.323 |

*Table 3*: From simulations of omega network with 4 stages for Poisson packet traffic at sources and unit time for transmission across each link.

| n | Mean Time from Source to Destination | | | |
|---|---|---|---|---|
| | $\lambda = 0.2$ | $\lambda = 0.4$ | $\lambda = 0.6$ | $\lambda = 0.8$ |
| 4 | 7.529 | 8.512 | 10.544 | 16.954 |
| 6 | 11.801 | 13.292 | 16.390 | 26.249 |
| 8 | 16.072 | 18.073 | 22.235 | 35.544 |
| 10 | 20.344 | 22.854 | 28.081 | 44.839 |
| 12 | 24.615 | 27.635 | 33.927 | 54.134 |
| 14 | 28.887 | 32.416 | 39.772 | 63.428 |

*Table 4*: Extrapolated from data in Table 3. Compare with Table 2.

# A Comparison of Two Synchronization Primitives in an Operating System for Parallel Processing Applications

J. Eric Roskos
Concurrent Computer Corporation
Southern Development Center
2486 Sand Lake Road
Orlando, FL 32809-7642
*jer@peora.CCUR.UUCP*

Abstract — It has been claimed [REED79] that the synchronization primitives termed *eventcounts* and *sequencers* may be used to implement semaphores, and thus that they are "primitives at a lower level than semaphores". However, by expressing the functionality of conventional semaphores, and that of semaphores implemented via eventcounts and sequencers, via a common set of primitives, it may be shown that in fact the eventcount/sequencer pair imposes restrictions on process synchronization that do not exist with the traditional semaphore. Two such restrictions exist. First, the eventcount/sequencer pair imposes an ordering on the activation of suspended processes whereas semaphores activate the processes nondeterministically. Second, it is difficult to implement a "conditional **P**" operation with eventcounts and sequencers because one cannot return a ticket obtained from a sequencer to the ticket pool: a ticket, once obtained, must be used. Thus, the claim that eventcounts and sequencers are lower-level primitives than the traditional semaphore is contradicted by this analysis.

**Introduction**

D. P. Reed and R. K. Kanodia, in their 1979 paper "Synchronization with Eventcounts and Sequencers" [REED79] present a new process synchronization method with two primitives, **advance** and **await**. A process may **await**($E, V$) an eventcount $E$'s reaching a certain value $V$; the eventcount is made to reach this value eventually by other processes performing an **advance**($E$). A separate **ticket**($S$) primitive is defined to give unique, consecutive, increasing integer vaules on each invocation.[1]

The authors observe that eventcounts and sequencers are "primitives at a lower level than semaphores," and that semaphores can be built out of them as a result. They also demonstrate that some more powerful operations on semaphores can be built.

Concurrent Computer Corporation is presently involved in research and development on primitives to be used in synchronizing OS-related operations on general-purpose, symmetrical, parallel processors. In investigating the synchronization primitives available in the literature, we chose Eventcounts and Sequencers as a synchronization primitive that would be compatible with our planned OS and hardware architecture. During the course of the implementation, however, it was found that problems existed which would have not occurred if conventional semaphores had been used, particularly in situations in which entry to a critical section was desired only if such entry would not cause suspension of the process. These situations tend to be common in real-time applications, including our application of I/O with a goal of maximum parallelism in tightly-coupled multiprocessors. In such an application, precise process synchronization is required, but delaying of a process which cannot enter a critical section is not desirable: the process often is able to perform some other task until the critical section becomes available. Certain deadlock avoidance algorithms also needed to function in this way.

As a result of the apparent limitations in eventcounts and sequencers, the mechanisms underlying these primitives were examined using methods previously employed in investigating interprocess communication primitives in multiprocessors [ROSK84]. This paper demonstrates that the implementation of semaphores given in REED79 does not provide the flexibility of Dijkstra's original primitives [DIJK68] due to the combining of two required primitives, those for *token-oriented synchronization* and *sequencing*, into the one **ticket** primitive. This is done by expressing both in terms of comparable primitive operations; the differences then become apparent.

[1] A third eventcount primitive, **read**($E$), returns the current value of the eventcount.

### Process Sequencing/Suspending Primitives

We first define two primitives which may be used to effect the process suspending and resumption needed in order to cause process synchronization. There is one suspension primitive, which stops a process, and assigns it a specified integer "tag," and one resumption primitive, which selectively resumes all processes having a given tag.

**stop**($p$,$L$).

Let **stop**($p$,$L$) denote an operation which places the process executing it on a list L, assigning an associated integer "process group tag" $p$. Execution of the process is then suspended. The process group tag is simply an integer which may be used to selectively resume the process or group of processes which have been assigned that tag.

**start**($L$,$p$).

If the set of processes in $L$ with tag $p$ is nonempty, the processes with tag $p$ are removed from $L$. Execution of the processes thus removed are resumed.

### Token-Oriented Primitives

We next define a set of *token-oriented primitives* used to arbitrate access to critical sections of code.

Let T be a set of $n$ **tokens**, $t_i$, $1 \leq i \leq$n.

**g**($T$).

Let **g**($T$) denote a **get** operation defined as follows. If $T \neq \emptyset$, **g**($T$) returns an element $t_j \in T$, with $j$ arbitrary; and indivisibly sets $T \overset{j}{\leftarrow} T - \{t_j\}$.

*If* $T = \emptyset$, **g**($T$) returns the null value $\phi$.

**p**($T$,$t$).

Let **p**($T$,$t$) denote a **put** operation which sets $T \leftarrow T \cup \{t\}$.

**ticket**($T$).

Let the number of tokens in a set $T$ be countably infinite; and let **name**($t$) denote an integer which may be arbitrarily assigned to a token $t \in T$. Then let **ticket**($T$) return **g**($T$), such that if on a given invocation of **ticket**($T$), **name**(**ticket**($T$)) = $i$, then the next consecutive invocation yields **name**(**ticket**($T$)) = $i$+1; and on the initial invocation, **name**(**ticket**($T$)) = 0.

### Comparison of Semaphores with Eventcounts/Sequencers

We can now compare Dijkstra's original semaphore operations [DIJK68] with the implementation of semaphores described by Reed and Kanodia.

Dijkstra's semaphore operations may be defined in terms of the above primitives as follows. Assume for simplicity that $t$ is a global variable in the calling process' private address space, and thus is part of the program state of the process invoking the synchronization primitive.

As is the case for most semaphore implementations, the sequences of primitive operations comprising the P and V operations are themselves critical sections: wherever a process has a copy of the state of some outside object (a pool of tokens, or a counter) in a local variable, the actual state of the object cannot be changed as long as the process will in the future act upon the copy of the state which it has in its posession. This is an instance of the implicit **copy** operation that occurs when a conventional memory is read, as discussed in ROSK84.

```
P(S):
        repeat
            t := g(S.tokens);
            if t=$\phi$ then stop(0,S.queue);
        until t<>$\phi$;

V(S):
        p(t, S.tokens);
        start(0,S.queue);
```

In the above definition, a **V** causes all waiting processes to briefly awaken and attempt to get a token; but only one will succeed for each execution of **V**, so the others remain blocked. An alternative (and more commonly seen) implementation would be only to awaken one arbitrary suspended process for each execution of **V**; but the synchronization results are equivalent, and the latter approach complicates comparison with the eventcount-based semaphores.

The eventcount/sequencer semaphore implementation as presented by Reed and Kanodia may likewise be defined in terms of the above primitives as follows. Assume that prior to the first **V**, *S.count* is initialized to zero.

```
$P_{ES}$(S):
        p := ticket(S.sequencer);
        if S.count < name(p) then
            stop(name(p),S.queue);

$V_{ES}$(S):
        S.count := S.count+1;
        start(S.queue,S.count);
```

Clearly, these are not equivalent semaphore operations. Dijkstra's semaphore primitives do not employ the priority queueing portion of the **stop** primitive, and arbitrate the stop/proceed decision using anonymous tokens which are returned to a common pool of tokens after use. The eventcount/sequencer

[2] This may be generalized by making $t$ a variable denoting a set, with the assignment to t adding a member to the set, and the reference in **P(t,S.token)** removing one member from this set.

implementation does employ priority queueing, such that the processes, if required to stop, are started in the order in which they were stopped; and it employs tokens which are labelled by a sequence number and discarded after use. Furthermore, the actual usage of the tokens differs: in Dijkstra's semaphore, posession of the token indicates the right to proceed; whereas with eventcounts and sequencers, the token merely provides an associated integer value which the process must wait for the eventcount to reach. This latter is fundamental to the distinction between the two kinds of semaphore.

Except for the ordering imposed on processes by the latter version of **P** and **V**, it might nevertheless be argued that the two are equivalent, were it not that a third semaphore operation, the **conditional P**, is possible on Dijkstra's semaphore which is not possible without great difficulty on the eventcount/sequencer pair. The conditional **P** may defined as follows, when used with Dijkstra's semaphore.

```
CP($S$):
        t := g(S.tokens);
        if t=$\phi$ return FALSE;
        else return TRUE;
```

The conditional **P** is equivalent to Dijkstra's **P**, except that it does not wait if no token is available. It is useful in deadlock avoidance; see, for example, BACH84 for an example of its use in a large-scale operating system.

In the eventcount/sequencer implementation, the "token" used to arbitrate access is inseparably joined with the sequencing mechanism built in to the **ticket** primitive. This mechanism causes the priority used in the call to the above **stop** and **start** primitives to be inseparably joined with the tokens used to arbitrate the right to proceed.

Consequently, once the **ticket** is obtained in the process of determining the right to proceed, it is impossible to simply return the ticket to the sequencer; another process may have performed another **ticket** operation in the interim. On the other hand, it cannot be discarded, since it is the responsibility of the process taking a ticket to advance the eventcount past the value on the ticket, to allow the next process to proceed.

Such problems do not exist for **CP** when used with Dijkstra's semaphore, since the nature of the anonymous tokens is such that there is a limited supply, and their absence indicates the need to wait, as compared to the infinite supply of tickets, whose values in relation to an associated eventcount indicate the need to wait (and impose an ordering on the waiting immediately upon taking a ticket).

The distinction between the two definitions of **P** and **V**, while subtle, leads to the above difficulty in backing out of a series of P operations in order to avoid a deadlock. While the authors do provide a simultaneous **P** operation, it implies use of the strategy of deadlock avoidance by locking all resources prior to using any of them. The relative merits of various deadlock avoidance strategies are an issue beyond the scope of this paper; yet it should be borne in mind that strategies other than that of locking all required resources before using any of them may be considered necessary in certain applications.

### Conclusion

The above decomposition demonstrates that fundamental differences exist between Dijkstra's P and V, and Reed and Kanodia's implementation of the same primitives. It further suggests that the sequencer primitives differ from those required to implement P and V in that they combine two underlying primitives: the token primitive presented above, and a sequencing primitive. As such, the P and V presented in REED79 could more accurately be considered sequencing semaphores, since they impose a sequencing on the waiting processes. They also make implementation of the conditional P operation less straightforward, due to the inability to put back a sequenced token without using it.

**ABSTRACT-- The design of an operating system kernel for Star is presented. Star is a reconfigurable multiprocessor system based upon a multistage interconnection network. The kernel is intended to serve as a basis for further operating system research. The kernel provides mechanisms for process management, local resource allocation, and inter-process communication.**

**A key design goal of the kernel was to minimize loss of transparency in the underlying hardware. This led to the development of a novel communication system to support the broadcast and merging capabilities of the interconnection network. The communication system presented provides for asynchronous multicast communication between processes which simplifies the tasks of creating distributed applications and of synchronizing cooperating processes.**

**The current status of our system is that we have a four node machine running and have implemented the kernel in MODULA-2.**

## 1 Introduction

In this paper we present the design of the Star operating system kernel. This kernel is replicated at each processor node of Star, a reconfigurable multiprocessor system [1]. The kernel represents a common core of software which will be used to investigate the problems of resource management and processor scheduling. The kernel provides the low level primitives to interface the operating system with the hardware and it provides the primitives for process management, interprocess communication (including inter-node communication) and memory management.

This work is motivated by a desire to develop an operating system which can fully exploit the inherent power of reconfigurable computer systems. Achieving this goal will require further research in the areas of resource management and scheduling. Our kernel design is a step towards this goal and has the following important characteristics:

- Loss of transparency in the hardware is minimized; by loss of transparency we mean any operation that is feasible in the underlying hardware but is not feasible using the primitives provided by the kernel.

- All decisions concerning resource management, program models, and scheduling are left to higher levels of the operating system.

- The kernel provides a convenient basis upon which a complete operating system can be built and is designed to simplify this task.

There is a substantial body of previous work in multiprocessor operating systems including: Hydra[2], Medusa[3], Eden[4], Micros [5] and many others. The architectures which these operating systems support vary widely. Star is different from most machines because of its reconfigurable topology; however, there are other reconfigurable systems including: TRAC [6], Cedar [7], PASM [8], and RP3 [9]. All of these reconfigurable systems feature shared memory while Star does not.

A common trend in multiprocessor operating systems is to design the operating system to hide the underlying communication system. Designs like HPC [10] , Eden, and Micros ignore topological issues altogether. In the Star system we are trying to address the topology issue by tailoring our operating system to obtain maximum performance given the very real constraints of a communication network.

Our work was influenced by a desire to ultimately provide the kind of support for distributed programs that Eden and HPC provide; however, while these projects were principally concerned with programability, we are principally concerned with developing a system which will efficiently utilize the interconnection network.

Because many of the design decisions of the overall operating system are topics for future investigation, it was essential that the kernel design be flexible, simple and easily modified. The kernel has been written entirely in MODULA-2 [11]. MODULA-2 is a convenient language for operating system design because it provides the mechanisms for modular design (Modules), the convenience of a higher level language, and reasonable access to the system hardware. MODULA-2 separates the definition of software from the implementation. The implementation of a software module can be modified at will without affecting other parts of the design. By implementing the kernel software in MODULA-2 we have been able to quickly prototype the system with confidence that the design can easily be refined.

Our experimental system has a limited number of processors; however, we are interested in developing application software which could be used on machines with

0190-3918/86/0000/0234 $01.00 © 1986 IEEE

large numbers of processors. One way of facilitating this goal is to assume that application software is structured as a number of communicating processes. Because there may not be enough processors available to allocate a separate processor to each process of an application, the kernel supports the scheduling of multiple processes at a single processor. In addition, we believe that the writer of an application program should not have to be concerned with how the processes of that application might be scheduled for execution.

Because the processes of an application program might or might not share processors, our kernel provides the application programmer with a global communication model which, to communicating processes, appears the same whether the processes are at the same or different nodes.

The Star kernel is level structured and consists of three basic levels [12]:

| | |
|---|---|
| LEVEL 1 | Process Manager |
| LEVEL 2 | Memory Manager |
| LEVEL 3 | Global Communication |

The process manager provides support for multiple processes and the primitives necessary for sharing of local resources among processes which are scheduled at that node. The memory manager controls an important shared resource, local memory, and uses the primitives of the process manager. The global communication layer provides the mechanisms necessary for communication among processes which are not scheduled at the same node. In order to provide a consistent view of the system to application programs, the global communication layer also permits communication among locally scheduled processes.

In this paper we will examine levels 1 and 3. Level 2, the memory manager, provides facilities for managing the storage of a processor node and is not novel. The design decisions which led to this level decomposition are considered in later sections of the paper. In designing the kernel we followed one basic principle; design decisions were delayed as long as was feasible; each layer provides only a simple, basic set of operations while more specific operations were postponed, wherever possible, to higher levels of the operating system.

The organization is as follows. In Section 2 we present a description of the target system, called Star. In Section 3 we present the process manager and in Section 4 the global communication system. In section 5 we discuss building a distributed operating system on top of the kernel and consider the ways in which our design results in loss of transparency.

## 2 Target System

Star , as illustrated in Figure 1, is composed of a collection of N processor elements (PE) and a communication network, called Starnet. N is generally a power of 2. Starnet can be composed of multiple baseline networks [13]. The prototype system, which is currently running, has one baseline network and four processor nodes.

The baseline network, as illustrated in Figure 2, is a multistage interconnection network which has the characteristic of being reconfigurable under the control of the processor nodes and can form such topologies as rings, trees, and meshes [14]. The baseline network does have the property of blocking; that is, the creation of a connection prevents some set of connections that would otherwise be feasible. Therefore, the management of interconnection resources is an important consideration in designing an operating system. Connections in the baseline network originate on the left (in Figure 2) and may connect several destination nodes on the right (called multicasting). In addition the network provides the capability of merging connection requests from the left to a common destination on the right.

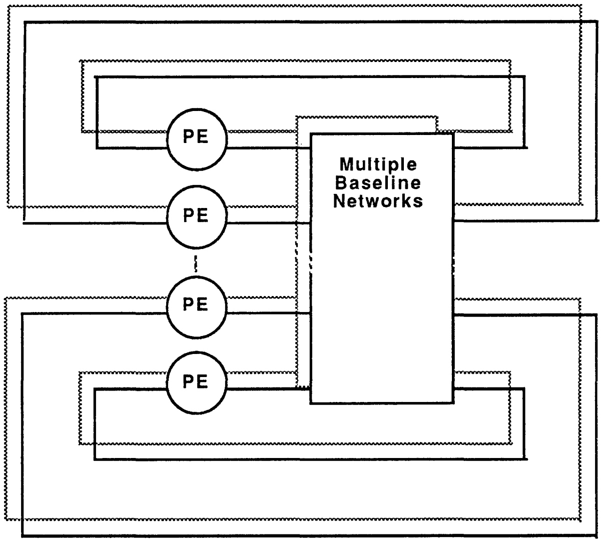

**FIGURE 1 Star System**

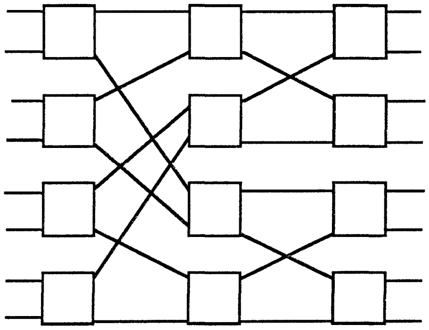

**FIGURE 2 An 8x8 Baseline Network**

Processor nodes are connected to the interconnection network by hardware interface units which have limited buffering capacity and an additional processor to handle communications. The hardware interface is illustrated in Figure 3. The communication processor interfaces to the interconnection network and the main processor exchanges data with the communication processor through an area of shared memory.

The essential characteristic of Starnet is that it is reconfigurable and may, at any moment, be partitioned into a number of private buses connecting two or more processor nodes. We will refer to a group of nodes connected by such a bus as a multicast group.

The details of how the network is reconfigured are immaterial to this paper. Assuming such a multicast group exists, there is, at any moment, exactly one node which is the sender (has the right to send data over the bus). All other nodes are receivers. Receivers may, through hardware control, stop the flow of data and request the right to become the sender. The sender may send data (unless blocked by one of the receivers) or it may relinquish the right to talk. In order for data transmission to occur, all the receivers connected to a bus must accept every word of data transmitted.

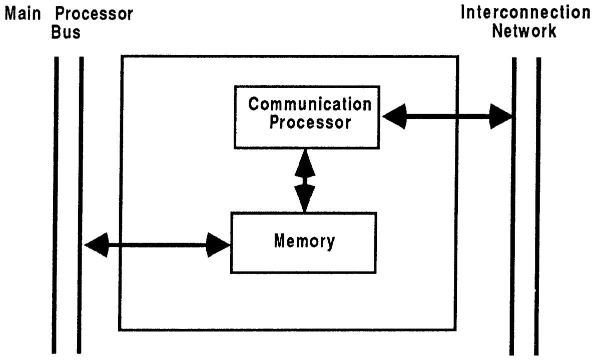

**FIGURE 3 Hardware Interface**

The hardware supports a mode of communication which we will refer to as *reliable multicasting*. This is because message broadcasting within a multicasting group is both error free and order preserving. Reliable multicast is an important mode of communication. Gehani has shown that multicasting simplifies the development of distributed applications [15]. In addition, multicasting greatly reduces the message traffic between processors needed for insuring mutual exclusion of access to critical sections. The distributed mutual exclusion problem was studied by Lamport [16] and Ricart [17]. Ricart showed that in a general message based system which supports broadcast, but not strict message sequencing, N messages (where N is the number of processors) are needed to invoke a critical section. With strict message sequencing only 2 messages are needed to invoke a critical region. Because of the efficiency which reliable multicasting provides in insuring mutual exclusion and the ease of use which Gehani has demonstrated, we concluded that the multicast capability of the hardware is a powerful feature which the kernel must support.

## 3 Process Manager

Support for the process abstraction is provided at the lowest level of the Star kernel by a process manager. The process manager provides mechanisms to create and destroy processes and low level synchronization and communication primitives. The primitives of the process manager may be invoked only by processes which are local to the node. Although these local primitives are not directly used by application programs, they are used in implementing the global communication system provided for application programs and distributed portions of the operating system.

The choice of primitive operations and the major design issues addressed in the process manager have a profound influence on the rest of the operating system. In Section 3.1 we discuss two important design issues: scheduling and memory management. The communication and synchronization primitives provided by the process manager are used in implementing the communication system provided by level 3 of the operating system. In Section 3.2 we discuss the functional characteristics of the process manager.

### 3.1 Design Considerations

Two issues which affected the process manager design involve scheduling and memory management. Although the process manager does not make scheduling decisions, the design had to be flexible enough to permit the implementation of a process scheduler at a later phase of the operating system design. The second issue is whether memory management should have been provided at a level below the process manager.

We chose not to implement the memory manager below the process manager, because we felt that it would be easier to implement using the primitives of the process manager. The process manager provides support for the objects *process* and *semaphore*. Creation and destruction of these two object types does involve the allocation and deallocation of memory. In addition the process manager must manipulate queues of process descriptors. However, in both cases the amounts of memory involved are small and are handled using statically allocated tables.

One of the major responsibilities of the process manager is to maintain a list (the Ready List) of processes which are ready to run. The discipline followed in queuing processes on the ready list and in transferring processor control to a ready process clearly has an impact on the processor scheduling algorithms which may be implemented. It is of great importance that this queuing discipline be sufficiently general to support a wide variety of scheduling policies. We defined the following characteristics of our process manager:

- The process manager supports priorities; operations are provided which permit the process priorities to be examined and modified. Processes are selected for execution based upon these priorities. The priority of the running process is at least as large as that of any ready process.

- The ready list is structured as a priority queue using a FIFO discipline to break ties.

- Although time slicing is not implemented in our kernel, this feature could be added to the process manager without modifying the interface to the process manager.

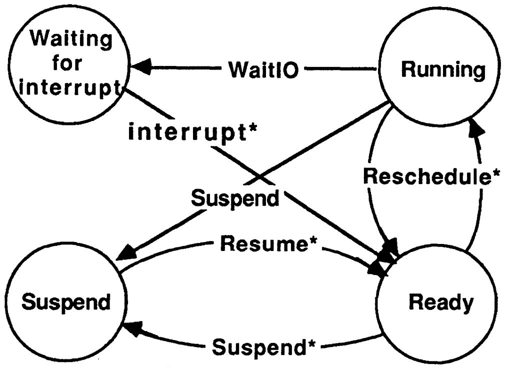
Ruschitzka and Fabry [18] have shown that given these characteristics a function for assigning priorities can be found so that the following scheduling algorithms can be implemented: FIFO, LIFO, preemptive shortest job first. With the addition of time slicing, round robin and feedback algorithms can be implemented. Thus process scheduling disciplines are not unduly restricted by the design of the process manager.

## 3.2 Facilities of Process Manager

The process manager provides support for processes and for communication between processes. The procedures provided by the process manager fall into four catagories: Process Control, Process Synchronization, Process Communication and Utility procedures. The process control procedures include:

| | |
|---|---|
| *CreateProcess* | Create a new process; |
| *DestroyProcess* | Destroy a process; |
| *Suspend* | Prevent a process from executing; |
| *Resume* | Resume a suspended process; |
| *GetPriority* | Get the priority of a process; |
| *SetPriority* | Set the priority of a process; |
| *CurrentProcess* | Get the identity of the current process; and |
| *WaitIO* | Allows a process to wait on a particular hardware interrupt vector. When the interrupt occurs, the process is placed on the ready queue. This permits the structuring of device drivers as separate processes. |

The control procedures lead to the process state diagram shown in Figure 4. A running process may suspend itself, wait on an interrupt, or lose control of the processor through a rescheduling operation. Rescheduling occurs whenever a process with a priority higher than the running process becomes ready to run.



*EXTERNAL EVENTS

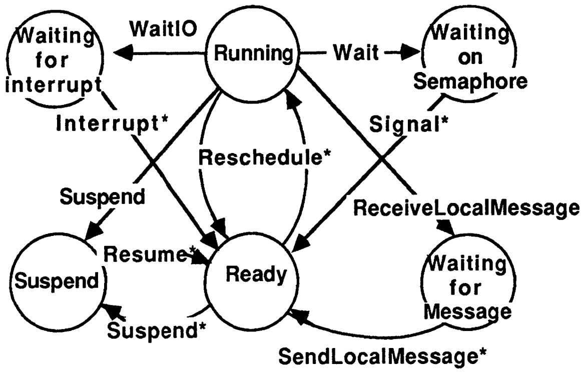
FIGURE 4 Basic Process States

In addition to the process control procedures, the process manager provides abstract data types and procedures for process synchronization and communication.

The synchronization and communication primitives of the process manager were chosen to provide a convenient basis for higher levels of the operating system. In the interest of flexibility, the process manager provides both semaphores and a primitive form of messages.

Semaphores have been widely discussed in the literature [19]; we will say nothing further about them except to list the operations provided by the process manager : *CreateSemaphore, DestroySemaphore, Wait, Signal.*

There are many different message systems and the design possibilities included blocking or non-blocking send, blocking or non-blocking receive, and buffering mechanisms. Because a fully synchronized message system may easily be implemented using semaphores, we concluded that a less tightly synchronized message system was appropriate at this level. Because there is no memory management facility available to the process manager, buffering had to be strictly limited. Process manager level messages (*LocalMessage*) are not intended to be used for transferring large amounts of data, but rather to provide what amounts to a private event flag with state information. In order to provide this capability at a minimum cost, *LocalMessage*s were restricted to positive integers and the following *LocalMessage* primitives provided: *SendLocalMessage* (non-blocking), *ReceiveLocalMessage* (blocking), *LocalMessageFlush* (non-blocking receive). Because buffer space is limited (to a single *LocalMessage*) and *SendLocalMessage* is non-blocking, overflow *LocalMessages* are simply discarded. The process synchronization and communication primitives lead to the process state diagram shown in Figure 5. In addition to the state transitions shown in Figure 4, a running process may also lose control of the processor if it waits on a semaphore or waits for a local message.



*EXTERNAL EVENTS

FIGURE 5 Complete Process State Diagram

A significant issue in the design of the process manager was the question of process termination. In general, the destruction of processes may affect the higher levels of the operating system. This is because higher levels of the operating system may associate further object types with processes and may need to perform some bookkeeping when a process is destroyed. For this reason, the process manager provides a general facility for installing termination procedures. The process manager maintains a list of termination procedures, each of which is called when a process is destroyed. These procedures enable higher levels of the operating system to be notified at process destruction time so that they may perform any necessary bookkeeping operations. This feature is both powerful and dangerous; however, some protection is provided by dictating that only the initial process of the node may install these termination procedures.

## 4 Global Communication Layer

As mentioned in Section 3, the process manager provides some local communication primitives. These primitives are provided to facilitate the implementation of higher levels of the kernel. In a distributed system such as Star a more general interprocess communication system is needed which can cross processor boundaries. In order to provide a coherent view of the system to application programs, the global communication system may also be used for local communications. The global communication system of the kernel is a message passing system supporting reliable multicasting. The design criteria for the low level communication system were:

- To support hardware communication modes;
- To support location independence of processes. The user of the system should not have to modify his code depending upon whether or not two communicating processes are to be scheduled at the same node; and
- To keep the primitive system both simple and efficient.

Because this is the first level of software above the underlying communication hardware, it was essential that it closely adhere to a communication model which the underlying hardware can efficiently support. In particular, we were concerned that the communication software fully support the multicasting capability of the hardware. The communication system provides for location independence of processes by providing a unified model of communication between locally executing and distributed processes.

### 4.1 Global Communication System Definition

The global communication system for Star supports the multicasting capability provided by multicast and merge in the hardware. The communication system is based upon the following abstractions. All communication occurs asynchronously between privately owned *ports* . Two *ports* may communicate if they are attached to the same *channel. Channels* are multiway, multidirectional communication paths. An arbitrary number of *ports* may be connected to a single *channel.* Communication between two *ports* occurs when a process writes a message to one of its *ports* and a receive operation is performed by a process on a *port* connected to the same *channel.* The *channel* model was chosen to closely match the multicasting buses which are supported by the interconnection network.

All messages sent by a port are received, in the order sent, by all ports connected to the same channel. There are two types of channels, local and distributed. A local channel may connect ports which reside on a single processor node. Distributed channels may connect ports on different nodes. Distributed channels exist only where hardware connections between nodes exist. More specifically, distributed channels are realized by a particular configuration of the underlying interconnection network.

### 4.2 Ports and Channels

In this section we will consider what ports and channels are. There is a single interface for both local and distributed channels; however, the implementation of the two is different. When discussing implementation details we mean, for the moment, local channel. We will consider the implementation of distributed channels in Section 4.4.

A channel is essentially a shared data structure consisting of a record for each connected port (the PortList), a fixed buffer space, and a pointer into the buffer space indicating where the next message should be deposited. The set of operations which can be performed on a channel is:

| | |
|---|---|
| *CreateChannel* - | Create a new channel. With a specified name and buffer size. |
| *DestroyChannel*- | A channel with no attached ports may be destroyed. |
| *ConnectPort* - | Connect the specified port to the channel. Does not block if the named channel does not exist. |
| *DisconnectPort* -- | Disconnect the specified port from the channel. |

Ports may be connected to or disconnected from channels at any time. In theory, an arbitrary number of ports may be connected to a channel (in practice this is limited by our implementation). Monitoring of communication can be achieved without introducing delay by attaching a monitor port to the channel.

A port is a privately owned object. Only the owner of a port may read data from or write data to a port; however, a port may be connected to or disconnected from a channel by a process other than its owner. The communication system supports the notion of a process waiting to receive data from any subset of its ports. This is implemented using LocalMessages. Any port which is connected to a channel may enable or disable a notification mode. If the notification mode of the port is enabled, a LocalMessage is sent to the owner of the port whenever a message is added to the buffer of the channel to which the port is connected.

The following operations may be performed upon a port.

| | |
|---|---|
| *ReadFromPort---* | Read next message. This is non-blocking and returns NIL if no message is available. |
| *SendToPort--* | Send a message through a port. If the port is not connected to the channel, the message will be lost. |
| *EnableNotification--* | When the notification mode of a port is enabled, a LocalMessage is sent to the owner of the port whenever a message is added to the buffer of the channel to which the port is attached. |
| *DisableNotification--* | Disable notification mode. |

The ports connected to a channel may read the messages in the channel buffer at their own pace. We may view each port as having a private pointer into a shared list of messages. This private pointer is maintained as part of the channel data structure and is directly accessed only by the channel software. In Figure 6 the channel buffer model and the function of these private pointers is illustrated. In this figure, three ports are connected to the channel. Each port is represented by a private pointer into the channel buffer.

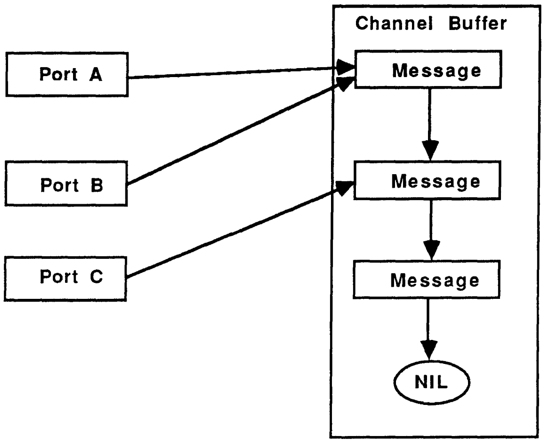


**FIGURE 6 Channel Buffer**

Because buffer space for a given channel is fixed, we can view the buffer as being circular with new messages eventually overwriting old ones. Although this event is not an error it is important to know when it has occurred. For this purpose a *tail pointer* is maintained by the channel, which indicates the oldest message which has not been read by all attached ports. The channel data structure also consists of some status flags including a *note flag* indicating whether any of the attached ports have enable their notification mode, a *nil flag*, indicating whether any of the attached ports have read the most recent message.

The PortList of a channel consists of a record for each connected port. This record includes the port name, a pointer the the next message to be read, a *notificationmode flag*, a *nil flag*, and an *overflow flag*. The *notificationmode flag* indicates whether the port should be notified when a new message is written, the *overflow flag* indicates whether a message has been lost since the last read, the *nil flag* indicates whether there are any messages to read.

## 4.3 Buffering

The choice of asynchronous communication implied that some buffering capability must be built into the communication system. Because buffering is, of necessity, limited, we had to either institute flow control or accept the potential loss of data due to buffer overflow. We regarded the introduction of flow control at this level as a poor idea because it introduces additional overhead for all communication when some applications may not need it. This is particularly true if the communication protocol of an application is inherently bounded (can have a finite limit on the number of outstanding messages) and the bound is sufficiently small that overflow is impossible. Flow control may be easily introduced at a higher level.

The question remained -- how much buffer capacity should be provided. Reid [20] solved this by providing a single message buffer. Each successive message overwrites the previous message. This approach has a serious flaw in that it is impossible to use broadcast to provide synchronization because we cannot be certain that a reply message did not overwrite the original message before all ports had read it. Any fixed buffering scheme has the limitation that it renders some communication protocols either impossible or difficult and provides excess capacity for others.

In solving this problem we made the following assumption: a particular channel is shared by ports which use the same communication protocol. The protocol used must either be bounded or must handle potential message loss. In either case it is possible to allocate a fixed buffer space when the channel is first created. The buffer size is specified in the initial allocation request. Obviously it is possible that this request may not be met; however, this event will be discovered at the outset rather than at some point well into the execution of an application.

## 4.4 Implementing Distributed Channels

We have delayed discussing the implementation of distributed channels until now because their implementation is significantly different from local channels, although they respond to exactly the same set of operations. Distributed channels are realized through the coordinated efforts of two or more connected processor nodes.

In the local channel model we can view a channel as a shared data structure with a number of attached ports. Each port is uniquely owned by a process. Unfortunately this model is much more complicated in the distributed case. First because the distributed channel cannot be implemented through shared memory and second because the communicating ports are on different nodes.

In order to realize the channel model in the distributed case we maintain, at each connected node, a copy of the message buffer. The other parts of the channel data structure are provided for maintaining port status and are only maintained locally. Thus each node which is connected maintains separate data for the channel; part of which is replicated and part of which is unique.

Recall that the multicasting buses realized in the interconnection network have the capability of controlling data flow across the interconnection network and there is always a unique sender on the bus. The capability of controlling data flow insures that a receiving node can process messages as they are received. The fact that there is a single sender insures that only one node will be able to transmit messages at any moment. Updates to a copy of the channel buffer occur in only two ways: the node is the current sender and a send is performed by one of its connected ports or the node is a receiver and a message is received in the buffer of the hardware interface.

In practice multiple distributed channels can be supported over each multicasting bus. The multiple distributed channels share the bandwidth provided by the multicasting bus.

## 5 Discussion

In this section we discuss how the kernel can be used to build a complete operating system, how the design avoids loss of transparency, and the current status of the system

### 5.1 Building a Complete Operating System

The kernel is not an operating system; however, it provides the facilities needed to build a distributed operating system. A distributed operating system for Star would consist of a copy of the kernel and some statically defined set of initial processes at each processor of the system. It would need a file system, some user interface, and a resource manager. An early version of a resource manager for Star has been described in [21].

When the system is initialized, the hardware is not configured and there are no communication channels. Therefore, it must be possible for the set of statically defined processes to create a set of communication channels so that they may cooperate to perform the operating system functions. The feasibility of this initialization step is illustrated by a simple example. Imagine that there is a process **x** residing at node **X** and a process **y** residing at node **Y**. The following code fragments demonstrate a method in which the two processes can become connected to a common channel.

```
(* code fragment for x *)

CONST    buffersize = ?;
VAR      myport : port; success : BOOLEAN;

BEGIN
   CreateChannel("channelone",{X,Y} ,buffersize);
   success := ConnectPort(myport, "channelone");
   ........

(* code fragment for y *)

VAR      myport : port; success : BOOLEAN;

BEGIN
   REPEAT
      success := ConnectPort(myport, "channelone") ;
   UNTIL success
   ........
```

Additional protocol steps involving message passing between **x** and **y** are needed so that the two processes may reach an agreed upon state. Although this initialization process may seem to be a great deal of trouble, it is only necessary for initializing the higher levels of the operating system and should not be necessary for application programs.

### 5.2 Loss of Transparency

In Section 1 we mentioned that minimization of loss of transparency was a key design goal. We have achieved this by tailoring our global communication system to the capabilities of the interconnection network. The channel model supports the multicast connections among multiple processors. In addition the channel maintains the strict message sequencing provided by the underlying hardware.

We have introduced some loss of transparency by forcing channel buffers to be fixed at creation; this introduces the possibility of message loss which does not exist in the hardware; however, we have argued that with a proper choice of communication protocols message loss can be avoided.

### 5.3 Concluding Remarks

In this paper we have presented the operating system kernel for Star, a reconfigurable multiprocessor system. The kernel is intended to serve as a basis for further operating systems research. It provides process management, local resource allocation, and inter-process communication mechanisms. The design is simple and avoids loss of transparency in the hardware by supporting the communication modes provided by the interconnection network.

The kernel supports multiple processes and, at the process manager level, provides simple, yet powerful inter-process communication mechanisms. In addition the process manager provides for the implementation of a wide range of process scheduling algorithms.

The global communication mechanism was designed to closely support the communication modes provided for by the underlying hardware. It supports the general notion of merging by allowing additional communicating entities (ports) to join into a conversation (a channel) at will. In addition the communication mechanism maintains the capability of the hardware to provide reliable multicasting of messages.

The present status of our system is that we have a four node machine running. We have implemented and tested the process manager, memory manager and local portion of the distributed communication system. In addition we have implemented a linking loader which allows separately compiled MODULA-2 programs to be loaded, linked to the operating system and executed as independent processes. The implemented code constitutes about two thousand lines of MODULA-2. We plan to extend our work to provide greater support for distributed programs.

# THE INTERFACE BETWEEN DISTRIBUTED OPERATING SYSTEM AND HIGH-LEVEL PROGRAMMING LANGUAGE

Michael L. Scott

Computer Science Department
University of Rochester
Rochester, NY 14627

**Abstract** — A distributed operating system provides a process abstraction and primitives for communication between processes. A distributed programming language regularizes the use of the primitives, making them both safer and more convenient. The level of abstraction of the primitives, and therefore the division of labor between the operating system and the language support routines, has serious ramifications for efficiency and flexibility. Experience with three implementations of the LYNX distributed programming language suggests that functions that can be implemented on either side of the interface are best left to the language run-time package.

## Introduction

Recent years have seen the development of a large number of distributed programming languages and an equally large number of distributed operating systems. While there are exceptions to the rule, it is generally true that individual research groups have focused on a single language, a single operating system, or a single language/O.S. pair. Relatively little attention has been devoted to the relationship between languages and O.S. kernels in a distributed setting.

Amoeba [15], Demos-MP [16], Locus [26], and the V kernel [7] are among the better-known distributed operating systems. Each by-passes language issues by relying on a simple library-routine interface to kernel communication primitives. Eden [5] and Cedar [24] have both devoted a considerable amount of attention to programming language issues, but each is very much a single-language system. The Accent project at CMU [17] is perhaps the only well-known effort to support more than one programming language on a single underlying kernel. Even so, Accent is only able to achieve its multi-lingual character by insisting on a single, universal model of interprocess communication based on remote procedure calls [11]. Languages with other models of process interaction are not considered.

In the language community, it is unusual to find implementations of the same distributed programming language for more than one operating system, or indeed for any *existing* operating system. Dedicated, special-purpose kernels are under construction for Argus [14], SR [1,2], and NIL [22,23]. Several dedicated implementations have been designed for Linda [6,10]. No distributed implementations have yet appeared for Ada [25].

If parallel or distributed hardware is to be used for *general-purpose* computing, we must eventually learn how to support multiple languages efficiently on a single operating system. Toward that end, it is worth considering the division of labor between the language run-time package and the underlying kernel. Which functions belong on which side of the interface? What is the appropriate level of abstraction for universal primitives? Answers to these questions will depend in large part on experience with a variety of language/O. S. pairs.

This paper reports on implementations of the LYNX distributed programming language for three existing, but radically different, distributed operating systems. To the surprise of the implementors, the implementation effort turned out to be substantially easier for kernels with low-level primitives. If confirmed by similar results with other languages, the lessons provided by work on LYNX should be of considerable value in the design of future systems.

The first implementation of LYNX was constructed during 1983 and 1984 at the University of Wisconsin, where it runs under the Charlotte distributed operating system [3,9] on the Crystal multicomputer [8]. The second implementation was designed, but never actually built, for Kepecs and Solomon's SODA [12,13]. A third implementation has recently been released at the University of Rochester, where it runs on BBN Butterfly multiprocessors [4] under the Chrysalis operating system.

Section 2 of this paper summarizes the features of LYNX that have an impact on the services needed from a distributed operating system kernel. Sections 3, 4, and 5 describe the three LYNX implementations, comparing them one to the other. The final section discusses possible lessons to be learned from the comparison.

## LYNX Overview

The LYNX programming language is not itself the subject of this article. Language features and their rationale are described in detail elsewhere [19,20,21]. For present purposes, it suffices to say that LYNX was designed to support the loosely-coupled style of programming encouraged by a distributed operating system. Unlike most existing languages, LYNX extends the advantages of high-level communication facilities to processes designed in isolation, and compiled and loaded at disparate times. LYNX supports interaction not only between the pieces of a multi-process application, but also between separate applications and between user programs and long-lived system servers.

Processes in LYNX execute in parallel, possibly on separate processors. There is no provision for shared memory. Interprocess communication uses a mechanism similar to remote procedure calls (RPC), on virtual circuits called **links**. Links are two-directional and have a single process at each end. Each process may be divided into an arbitrary number of threads of control, but the threads execute in mutual exclusion and may be managed by the language run-time package, much like the coroutines of Modula-2 [27].

### Communication Characteristics

(The following paragraphs describe the communication behavior of LYNX processes. The description does not provide much insight into the way that LYNX programmers think about their programs. The intent is to describe the externally-visible characteristics of a process that must be supported by kernel primities.)

At the University of Wisconsin, this work was supported in part by NSF grant number MCS-8105904, DARPA contract number N0014-82-C-2087, and a Bell Telephone Laboratories Doctoral Scholarship. At the University of Rochester, the work is supported in part by NSF grant number DCR-8320136 and DARPA contract number DACA76-85-C-0001.

Messages in LYNX are not received asynchronously. They are queued instead, on a link-by-link basis. Each link end has one queue for incoming requests and another for incoming replies. Messages are received from a queue only when the queue is **open** and the process that owns its end has reached a well-defined **block point**. Request queues may be opened or closed under explicit process control. Reply queues are opened when a request has been sent and a reply is expected. The set of open queues may therefore vary from one block point to the next.

A blocked process waits until one of its previously-sent messages has been received, or until an incoming message is available in at least one of its open queues. In the latter case, the process chooses a non-empty queue, receives that queue's first message, and executes through to the next block point. For the sake of fairness, an implementation must guarantee that no queue is ignored forever.

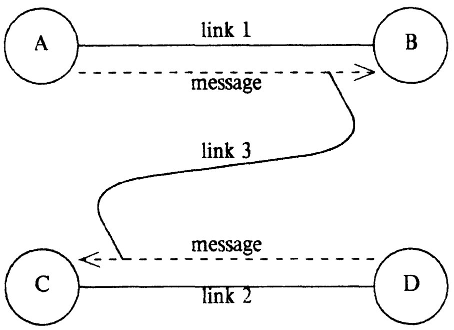

**figure 1: link moving at both ends**

Messages in the same queue are received in the order sent. Each message blocks the sending coroutine within the sending process. The process must be notified when messages are received in order to unblock appropriate coroutines. It is therefore possible for an implementation to rely upon a stop-and-wait protocol with no actual buffering of messages in transit. Request and reply queues can be implemented by lists of blocked coroutines in the run-time package for each sending process.

The most challenging feature of links, from an implementor's point of view, is the provision for *moving* their ends. Any message, request or reply, can contain references to an arbitrary number of link ends. Language semantics specify that receipt of such a message has the side effect of moving the specified ends from the sending process to the receiver. The process at the far end of each moved link must be oblivious to the move, even if it is currently relocating its end as well. In figure 1, for example, processes A and D are moving their ends of link 3, independently, in such a way that what used to connect A to D will now connect B to C.

It is best to think of a link as a flexible hose. A message put in one end will eventually be delivered to whatever process happens to be at the other end. The queues of available but un-received messages for each end are associated with the link itself, not with any process. A moved link may therefore (logically at least) have messages inside, waiting to be received at the moving end. In keeping with the comment above about stop-and-wait protocols, and to prevent complete anarchy, a process is not permitted to move a link on which it has *sent* unreceived messages, or on which it owes a reply for an already-received request.

## Kernel Requirements

To permit an implementation of LYNX, an operating system kernel must provide processes, communication primitives, and a naming mechanism that can be used to build links. The major questions for the designer are then 1) how are links to be represented? and 2) how are RPC-style request and reply messages to be transmitted on those links? It must be possible to move links without losing messages. In addition, the termination of a process must destroy all the links attached to that process. Any attempt to send or receive a message on a link that has been destroyed must fail in a way that can be reflected back into the user program as a run-time exception.

# The Charlotte Implementation

## Overview of Charlotte

Charlotte [3,9] runs on the Crystal multicomputer [8], a collection of 20 VAX 11/750 **node** machines connected by a 10-Mbit/second token ring from Proteon Corporation.

The Charlotte **kernel** is replicated on each node. It provides direct support for both **processes** and **links**. Charlotte links were the original motivation for the circuit abstraction in LYNX. As in the language, Charlotte links are two directional, with a single process at each end. As in the language, Charlotte links can be created, destroyed, and moved from one process to another. Charlotte even guarantees that process termination destroys all of the process's links. It was originally expected that the implementation of LYNX-style interprocess communication would be almost trivial. As described in the rest of this section, that expectation turned out to be naive.

Kernel calls in Charlotte include the following:

MakeLink (var end1, end2 : link)
    Create a link and return references to its ends.

Destroy (myend : link)
    Destroy the link with a given end.

Send (L : link; buffer : address; length : integer; enclosure : link)
    Start a **send activity** on a given link end, optionally enclosing one end of some other link.

Receive (L : link; buffer : address; length : integer)
    Start a **receive activity** on a given link end.

Cancel (L : link; d : direction)
    Attempt to cancel a previously-started send or receive activity.

Wait (var e : description)
    Wait for an activity to complete, and return its description (link end, direction, length, enclosure).

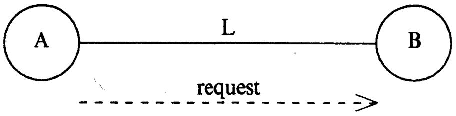
All calls return a status code. All but *Wait* are guaranteed to complete in a bounded amount of time. *Wait* blocks the caller until an activity completes.

The Charlotte kernel matches send and receive activities. It allows only one outstanding activity in each direction on a given end of a link. Completion must be reported by *Wait* before another similar activity can be started.

## Implementation of LYNX

The language run-time package represents every LYNX link with a Charlotte link. It uses the activities of the Charlotte kernel to simulate the request and reply queues described in section 2.1. It starts a send activity on a link whenever a process attempts to send a request or reply message. It starts a receive activity on a link when the corresponding request or reply queue is opened, if both were closed before. It attempts to cancel a previous-started receive activity when a process closes its request queue, if the reply queue is also closed. The multiplexing of request and reply queues onto receive activities was a major source of problems for the implementation effort. A second source of problems was the inability to enclose more than one link in a single Charlotte message.

**Screening Messages.** For the vast majority of remote operations, only two Charlotte messages are required: one for the request and one for the reply. Complications arise, however, in a number of special cases. Suppose that process **A** requests a remote operation on link **L**.



Process **B** receives the request and begins serving the operation. **A** now expects a reply on **L** and starts a receive activity with the kernel. Now suppose that before replying **B** requests another operation on **L**, in the reverse direction (the coroutine mechanism mentioned in section 2 makes such a scenario entirely plausible). **A** will receive **B**'s request before the reply it wanted. Since **A** may not be willing to serve requests on **L** at this point in time (its request queue is closed), **B** is not able to assume that its request is being served simply because **A** has received it.

A similar problem arises if **A** opens its request queue and then closes it again, before reaching a block point. In the interests of concurrency, the run-time support routines will have posted a *Receive* with the kernel as soon as the queue was opened. When the queue is closed, they will attempt to cancel the *Receive*. If **B** has requested an operation in the meantime, the *Cancel* will fail. The next time **A**'s run-time package calls *Wait*, it will obtain notification of the request from **B**, a message it does not want. Delaying the start of receive activities until a block point does not help. **A** must still start activities for *all* its open queues. It will continue execution after a message is received from exactly *one* of those queues. Before reaching the *next* block point, it may change the set of messages it is willing to receive.

It is tempting to let **A** buffer unwanted messages until it is again willing to receive from **B**, but such a solution is impossible for two reasons. First, the occurrence of exceptions in LYNX can require **A** to cancel an outstanding *Send* on **L**. If **B** has already received the message (inadvertently) and is buffering it internally, the *Cancel* cannot succeed. Second, the scenario in which **A** receives a request but wants a reply can be repeated an arbitrary number of times, and **A** cannot be expected to provide an arbitrary amount of buffer space.

**A** must return unwanted messages to **B**. In addition to the **request** and **reply** messages needed in simple situations, the implementation now requires a **retry** message. *Retry* is a negative acknowledgment. It can be used in the second scenario above, when **A** has closed its request queue after receiving an unwanted message. Since **A** will have no *Receive* outstanding, the re-sent message from **B** will be delayed by the kernel until the queue is re-opened.

In the first scenario, unfortunately, **A** will still have a *Receive* posted for the reply it wants from **B**. If **A** simply returned requests to **B** in retry messages, it might be subjected to an arbitrary number of retransmissions. To prevent these retransmissions we must introduce the **forbid** and **allow** messages. *Forbid* denies a process the right to send requests (it is still free to send replies). *Allow* restores that right. *Retry* is equivalent to *forbid* followed by *allow*. It can be considered an optimization for use in cases where no replies are expected, so retransmitted requests will be delayed by the kernel.

Both *forbid* and *retry* return any link end that was enclosed in the unwanted message. A process that has received a forbid message keeps a *Receive* posted on the link in hopes of receiving an allow message.[1] A process that has sent a forbid message remembers that it has done so and sends an allow message as soon as it is either willing to receive requests (its request queue is open) or has no *Receive* outstanding (so the kernel will delay all messages).

**Moving Multiple Links.** To move more than one link end with a single LYNX message, a request or reply must be broken into several Charlotte messages. The first packet contains non-link data, together with the first enclosure. Additional enclosures are passed in empty **enc** messages (see figure 2). For requests, the receiver must return an explicit **goahead** message after the first packet so the sender can tell that the request is wanted. No *goahead* is needed for requests with zero or one enclosures, and none is needed for replies, since a reply is always wanted.

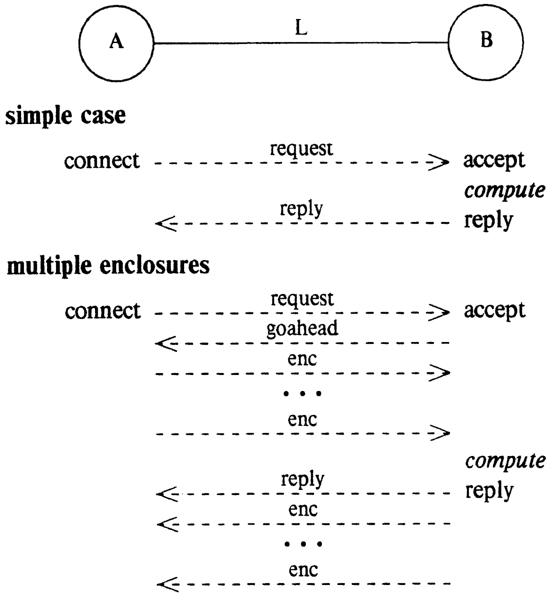


**figure 2: link enclosure protocol**

One consequence of packetizing LYNX messages is that links enclosed in unsuccessful messages may be lost. Consider the following chain of events:

a) Process **A** sends a request to process **B**, enclosing the end of a link.

b) **B** receives the request unintentionally; inspection of the code allows one to prove that only replies were wanted.

c) The sending coroutine in **A** feels an exception, aborting the request.

d) **B** crashes before it can send the enclosure back to **A** in a forbid message. From the point of view of language semantics, the message to **B** was never sent, yet the enclosure has been lost. Under such circumstances the Charlotte implementation cannot conform to the language reference manual.

The Charlotte implementation also disagrees with the language definition when a coroutine that is waiting for a reply message is aborted by a local exception. On the other end of the link

[1] This of course makes it vulnerable to receiving unwanted messages itself.

the server should feel an exception when *it* attempts to send a no-longer-wanted reply. Such exceptions are not provided under Charlotte because they would require a final, top-level acknowledgment for reply messages, increasing message traffic by 50%.

## Measurements

The language run-time package for Charlotte consists of just over 4000 lines of C and 200 lines of VAX assembler, compiling to about 21K of object code and data. Of this total, approximately 45% is devoted to the communication routines that interac' with the Charlotte kernel, including perhaps 5K for unwanted messages and multiple enclosures. Much of this space could be saved with a more appropriate kernel interface.

A simple remote operation (no enclosures) requires approximately 57 ms with no data transfer and about 65 ms with 1000 bytes of parameters in both directions. C programs that make the same series of kernel calls require 55 and 60 ms, respectively. In addition to being rather slow, the Charlotte kernel is highly sensitive to the ordering of kernel calls and to the interleaving of calls by independent processes. Performance figures should therefore be regarded as suggestive, not definitive. The difference in timings between LYNX and C programs is due to efforts on the part of the run-time package to gather and scatter parameters, block and unblock coroutines, establish default exception handlers, enforce flow control, perform type checking, update tables for enclosed links, and make sure the links are valid.

# The SODA Implementation

## Overview of SODA

As part of his Ph. D. research [12, 13], Jonathan Kepecs set out to design a minimal kernel for a multicomputer. His "Simplified Operating system for Distributed Applications" might better be described as a communications protocol for use on a broadcast medium with a very large number of heterogeneous nodes.

Each node on a SODA network consists of two processors: a **client processor**, and an associated **kernel processor**. The kernel processors are all alike. They are connected to the network and communicate with their client processors through shared memory and interrupts. Nodes are expected to be more numerous than processes, so client processors are not multi-programmed.

Every SODA process has a unique **id**. It also **advertises** a collection of **names** to which it is willing to respond. There is a kernel call to generate new names, unique over space and time. The **discover** kernel call uses unreliable broadcast in an attempt to find a process that has advertised a given name.

Processes do not necessarily *send* messages, rather they **request** the transfer of data. A process that is interested in communication specifies a name, a process id, a small amount of out-of-band information, the number of bytes it would like to send and the number it is willing to receive. Since either of the last two numbers can be zero, a process can request to send data, receive data, neither, or both. The four varieties of request are termed **put**, **get**, **signal**, and **exchange**, respectively.

Processes are informed of interesting events by means of software interrupts. Each process establishes a single **handler** which it can close temporarily when it needs to mask out interrupts. A process feels a software interrupt when its id and one of its advertised names are specified in a request from some other process. The handler is provided with the id of the requester and the arguments of the request, including the out-of-band information. The interrupted process is free to save the information for future reference.

At any time, a process can **accept** a request that was made of it at some time in the past. When it does so, the request is completed (data is transferred in both directions simultaneously), and the requester feels a software interrupt informing it of the completion and providing it with a small amount of out-of-band information from the accepter. Like the requester, the accepter specifies buffer sizes. The amount of data transferred in each direction is the smaller of the specified amounts.

Completion interrupts are queued when a handler is busy or closed. Requests are delayed; the requesting kernel retries periodically in an attempt to get through (the requesting user can proceed). If a process dies before accepting a request, the requester feels an interrupt that informs it of the crash.

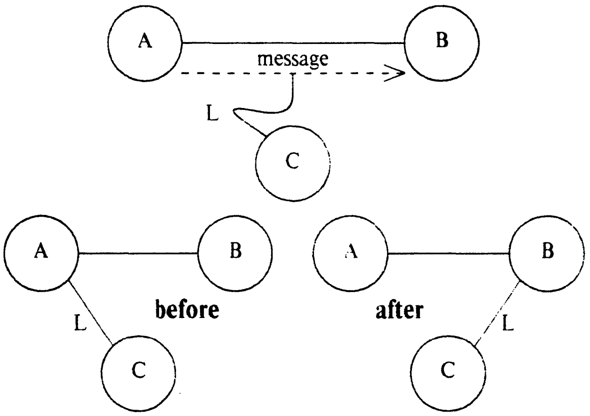
## A Different Approach to Links

A link in SODA can be represented by a pair of unique names, one for each end. A process that owns an end of a link advertises the associated name. Every process knows the names of the link ends it owns. Every process keeps a **hint** as to the current location of the far end of each of its links. The hints can be wrong, but are expected to work most of the time.

A process that wants to send a LYNX message, either a request or a reply, initiates a SODA *put* to the process it thinks is on the other end of the link. A process moves link ends by enclosing their names in a message. When the message is SODA-accepted by the receiver, the ends are understood to have moved. Processes on the fixed ends of moved links will have incorrect hints.

A process that wants to receive a LYNX message, either a request or a reply, initiates a SODA *signal* to the process it thinks is on the other end of the link. The purpose of the signal is allow the aspiring receiver to tell if its link is destroyed or if its chosen sender dies. In the latter case, the receiver will feel an interrupt informing it of the crash. In the former case, we require a process that destroys a link to accept any previously-posted status *signal* on its end, mentioning the destruction in the out-of-band information. We also require it to accept any outstanding *put* request, but with a zero-length buffer, and again mentioning the destruction in the out-of-band information. After clearing the *signals* and *puts*, the process can **unadvertise** the name of the end and forget that it ever existed.

Suppose now that process **A** has a link **L** to process **C** and that it sends its end to process **B**.



If **C** wants to send or receive on **L**, but **B** terminates after receiving **L** from **A**, then **C** must be informed of the termination so it knows that **L** has been destroyed. **C** will have had a SODA request posted with **A**. **A** must accept this request so that **C** knows to watch **B** instead. We therefore adopt the rule that a process that moves a link end must accept any previously-posted SODA request from the other end, just as it must when it destroys the link. It specifies a zero-length buffer and uses the out-of-band information to tell the other process where it moved its end. In the above example, **C** will re-start its request with **B** instead of **A**.

The amount of work involved in moving a link end is very small, since accepting a request does not even block the accepter. More than one link can be enclosed in the same message with no more difficulty than a single end. If the fixed end of a moving link is not in active use, there is no expense involved at all. In the above example, if C receives a SODA request from B, it will know that L has moved.

The only real problems occur when an end of a dormant link is moved. If our example, if L is first used by C after it is moved, C will make a SODA request of A, not B, since its hint is out-of-date. There must be a way to fix the hint. If each process keeps a cache of links it has known about recently, and keeps the names of those links advertised, then A may remember it sent L to B, and can tell C where it went. If A has forgotten, C can use the *discover* command in an attempt to find a process that knows about the far end of L.

A process that is unable to find the far end of a link must assume it has been destroyed. If L exists, the heuristics of caching and broadcast should suffice to find it in the vast majority of cases. If the failure rate is comparable to that of other "acceptable" errors, such as garbled messages with "valid" checksums, then the heuristics may indeed be all we *ever* need.

Without an actual implementation to measure, and without reasonable assumptions about the reliability of SODA broadcasts, it is impossible to predict the success rate of the heuristics. The SODA *discover* primitive might be especially strained by node crashes, since they would tend to precipitate a large number of broadcast searches for lost links. If the heuristics failed too often, a fall-back mechanism would be needed.

Several absolute algorithms can be devised for finding missing links. Perhaps the simplest looks like this:

- Every process advertises a **freeze** name. When C discovers its hint for L is bad, it posts a SODA request on the freeze name of every process currently in existence (SODA makes it easy to guess their ids). It includes the name of L in the request.
- Each process accepts a freeze request immediately, ceases execution of everying but its own searches (if any), increments a counter, and posts an **unfreeze** request with C. If it has a hint for L, it includes that hint in the freeze accept or the unfreeze request.
- When C obtains a new hint or has unsuccessfully queried everyone, it accepts the unfreeze requests. When a frozen process feels an interrupt indicating that its unfreeze request has been accepted or that C has crashed, it decrements its counter. If the counter hits zero, it continues execution. The existence of the counter permits multiple concurrent searches.

This algorithm has the considerable disadvantage of bringing every LYNX process in existence to a temporary halt. On the other hand, it is simple, and should only be needed when a node crashes or a destroyed link goes unused for so long that everyone has forgotten about it.

**Potential Problems.** As mentioned in the introduction, the SODA version of LYNX was designed on paper only. An actual implementation would need to address a number of potential problems. To begin with, SODA places a small, but unspecified, limit on the size of the out-of-band information for *request* and *accept*. If all the self-descriptive information included in messages under Charlotte were to be provided out-of-band, a minimum of about 48 bits would be needed. With fewer bits available, some information would have to be included in the messages themselves, as in Charlotte.

A second potential problem with SODA involves another unspecified constant: the permissible number of outstanding requests between a given pair of processes. The implementation described in the previous section would work easily if the limit were large enough to accommodate three requests for every link between the processes (a LYNX-request *put*, a LYNX-reply *put*, and a status *signal*). Since reply messages are always wanted (or can at least be discarded if unwanted), the implementation could make do with two outstanding requests per link and a single extra for replies. Too small a limit on outstanding requests would leave the possibility of deadlock when many links connect the same pair of processes. In practice, a limit of a half a dozen or so is unlikely to be exceeded (it implies an improbable concentration of simultaneously-active resources in a single process), but there is no way to reflect the limit to the user in a semantically-meaningful way. Correctness would start to depend on global characteristics of the process-interconnection graph.

### Predicted Measurements

Space requirements for run-time support under SODA would reflect the lack of special cases for handling unwanted messages and multiple enclosures. Given the amount of code devoted to such problems in the Charlotte implementation, it seems reasonable to expect a savings on the order of 4K bytes.

For simple messages, run-time routines under SODA would need to perform most of the same functions as their counterparts for Charlotte. Preliminary results with the Butterfly implementation (described in the following section) suggest that the lack of special cases might save some time in conditional branches and subroutine calls, but relatively major differences in run-time package overhead appear to be unlikely.

Overall performance, including kernel overhead, is harder to predict. Charlotte has a considerable hardware advantage: the only implementation of SODA ran on a collection of PDP-11/23's with a 1-Mbit/second CSMA bus. SODA, on the other hand, was designed with speed in mind. Experimental figures reveal that for small messages SODA was three times as fast as Charlotte.[2] Charlotte programmers made a deliberate decision to sacrifice efficiency in order to keep the project manageable. A SODA version of LYNX might well be *intrinsically* faster than a comparable version for Charlotte.

## The Chrysalis Implementation

### Overview of Chrysalis

The BBN Butterfly Parallel Processor [4] is a 68000-based shared-memory multiprocessor. The Chrysalis operating system provides primitives, many of them in microcode, for the management of system abstractions. Among these abstractions are **processes**, **memory objects**, **event blocks**, and **dual queues**.

Each process runs in an address space that can span as many as one or two hundred memory objects. Each memory object can be mapped into the address spaces of an arbitrary number of processes. Synchronization of access to shared memory is achieved through use of the event blocks and dual queues.

An event block is similar to a binary semaphore, except that 1) a 32-bit datum can be provided to the *V* operation, to be returned by a subsequent *P*, and 2) only the **owner** of an event block can **wait** for the event to be **posted**. Any process that knows the name of the event can perform the post operation. The most common use of event blocks is in conjunction with dual queues.

A dual queue is so named because of its ability to hold either data or event block names. A queue containing data is a simple bounded buffer, and enqueue and dequeue operations proceed as

[2] The difference is less dramatic for larger messages; SODA's slow network exacted a heavy toll. The figures break even somewhere between 1K and 2K bytes.

one would expect. Once a queue becomes empty, however, subsequent dequeue operations actually *enqueue* event block names, on which the calling processes can wait. An enqueue operation on a queue containing event block names actually posts a queued event instead of adding its datum to the queue.

## A Third Approach to Links

In the Butterfly implementation of LYNX, every process allocates a single dual queue and event block through which to receive notifications of messages sent and received. A link is represented by a memory object, mapped into the address spaces of the two connected processes. The memory object contains buffer space for a single request and a single reply in each direction. It also contains a set of flag bits and the names of the dual queues for the processes at each end of the link. When a process gathers a message into a buffer or scatters a message out of a buffer into local variables, it sets a flag in the link object (atomically) and then enqueues a notice of its activity on the dual queue for the process at the other end of the link. When the process reaches a block point it attempts to dequeue a notice from its own dual queue, waiting if the queue is empty.

As in the SODA implementation, link movement relies on a system of hints. Both the dual queue names in link objects and the notices on the dual queues themselves are considered to be hints. Absolute information about which link ends belong to which processes is known only to the owners of the ends. Absolute information about the availability of messages in buffers is contained only in the link object flags. Whenever a process dequeues a notice from its dual queue it checks to see that it owns the mentioned link end and that the appropriate flag is set in the corresponding object. If either check fails, the notice is discarded. Every change to a flag is eventually reflected by a notice on the appropriate dual queue, but not every dual queue notice reflects a change to a flag. A link is moved by passing the (address-space-independent) name of its memory object in a message. When the message is received, the sending process removes the memory object from its address space. The receiving process maps the object *into* its address space, changes the information in the object to name its own dual queue, and *then* inspects the flags. It enqueues notices on its own dual queue for any of the flags that are set.

Primitives provided by Chrysalis make atomic changes to flags extremely inexpensive. Atomic changes to quantities larger than 16 bits (including dual queue names) are relatively costly. The recipient of a moved link therefore writes the name of its dual queue into the new memory object in a non-atomic fashion. It is possible that the process at the non-moving end of the link will read an invalid name, but only *after* setting flags. Since the recipient completes its update of the dual-queue name *before* inspecting the flags, changes are never overlooked.

Chrysalis keeps a reference count for each memory object. To destroy a link, the process at either end sets a flag bit in the link object, enqueues a notice on the dual queue for the process at the other end, unmaps the link object from its address space, and informs Chrysalis that the object can be deallocated when its reference count reaches zero. When the process at the far end dequeues the destruction notice from its dual queue, it confirms the notice by checking it against the appropriate flag and then unmaps the link object. At this point Chrysalis notices that the reference count has reached zero, and the object is reclaimed.

Before terminating, each process destroys all of its links. Chrysalis allows a process to catch all exceptional conditions that might cause premature termination, including memory protection faults, so even erroneous processes can clean up their links before going away. Processor failures are currently not detected.

## Preliminary Measurements

The Chrysalis implementation of LYNX has only recently become available. It consists of approximately 3600 lines of C and 200 lines of assembler, compiling to 15 or 16K bytes of object code and data on the 68000. Both measures are appreciably smaller than the respective figures for the Charlotte implementation.

Message transmission times are also faster on the Butterfly, by more than an order of magnitude. Recent tests indicate that a simple remote operation requires about 2.4 ms with no data transfer and about 4.6 ms with 1000 bytes of parameters in both directions. Code tuning and protocol optimizations now under development are likely to improve both figures by 30 to 40%.

## Discussion

Even though the Charlotte kernel provides a higher-level interface than does either SODA or Chrysalis, and even though the communication mechanisms of LYNX were patterned in large part on the primitives provided by Charlotte, the implementations of LYNX for the latter two systems are smaller, simpler, and faster. Some of the difference can be attributed to duplication of effort between the kernel and the language run-time package. Such duplication is the usual target of so-called **end-to-end arguments** [18]. Among other things, end-to-end arguments observe that each level of a layered software system can only eliminate errors that can be described in the context of the interface to the level above. Overall reliability must be ensured at the application level. Since end-to-end checks generally catch *all* errors, low-level checks are redundant. They are justified only if errors occur frequently enough to make early detection essential.

LYNX routines never pass Charlotte an invalid link end. They never specify an impossible buffer address or length. They never try to send on a moving end or enclose an end on itself. To a certain extent they provide their own top-level acknowledgments, in the form of goahead, retry, and forbid messages, and in the confirmation of operation names and types implied by a reply message. They would provide additional acknowledgments for the replies themselves if they were not so expensive. For the users of LYNX, Charlotte wastes time by checking these things itself.

Duplication alone, however, cannot account for the wide disparity in complexity and efficiency between the three LYNX implementations. Most of the differences appear to be due to the difficulty of adapting higher-level Charlotte primitives to the needs of an application for which they are almost, but not quite, correct. In comparison to Charlotte, the language run-time packages for SODA and Chrysalis can

(1) move more than one link in a message

(2) be sure that all received messages are wanted

(3) recover the enclosures in aborted messages

(4) detect all the exceptional conditions described in the language definition, without any extra acknowledgments.

These advantages obtain precisely because the facilities for managing virtual circuits and for screening incoming messages are *not* provided by the kernel. By moving these functions into the language run-time package, SODA and Chrysalis allow the implementation to be tuned specifically to LYNX. In addition, by maintaining the flexibility of the kernel interface they permit equally efficient implementations of a wide variety of other distributed languages, with entirely different needs.

It should be emphasized that Charlotte was not originally intended to support a distributed programming language. Like the designers of most similar systems, the Charlotte group expected applications to be written directly on top of the kernel. Without the benefits of a high-level language, most programmers probably would prefer the comparatively powerful facilities of Charlotte to the comparatively primitive facilities of SODA or Chrysalis. With a language, however, the level of abstraction of underlying software is no longer of concern to the average programmer.

For the consideration of designers of future languages and systems, we can cast our experience with LYNX in the form of the following three lessons:

**Lesson one**: Hints can be better than absolutes.

The maintenance of consistent, up-to-date, distributed information is often more trouble than it is worth. It can be considerably easier to rely on a system of hints, so long as they usually work, and so long as we can tell when they fail.

The Charlotte kernel admits that a link end has been moved only when all three parties agree. The protocol for obtaining such agreement was a major source of problems in the kernel, particularly in the presence of failures and simultaneously-moving ends [3]. The implementation of links *on top of* SODA and Chrysalis was comparatively easy. It is likely that the Charlotte kernel itself would be simplified considerably by using hints when moving links.

**Lesson two**: Screening belongs in the application layer.

Every reliable protocol needs top-level acknowledgments. A distributed operating system can attempt to circumvent this rule by allowing a user program to describe *in advance* the sorts of messages it would be willing to acknowledge if they arrived. The kernel can then issue acknowledgments on the user's behalf. The shortcut only works if failures do not occur between the user and the kernel, and if the descriptive facilities in the kernel interface are sufficiently rich to specify precisely which messages are wanted. In LYNX, the termination of a coroutine that was waiting for a reply can be considered to be a "failure" between the user and the kernel. More important, the descriptive mechanisms of Charlotte are unable to distinguish between requests and replies on the same link.

SODA provides a very general mechanism for screening messages. Instead of asking the user to *describe* its screening function, SODA allows it to provide that function itself. In effect, it replaces a static description of desired messages with a formal subroutine that can be called when a message arrives. Chrysalis provides no messages at all, but its shared-memory operations can be used to build whatever style of screening is desired.

**Lesson three**: Simple primitives are best.

From the point of view of the language implementor, the "ideal operating system" probably lies at one of two extremes: it either provides everything the language needs, or else provides almost nothing, but in a flexible and efficient form. A kernel that provides some of what the language needs, but not all, is likely to be both awkward and slow: awkward because it has sacrificed the flexibility of the more primitive system, slow because it has sacrificed its simplicity. Clearly, Charlotte could be modified to support all that LYNX requires. The changes, however, would not be trivial. Moreover, they would probably make Charlotte significantly larger and slower, and would undoubtedly leave out something that some other language would want.

A high-level interface is only useful to those applications for which its abstractions are appropriate. An application that requires only a subset of the features provided by an underlying layer of software must generally pay for the whole set anyway. An application that requires features *hidden* by an underlying layer may be difficult or impossible to build. For general-purpose computing a distributed operating system must support a wide variety of languages and applications. In such an environment the kernel interface will need to be relatively primitive.

## Acknowledgments

Much of the research described in this article was conducted in the course of doctoral studies at the University of Wisconsin under the supervision of Associate Professor Raphael Finkel.

## Abstract

DRAGON SLAYER is a distributed operating system for microprocessor based networks. It is currently implemented on a Carrier Sense Multiple Access (CSMA) network of 16 Leading Edge PCs. It provides message passing and uses a standard client/server model. A unique aspect of the system is the lack of any global process existence, global system kernel or central authority. In this paper, we explain our use of broadcast messaging and our mechanism for consistent and unique process naming. We achieve fair resource scheduling without any assumption on global management or control using a novel distributed algorithm derived from constructions using the Theory of Interaction Systems. Further, we address the usefulness of DRAGON SLAYER for dealing with data integrity in distributed data bases, for distributed vision processing applications, and for providing cheap, efficient, robust solutions for real-time process control problems in automatic manufacturing (factory-of-the-future).

## Introduction

An increasing number of operating systems for distributed applications on microprocessor networks have been developed during the past five or six years. If one considers as typical and established examples the Stanford V-Kernel [6,7] or the INRIA CHORUS [1,2,9] systems, one finds that in order to achieve a high modularity and flexibility at design and run time, all communication is based on message passing mechanisms. These systems create and maintain global name tables at every site through a remainder central service, a global kernel. Such an architecture makes sense in a local area network, with a central node responsible for message handling, name tables, process scheduling, managing large data files, etc., and with a standard connection (Ethernet). In a network with peer authority at all nodes, there should be no asymmetrical solution to handling control and management problems. Asymmetric solutions can cause undesirable message overheads in view of envisioned large distances between nodes of future distributed systems. Also, systems built on a master-slave relationship are vulnerable to failure since a master breakdown immediately halts all communication.

With DRAGON SLAYER, a successful attempt has been made to develop and implement a distributed operating system without any form of centralized service or global kernel. We are not aware of any other system of this type. In DRAGON SLAYER, resource management has been distributed to the process level, requiring that we solve the general conceptual problem of fair distributed resource scheduling. Since resources or server processes are normally available at several sites, we insure that a set of resources requested by a process will eventually be assigned so long as such resources are available anywhere in the system. This restriction holds even if server processes initially dedicated to providing the requested resources fail (e.g. through node or link communication failures). Our system is therefore extremely **robust**. Robustness and peer authority at all nodes were major design goals for DRAGON SLAYER. In our paper, we describe the main ideas and structures of this development.

After explaining the hardware configuration for our current implementation, we mention our integration of available software (MS-DOS) and the principles behind our system construction. We discuss the particularities of our message passing mechanism, broadcast messages and distributed naming scheme. A detailed outline is given of our distributed process scheduling and resource allocation handling algorithm.

Acknowledgements

This work was partially supported by the US Army (DAAE07-83-C-R094), under DARPA grant no. MDA 903-85-C-0056, and by the State of Michigan (IPPRI-85-140625).

In order to construct the needed distributed algorithm, we made use of formal results of the Theory of Interaction Systems, enhancing a deadlock-free, but not necessarily fair, algorithm by J. Winkowski [19] which was already in a suitable format and which was the first algorithm presented for this purpose which placed no unrealistic restrictions on the behavior of the processes involved. This algorithm and the formal background mentioned are specified in an appendix. Finally, the conceptual and developmental achievements of the DRAGON SLAYER operating system are discussed in light of existing solutions and of similar conceptual results. We point out the advantages of completely distributed operating systems like DRAGON SLAYER for future distributed applications in real-time processing (factory-of-the-future). We also discuss how DRAGON SLAYER provides for cheap, efficient, robust implementations of distributed algorithms for canonical vision tasks.

## 1. The Hardware Environment

DRAGON SLAYER was targeted for use on a network of Intel 8088 or 8086 based systems. It currently runs on a Carrier Sense Multiple Access (CSMA) network of 16 Leading Edge Personal Computer systems. These systems each contain 512K of local memory, a memory mapped character display and two 320k byte floppy disk drives (see figure 1). The systems are interconnected with a 1 Megabit per second network. Two of the systems have printers connected to them, two of the systems are connected via 9600 BAUD lines to the university mainframe host and one of the systems has an additional 10 megabyte disk drive (see figure 2). None of the individual systems is truly dedicated to any particular function, and the operating system kernel resident on any given system has not been tailored to augment particular functions. However, the systems to which the printers are connected must function as print servers at some time, the systems connected to the mainframe host must serve as gateways and the system connected to the winchester disk must serve as a file server. Our intention has been to allow each system to fulfill its service function without requiring dedication to that particular function.

## 2. The Software Environment

The DRAGON SLAYER system functions within and augments the operation of the MS-DOS or PC-DOS operating system, a single user operating system not designed to allow process communication, multiprocess execution, multitasking, concurrency or parallel program execution. Of chief concern during the design and construction of DRAGON SLAYER has been the philosophical imperative that MS-DOS functions would be unchanged and available to user processes. We have deviated from that philosophy as little as possible. Maintaining the MS-DOS functions has allowed development of applications under existing MS-DOS program development tools. Most user programs that currently can run under MS- DOS continue to run under DRAGON SLAYER's guidance. No disk or other hardware support facilities, other than network message facilities have been added. One clear advantage to using this approach was our ability to add a few procedures to TURBO PASCAL, a commercially available version of PASCAL for Personal Computer systems, and create a usable multiprogramming language in which to develop our application base.

Network Configuration

## 3. Principles of System Construction

The DRAGON SLAYER System is based on the client/server model which is common to many of today's distributed systems[1,2]. System resources are provided to the client processes through server processes while the operating system attempts to ensure fairness of resource allocation and efficiency of operation. When a client process wishes to use a

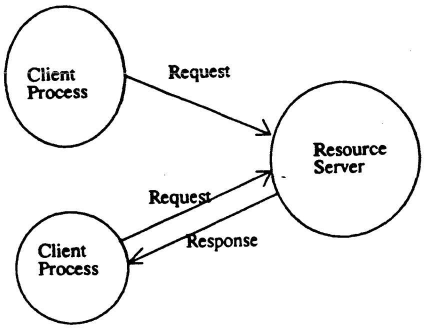

Figure 3.
Client/server Model

particular system resource it must request use of that resource from the resource server and then become a client of the resource server (see figure 3). The use of self scheduling servers without global control of resources introduces a conceptual problem of synchronization and fair resource scheduling that is not present in systems which feature centralized scheduling strategies. Our system requires that processes follow a strict model for resource request and use.

The resource client is insulated from the details of handling a particular resource by the server which presents a well defined interface, an abstract or virtual resource, to the client process. In the DRAGON SLAYER system, the client and server are further insulated by the necessity of communicating through use of the message passing primitives provided by the operating system. All server interfaces are defined in terms of the messages sent to the server by client processes.

The DRAGON SLAYER system has been developed without any form of central control. As a result, client and server processes act with a maximum amount of process autonomy and a large share of the responsibility for allowing the system to function properly. As in other message passing environments, DRAGON SLAYER processes, compete for access to resources which are available only for one of them at a time, and can be considered as members of temporarily groups of processes requesting overlapping sets of resources. However, we have no main process or group manager, and the group members do not have information about other group members other than information available from the resources over which, peers may compete. The sequence of activities through which a process accesses a mutually exclusive set of resources needed for a particular process step or **critical section** are as follows:

1. Establish a list of servers on the system.
2. Request commitment from servers in the resource list.
3. Initiate processing, once the resources/services are available.
4. Return resources and
5. Free the servers.

Once a process reaches step five, it may either terminate existence or return to step two and initiate another processing cycle in which it utilizes a new set of resources. The main process may look for new resource servers to add to its list at any time.

## 4. Message Passing

The DRAGON SLAYER operating system incorporates novel concepts in process addressing and organization. It is a message passing operating system based on a standard client/server model. The sending mechanism is displayed in figure 4. Unique aspects of this work include the lack of use of any global process existence, name or address table, and the use of only asynchronous non-blocking messages. Each processor on the network has a unique name assigned in hardware on the network interface board. Each active, memory resident process has a unique name composed of the name of the processor on which it resides and the segment-offset address of the first byte of executable code within the process. (In this way unique process naming is an indirect product of a process coming into existence at a node.) The mechanism utilized to locate a process is the universal broadcast primitive of the message passing function. This primitive replicates a transmitted message to all processes troughout the network system. As every process instantiation will receive a copy of such a message, locating the process becomes the act of sending an "are you there" message and receiving a "yes I am" reply. Once two processes have exchanged addresses they can communicate directly. The lack of any centralized numbering or naming convention

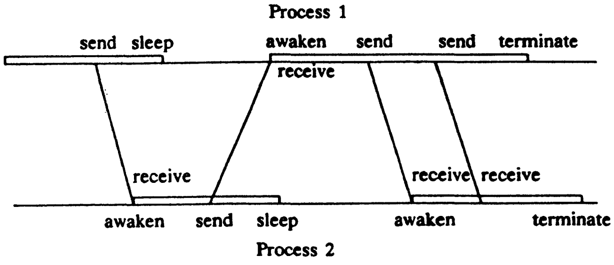

Figure 4
Interprocess Communication

allows the user complete flexibility in the broadcast messages which he wishes to use and to which he wishes to respond. (Obviously, if a user wishes to communicate with a printer he will have to obey the semantics of the messagesof printer servers.) Message passing and interprocess communication is handled through the functions of **message buffer request**, **message buffer free**, **message send** and **message retrieve**. Message buffer request is used to obtain a free message buffer from the operating system. This buffer may be used to transport information from one process to another. Message buffer free is used to return a used buffer to the operating system. Message send is used to request that a message buffer be transported from the current creating process to the process or processes identified as recipients of that message. Message buffer retrieve is used by a process to examine any message buffers that have been sent to it. Messages consist of a destination address, sender's address, control information and text information. High level interface functions remove the possibility of loss of message buffers by providing composite functions that properly integrate requests for, and release of, buffers. Message buffers are maintained in independent local pools. Each node maintains its local pool.

The sender's address is always the three part **segment number / offset number / processor number** address of the sending process. The destination address is either the specific segment / offset / processor address of the desired process or may be specified as a broadcast message to be delivered to all processes on all systems.

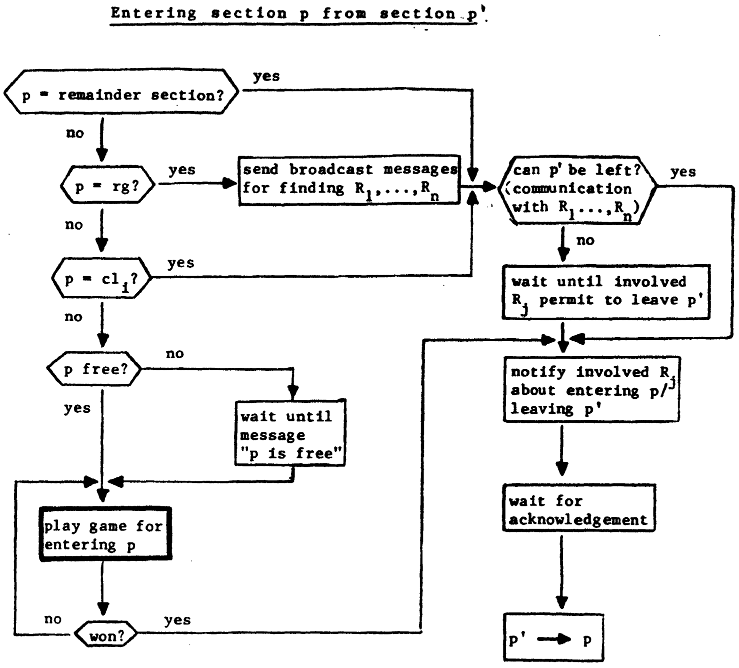
## 5. Process Scheduling

Each processor is engaged in scheduling the execution of the processes that are locally memory resident. Ready-to-run processes are scheduled for execution in a round-robin order. A process is deemed ready to run if its timer has been decremented to zero or if it has a message pending. A key problem in process scheduling is **fairness,** sometimes called starvation-freeness. Requested resources must be available after some finite time. Because a server can join more than one group simultaneously it is possible that processes in each of two groups may simultaneously attempt to utilize their shared resources. We achieve fairness in deciding conflicts between clients using a distributed algorithm which can be outlined as follows:

For entering one of its critical sections, say *cs(1)*, a process P must proceed through the sequence of activities mentioned in section 3. Communication, broadcast or direct, would have to occur in these activity sections. For short, we call "establish a list of servers on the system" *rg* ("registration"), the types of resources needed in order to execute *cs(1)* would be R(1),...,R(n). cl(1), cl(2),...,cl(n) will be names for the phases in which the servers providing access to R(1),...,R(n), respectively, would have been freed. Every section different from the critical one is accessible. The critical section is free for access only if none of the servers in the servers' list is serving another process. The **remainder section** (with respect to *cs(1)* is everything outside the activity sequence used to attach the particular set of resources needed in *cs(1)* (see section 3).

The behavior of process P in order to enter and execute a critical section is given by the flow chart scheme in figure 5 which explains the structure for making a transition from one of the sections specified above, into the next. As part of the algorithm processes will reach a state of competition in which they play a distributed game which is developed from an algorithm by J. Winkowski [19] and which is deadlock-free in the sense that one of the players wins after a finite time. This game is not fair. Fairness is achieved as follows: The servers/resource managers are responsible for communication about resources. In particular, they are responsible for communication with or among competing processes. In phase cl(i), the given process P is subject to a locking influence from a neighbor competing with P about R(i) if this neighbor were in *rg*. In *rg*, P exerts a similar influence on its neighbors when these have just released R(i). While P has not yet left *cs(1)* it is subject to a temporarily locking influence from any neighbor being in a state where it has released the shared resource but has not yet entered its remainder section. The corresponding communication is performed through the resource managers involved in the particular competition. Thus, it is really the partial knowledge of these managers alone on which the progress of the involved processes depends.Every process proceeds according to the scheme given in figure 5, and all servers react to the best of their knowledge. In this way, we guarantee that P will, after a finite time, be able to enter its critical section *cs(1)*.

The process and communication mechanism displayed in figure 5 for one process P, for entering one of its critical sections *cs(1)*, looks fairly straightforward because it is supposed only to give an idea about the two separate steps of communication needed for P to leave one section and enter the next, respectively. As usual for mutual exclusion problems, the correctness proof is not straightforward, even in the special case of only one critical section per process. It is not easy to see that no process can take advantage of a neighbor through a locking influence. The scheme in figure 5 is



Entering section p from section p'
p = remainder section?
yes
no
p = rg?
yes
send broadcast messages for finding R1,...,Rn
can p' be left? (communication with R1...Rn)
yes
no
wait until involved Rj permit to leave p'
p = cli?
yes
no
p free?
no
yes
wait until message "p is free"
notify involved Rj about entering p/ leaving p'
play game for entering p
wait for acknowledgement
no
won?
yes
p' → p

Figure 5
Critical Section entrance behavior of Process P

the same for cases of multiple critical sections with varying sets and kinds of requested resources. In order to verify this modularity of our design approach, it has been proven [14] that the mechanisms implemented for each critical section do not "interfere". More technical details about the implemented general algorithm and the game, can be found in the appendix.

## 6. Discussion and Future Work

We have briefly described some main features of the DRAGON SLAYER operating system. It allows fully distributed control of interacting and competing processes, without central control and without use of distributed relics of central control such as distributed name tables, group identifiers or multigroup identifiers. Through implementation, we have demonstrated the viability of our construction. The DRAGON SLAYER design principles feature novel aspects. Under completely decentralized control we use broadcast messages as universal communication primitives, and for resource scheduling we implemented a general and fair distributed algorithm.

Broadcast messaging is a necessary function to avoid use of central control for establishment of direct communication between processes. Rather than multicast, broadcast messaging was incorporated in DRAGON SLAYER and provides a means for any process to communicate with all other processes without invoking the operating system as a message filter. In a single broadcast network like ours, the network load for broadcast is the same as for multicast messaging. Under our scheme, the operating system need not maintain any tables with information regarding resident processes. Admittedly, the use of broadcast messages requires that all processes be awakened so that they may actively ignore broadcast messages. On the other hand, the use of multicast messages requires that the operating system be aware of all local elements of all multicast groups introducing a kind of centralized control. We have avoided the use of such distributed lists in our system.

A major focus of our current experimentation is on distributed vision applications: distributed scene analysis with moving objects to be located and identified, like in the Autonomous Land Vehicle project (DoD) or in factory-of-the-future environments. In such distributed applications, the amount of local computation is much higher than the amount of communication. Since broadcast messaging in DRAGON SLAYER only occurs when a process locates the resources needed, we can benefit from the high amount of process autonomy without being impacted by the broadcast costs. Currently, we are performing comparative studies using sequential and parallel versions of algorithms for canonical vision tasks – static object location and measurement of their features – as a benchmark test for our network performance. We compare up to 4 processors under

DRAGON SLAYER against a VAX 11/780. Similarly to the results reported in [13], our first results give evidence that the speedup resulting from the parallelization more than outweighs the relatively modest computational power of our micro-computers. A performance of a mid-size computer can be reached or surpassed at minimal hardware and software expense. While the parallel algorithms used for the benchmark tests could easily be realized in hardware, because of the primitivity and repetitivity of the used operations we envision a major practical benefit of our system for dynamic scene analysis, with moving objects and objects coming into, or leaving, a frame. In this application, higher-level software operations would typically be distributed into partitioned search tasks.

The scheduling algorithm we use results from solving a conceptual problem. The existence of such a general algorithm was investigated by using formal tools, within the Theory of Interaction Systems [11,18]. Our results easily allowed specification of another distributed algorithm for the same purpose, but without use of resource managers [14,15]. Recently another such algorithm, also not using resource managers, was found independently [5]. It uses the same idea of local precedence changes as found in [19].

In our implementation, time-out mechanisms prevent processes from being blocked in a situation where a node with resources dedicated to such processes breaks down during performance of its task. In case of such a node failure or link failure, the requesting process will make another request for the desired resources. Through our formal specification method, as an extended fairness requirement for which the proof can be found in [14], a process registered for accessing resources will eventually get them (maybe after several attempts) as long as such resources are available anywhere in the system. Thus, DRAGON SLAYER exhibits an unsurpassed degree of *robustness*, due to the complete lack of centralized control functions. Future research is targeted towards fault tolerance, data integrity, and error recovery at user levels, in the presence of faulty nodes.

Our development provides the basis for innovative forms of distributed real-time processing with peer authority at every node and cheap, long-distance communication, through the envisioned progress in fiber optics technology. Such developments are under discussion in the vendor industry [3]. In order to provide for high-level real-time applications of distributed microprocessor networks a really distributed compiler for a CSP-like language has been developed in Milan/ Italy [4]. It is now in the phase of becoming an industrial product (Olivetti). We are cooperating with this group to implement it on DRAGON SLAYER, as a first step into office automation applications. Another direction for distributed real-time applications research with the DRAGON SLAYER system, then running on a 68000-based network with Ethernet at Wayne State University, is to support a project in real-time, multi-layer distributed production control with distributed information management (factory-of-the-future).

## Appendix

The DRAGON SLAYER resource scheduling algorithm resulted from an exciting discussion about Dijkstra's Dining Philosophers years ago: In 1979, one of the authors was asked to study Dijkstra's most recent contribution to the theme of fair scheduling of distributed processes [8] which turned out not to be fair without substantial assumptions on centralized control. Using the Theory of Interaction Systems, a specification and analysis tool for distributed systems [11,14,18], a starvation-free solution for Dijkstra's generalized distributed process scheduling problem was developed in an **incremental** procedure and proven correct. The main idea behind the formal construction was a suitable enhancement method for any deadlock-free realization of mutual exclusion without central control. Given such an algorithm one could immediately write down a starvation-free or fair distributed algorithm. J. Winkowski presented such an algorithm in 1981 [19] and no problem remained.

Winkowski's algorithm, besides being based on explicit message passing, was the first to make no assumption on boundedness of "hungry" periods (called registration *rg* phases in section 5). In its main outline, the algorithm works as follows:

Each process is assumed to have just one critical section which may be periodically visited. Each process p, at a time when it wants to enter its critical section, needs a set A(p) of resources. In order to make the requests, p sends visiting cards to the resource/server processes in A(p). The requesting processes have a local priority list which contains priority information with respect to neighbor processes, i.e. processes also possibly requesting resources in A(p). The resource processes have queues for storing visiting cards and store the information about the local priorities obtained from their clients. In order to have coherent information, it is assumed that *initially* all local priorities are projections of a global precedence relation. (This is easily achieved in DRAGON SLAYER by using the processor, segment and offset numbers of the requesting processes.)

The algorithm is a game in which a process wins iff it succeeds in having all visiting cards in the top position of each resource queue in A(p).

If p is interested in accessing its critical section, it sends visiting cards while the following conditions hold:

-There are no winning cards of the neighbor players in resource queues.
-There are no visiting cards in resource queues from players with higher priority. P's card in such a queue already preceeds such a card.

P is to stop leaving cards and collect or take back already placed cards when one of the following situations occurs:

-A winning card from another player appears at a resource in A(p).
-A card from another player with a higher local priority is in the resource list before p has succeeded in getting its card enqueued.

After P wins and the other competing processes have removed their cards from the resource lists, p accesses its critical section. Then P reverses all its local priorities and notifies the resource processes which in turn notify p's neighbors in order to cause the corresponding changes. Then p releases the resources. The key idea of the algorithm is that all local priority lists, through the indicated local operations, can still be understood as local projections of a (changed) global precedence relation. No deadlock would occur in the game since one of the competing processes always wins.

The extension of this algorithm into a starvation-free one is constructed by using the Theory of Interaction Systems. The detail of this construction is available in [18]. The main idea is as follows:

The formal objects corresponding to distributed processes are called **parts**, their relevant sections are called **phases**. Two formal relations between phases of different parts are used as primitives to define any kind of interaction or cooperation between distributed processes: a **coupling relation** specifying mutual exclusion of process states, and an **excitement relation** defining basic asymmetric forms of influence between processes.

A concept of global state and of (formal) operational semantics is then developed without making any reference to global time, purely using local information such as local states or phases, process steps or local events. Entering a next phase is **possible** unless specified mutual exclusion requirements would be violated. In Dijkstra's original Dining Philosophers' Problem the 5 philosophers involved had a critical section ("eating") and a remainder section ("thinking"). Figure 6 shows a corresponding Interaction Systems representation in which all events in the remainder sections are possible and where section *e* can be entered only if **both** neighbors do not have access to their sections *e*. Thus figure 6 is a formal framework for a deadlock-free algorithm.

The excitement relations specify asymmetrical local influences from one part to another. If a part b(1), being in phase p(1), excites b(2), being in phase p(2), then b(1) cannot leave p(1) unless b(2) has not left p(2). The effect on b(2) is described by axioms which account for the absence of any form of global control or management. For an elementary example, consider a process P, being in section *r*, which requests a resource R: P cannot leave *r* until R has been allocated to P. The request triggers service processes through which the global resource manager, or supervisor in a conventional environment would eventually make the requested resource available.

This formal theory, though unconventional, has been proven to be a powerful and flexible modeling and analysis instrument for distributed systems [11,14,16,17,18]. In [18] it was used to construct, in an incremental procedure, an easy extension for the solution in figure 6 such that *gradually* all conflicting requirements of the problem were satisfied. The result is shown in figure 7. It has been proven that given the same interaction specification between neighbors in an arbitrary topology, the resulting formal system specifies a fair or starvation-free solution for Dijkstra's generalized resource scheduling problem. The flow diagram in figure 5 is then an immediate translation of this formal specification into an algorithmic one.

In general, processes may have several critical sections, with varying numbers, and different kinds, of resources requested. They also may die or be newly generated. The major advantage of our formal specification method is that it allows for an easy proof of the fact that communication mechanisms constructed for two different critical section problems, with an appropriate formal specification similar to that in figure 7, do not interfere. (The technical details can be found in [14].) Thus, the final general distributed resource scheduling algorithm can, in a modular way, be composed through iterating distributed procedures each of which solves a single section problem and which was a result of directly breaking down a formal specification, after formally proving its correctness.

# PROGRAMMING SOLUTIONS TO THE ALGORITHM CONTRACTION PROBLEM

Philip A. Nelson, Lawrence Snyder

## Abstract

Algorithms for the parallel solution of problems are usually designed assuming an unlimited number of processors. Physical parallel machines have a fixed number of processors. The algorithm contraction problem arises when an algorithm requires more processors than are available on the physical machine. We present tools for comparing algorithm contractions based on bottle neck communication paths. We apply these tools to minimum, matrix product and sorting.

## Introduction

Algorithms for parallel computers are usually designed assuming an unlimited number of processors. For non-shared memory parallel algorithms, this assumption generally manifests itself by the algorithm utilizing one processor "per point", or some other input size-dependent processor allocation. The physical machine has only a fixed number of processors, of course, which will almost certainly be less than the number required by the algorithm. In order to make the logical processes of the algorithm conform to the physical processors of the machine, we must group processes together into a module to be executed on a single physical machine. This activity is called *contraction*[13]. The way this contraction is performed can have a significant affect on performance.

Consider two examples based on an grid $n \times n$ of processes, *i.e.* the processes communicate with their four nearest neighbors:

(1) There is much process-to-process communication and approximately equal computation required of each process.

(2) There is little process-to-process communication and the amount of computation per process is proportional to its $j$ index, *e.g.* process $i,j$ iterates $j$ times.

Suppose we have only one fourth the required number of processors and now compare two ways of forming contractions of four processes per processor[4]: *Coalescing* groups of adjacent 2×2 subarrays; *folding* groups as if the grid is folded in half and then in half again, *i.e.* $i,j$ $(1 \le i,j \le \frac{n}{2})$ is associated with $i,n-j+1$, $n-i+1,j$ and $n-i+1,n-j+1$. Clearly, algorithm (1) should be contracted by coalescing because the process-to-process communication for the processes sharing the same processor will become intraprocessor communications (*i.e.* fast memory references) rather than slow interprocessor communication; folding would not be as attractive because no communication is saved by locality. Alternatively, algorithm (2) should be contracted by folding because the work is balanced since each processor will perform a matching amount of long and short computations; coalescing would not be as attractive because the processors receiving processes with large indexes will become a bottleneck.

Using the results of Berman and her colleagues[3], an algorithm can be be automatically contracted, and this seems to be the best approach when nothing is known about the algorithm. At the other end of the spectrum, however, the programmer has "complete" knowledge about the algorithm. How should he be guided when performing his own contraction? In this paper we develop some apparatus to guide the programmer who must contract an algorithm. We will provide some case studies of contraction that show an unexpected diversity and we offer some general contraction strategies that can find application in other algorithms. Contraction is a nontrivial problem for parallel programmers[13], and so a secondary goal here is to expose it as an important topic for study and a subject suitable for rigorous analysis.

## Definitions

The generic parallel architecture under consideration in this paper is a non-shared memory model. It is a collection of homogeneous sequential computers operating asynchronously and connected in a communication network that is a bounded degree graph[13]. A single "edge" in the graph provides bidirectional communication between two processors. The CHiP[11] architecture is an example of this generic architecture.

The method used for programming this model consists of defining a sequential program for each processor and a communication graph. We are assuming a configurable architecture. (The problem of mapping a communications graph onto a different processor connection graph is discussed by Berman and Snyder[4] and Bokhari[5].) Communication is explicitly shown in the sequential code by specifying a data value to be sent to the processor connected by a given edge.

The algorithm contraction problem arises when an algorithm that is designed for use on $n$ processors must be mapped to a physical parallel computer with only $p < n$ processors. The programmer must decide which logical processes are to be mapped to the physical processors. Assuming that the logical processes have balanced loads (they run for the same length of time), we would like the physical processors to have balanced loads. This is done by mapping the same number of logical processes to each physical processor. The number of logical processes assigned to two arbitrary physical processors should differ by at most an additive constant $c$. For most contractions, it would be best to have $c=1$.

The contraction induces a communication graph for the $p$ physical processors. This new graph is defined by logical processes needing to communicate with other logical processes not mapped to the same physical processor. We assume that if a logical process in processor $i$ needs to communicate with a logical process in processor $j$, there is a physical edge connecting the two processors in the new graph. The contraction may map many of these logical edges to one physical edge in the new graph. That is, we are allowing only one edge between physical processors. Under the assumption of a bounded degree graph for the generic architecture, this induced graph must also be of bounded degree.

As an example of contraction, let us assume we have an algorithm with a tree graph. Consider the contraction to 5 processors shown in Figure 1. This contraction caused an increase in the degree; for example, the new root vertex has four descendants. Using this kind of a contraction, it can be shown that given $p$ processors, contracting an algorithm with at least $p^2$ logical processes requires degree $p-1$. Figure 2a shows a contraction of the tree to 4 processors. An extension of this method yields a binary tree in the $p$ processors.

Figure 2b gives another contraction to 4 processors. This contraction is derived by the recursive tree construction given by Leiserson[9]. Given two instances of a tree each with an associated free node, we can build a new tree and an associated free node. This produces a linear area layout in the plane with several desirable properties, one of which is the constant number of external edges.

In this paper, we will be considering the contribution of the communication time to the performance of the contracted algorithm. Unless otherwise stated, we assume that a communication between processing elements costs a fixed time $t_c$. During this time, no other communication in

the same direction may take place. We are specifically allowing all edges to have simultaneous communication. Communication internal to a processor costs the fixed time $t_i$. We also assume that $t_c \gg t_i$.

We would like to develop tools for reasoning about the relative merits of different contractions. This includes their communication costs and their execution times. To aid in this objective we give the following definitions.

Let $A=(V,E)$ be an algorithm where $V$ is a set of logical processes ( vertices and associated programs ) and $|V|=n$, $E$ is a set of edges $(V_1,V_2)$, $V_1,V_2 \in V$.

Let $M(A,p)=B$ be a contraction of algorithm $A$ into algorithm $B$ where $B$ uses $p$ processors and $p < |V_A|$. The contraction $M$ maps elements of $V_A$ onto $V_B$ such that the number of elements of $V_A$ mapped to an arbitrary element of $V_B$ differs by no more one from the number of elements of $V_A$ mapped to any other element of $V_B$.

Let $w(e)$, the weight of $e$, for $e=(V_1,V_2)$, be the larger of the number of messages from $V_1$ to $V_2$ and the number of messages from $V_2$ to $V_1$.

Let $K(A) = \underset{e}{MAX}\, w(e)$, for $e \in E$, be the communication "cost" of A. This cost is an estimate of the minimum communication time required for the algorithm. Due to dependancies, the actual communication cost may be more.

Let $T(A)$ be the execution time for $A$.

**PROPOSITION 1:** For a given $A$, $p$, $M_1$, and $M_2$, and $t_c > t_i$, if $K(M_1(A,p)) < K(M_2(A,p))$ then $T(M_1(A,p)) \le T(M_2(A,p))$.

This proposition is formalizing the notion that the bottleneck edge will be a lower bound on the time required for the execution of the mapped algorithm. If the processors have a small amount of computation relative to the communication, the execution time will depend on the communication time. The bottleneck edge of the contraction $M_1$ will require a minimum of $t_c K(M_1(A,p))$ time, which is less than $t_c K(M_2(A,p))$. With a higher minimum communication time, we can not expect $M_2$ to execute in less time than $M_1$. If the processors have a large amount of computation in ratio to the communication, the computation time will dominate, yielding near equal times. Even in this case, $M_1$ uses less time for communication than $M_2$. This proposition then motivates us to map the busiest edges of an algorithm to internal edges.

## Case Studies

We now look at several parallel algorithms and some contractions. We approach these by considering algorithms with similar communication graphs. The three graphs considered are the tree, grid, and binary n-cube.

### Tree algorithms

There are several algorithms that run on complete binary trees (Figure 1) having similar characteristics, like the aggregation operations of minimum and global sum. All processors have a value and we want to compute a global value that depends on all these values. Leaf processors send their value to their parents. Internal processors take the minimum (sums) of their own value and their children's values and then send the result to their parents. The final value will be computed at the root processor in $O(\log n)$ time. The communication in these algorithms requires one message over each edge for each global minimum (sum). For a single minimum we have $K(minimum) = 1$.

Consider the contraction in Figure 2a. Let us call this contraction $M_1(minimum,p)$. Each edge in the original algorithm requires one message. Each edge in the smaller graph has 4 edges from the original graph. Since we have only one connection between the physical processors, we have 4 messages for each edge. For an arbitrary $n$ (size of original algorithm) and $p$ (the number of processors) we have $K(M_1(minimum,p)) = \frac{n}{p}$.

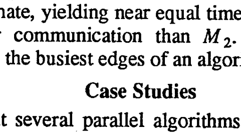

Figure 3: Berman and Snyder tree contraction.

A similar contraction to Figure 2a is touched on by Berman and Snyder[4]. Figure 3 shows this contraction. This is achieved by "folding" the tree. As Berman and Snyder notice, this contraction, $M_2$, has $K(M_2(minimum,p)) = \frac{n}{p}$.

Consider the contraction in Figure 2b. Let us call this contraction $M_3(minimum,p)$. We note that each edge in the smaller graph has at most one edge from the original graph in each direction. For an arbitrary $n$ and $p$ we have $K(M_3(minimum,p)) = 1$.

Proposition 1 tells us that since $M_3$ has a smaller $K$, it is the preferrable contraction. Both $M_1$ and $M_2$ depend on $n$ and $p$ for their cost. But, $M_3$ has a constant cost, regardless of $n$ and $p$. In fact, this contraction is optimum for all tree algorithms that have identical edge weights and unidirectional communication (all toward the root or all toward the leaves).

We first look for a lower bound. Since the tree is connected, the physical processors must be connected. This requires at least one incident edge for each physical processor. The smallest cost $K(M(A,p))$ would be where a maximum of one logical edge was mapped to a physical edge. Therefore, $K(M(A,p)) \ge K(A)$, the cost of the original algorithm.

**LEMMA 2:** For complete binary tree algorithms with balanced processor loads, equal edge weights, and unidirectional communication, algorithm contraction based on Leiserson's binary tree layout technique yields optimum results.

**PROOF:** For the mapping $M_3(A,p)$, each processor contains a complete subtree and an "extra" node. The extra nodes are used in the tree above the subtrees contained in the processors. Therefore, there at most 4 external connections. Of these four, two edges are used to receive(send) data from(to) the children of the extra node, and two edges are used to send(receive) data to(from) the subtree's and the extra node's parents. Since the root of the subtree and the extra node are not at the same level in the tree, edges with data flowing in the same direction can not be connected to the same physical processor. (It is possible to have two of these edges over the same physical edge, but the data moves in opposite directions.) This gives the same weight to the physical edges as the original edges. Therefore, $K(M_3(A,p)) = K(A)$, which is the lower bound. □

Notice that this layout technique will place two logical edges in the same physicial edge for some physical edge. For tree algorithms with bidirectional communication, we then get $K(M_3(A,p)) = 2K(A)$.

To help verify these results, the minimum algorithm was programmed using the Poker parallel programming environment[12]. Both $M_1$ and $M_3$ were programmed. Each contraction was timed using 4 and 16 data items per processor with 4 and 16 processors. The results of these timings are given in Table 1. Each "tick" represents a mircosecond on the 64 processor Pringle.

### Grid algorithms

We next look at algorithms that run on a grid interconnection. Consider the matrix product algorithm for the Wavefront Array Processor(WAP)[8]. It uses $n^2$ processors for the $n \times n$ matrix product $AB = C$. The data is fed in along the top $n$ processors and from the left $n$ processors. The matrix $A$ is arranged to enter column by column, starting with the first column. The matrix $B$ is arranged to enter row by row, starting with the first row. (See Figure 4.) All processors execute identical procedures. The result, $c_{ij}$, is initialized to zero. A loop is executed $n$ times that reads an $A$ value from the left and a $B$ value from above, multiplies them together, and adds the result to $c_{ij}$. The $A$ and $B$ values are sent to the right and down, respectively. This causes the upper left processor to be the first processor to start execution. As the data moves into the array, there is a wavefront of executing processors on the cross diagonal. Each edge is used to send all of one row of $A$ or one column of $B$. For the WAP algorithm we have $K(WAP) = n$.

Consider the contraction in Figure 5. Let us call this contraction $M_1(WAP,p)$. This is the contraction done by cutting the graph into $p$ equal size connected subgraphs and assigning one process from each subgraph selected from corresponding positions to a single processor. The

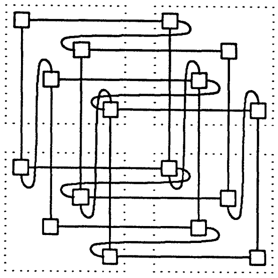

Figure 5: A contraction of 16 logical processes to 4 processors.

physical connection graph, shown in Figure 5, is a grid with end around (i.e. toroidal) connections. For each logical process in a physical processor, there are horizontal and vertical communication paths. Since we have $\frac{n^2}{p}$ logical processes in a processor, the number of logical edges using one processor-to-processor connection is $\frac{n^2}{p}$. Since all horizontal and vertical edges have the same number of messages, $n$, we have $K(M_1(WAP,p)) = \frac{n^3}{p}$.

Consider the contraction in Figure 6. Let us call this contraction $M_2(WAP,p)$. This is the contraction done by cutting the graph into $p$ equal size connected subgraphs and assigning an entire subgraph to a processor. We see that only the perimeter processes have edges that go from processor-to-processor. Also, notice that no end around connections are needed. The number of communication paths over one processor-to-processor connection is $\sqrt{\frac{n^2}{p}}$. Each communication path requires $n$ messages giving $K(M_2(WAP,p)) = \frac{n^2}{\sqrt{p}}$.

Comparing the two contractions, we see that $K(M_2(WAP,p))$ is smaller than $K(M_1(WAP,p))$ by a factor of $\frac{n}{\sqrt{p}}$. Proposition 1 tells us that $M_2$ is the better contraction. We conjecture that $M_2$ is the best contraction that can be achieved for grid algorithms. The basis for this conjecture is that this contraction has the smallest perimeter for a given area, and has been commonly used for contraction in published algorithms, for example for the Jacobi iterative method[1] and for the conjugate gradient method[6].

Both $M_1$ and $M_2$ were programmed using Poker. Table 2 summarizes the results of the timings. As predicted, $M_2$ was the faster contraction, but because the communication time is not the only time consuming part in these algorithms the difference is perhaps not as dramatic as might be seen on a larger problem.

**Binary n-cube algorithms**

We now look at two algorithms for the binary n-cube. The first algorithm is the divide-and-conquer algorithm for matrix product given by Nelson[10]. The other algorithm is Batcher's bitonic sorting algorithm[2].

The matrix product algorithm takes two $n \times n$ matrices, $A$, and $B$, and computes their product $C = AB$. $A$ and $B$ are assumed to be in row major order in the binary n-cube of order $2k$, where $k = \log n$. The algorithm views $A$ and $B$ as a 2x2 matrix of $\frac{n}{2} \times \frac{n}{2}$ matrices. The 2x2 matrix algorithm is then used to multiply the submatrices. Figure 7 shows a order 4 cube layed out in the plane using the CHiP architecture. The numbers in the boxes show the index of the matrix elements initially contained in that processor. We are assuming that the processors are numbered in row major order. The dotted boxes show cubes of order 2. These cubes, which generally have order $2(k-1)$ contain an $\frac{n}{2} \times \frac{n}{2}$ submatrix of both $A$ and $B$. Note that these cubes are constructed by "removing" the edges of order $k$ and $2k$, where and edge of order $k$ connects processors that are $2^{(k-1)}$ distance apart.

To compute the 2x2 matrix product, all processors exchange values of $B$ on the order $2k$ edge and values of $A$ on the order $k$ edge. After the exchange, each cube of order $2(k-1)$ contains 4 submatrices of size $\frac{n}{2} \times \frac{n}{2}$. This is all the data that is required for each cube of order $2(k-1)$ to compute its part of the 2x2 matrix product independantly. If the submatrix is not a single element, two matrix products of $\frac{n}{2} \times \frac{n}{2}$ matrices are required. These matrix products are done using the same algorithm. Matrix addition is done element by element. Because corresponding elements of the matrices are contained in the same processor, no communication is required.

To find the cost of this cube matrix multiply, $K(CMM)$, we need to find the edge with the most messages. At the first level of recursion, the order $k$ and $2k$ edges were used to send a message each way. This is the only use of these edges in the algorithm. Therefore, $w(e) = 1$, where $e$ is a order $k$ or $2k$ edge. At the second level of recursion, two matrix products are computed using the order $k-1$ and $2k-1$ edges. Each matrix product sends one message each way on each edge giving $w(e) = 2$, where $e$ is a order $k-1$ or $2k-1$ edge. At level $l$ of the recursion, $w(e) = 2^{l-1}$ messages over the order $k-(l-1)$ and $2k-(l-1)$ edges. The recursion stops when we have order 2 cubes. This is at the $\log n$ level of recursion. There are $\frac{n}{2}$ matrix multiplies done by order 2 cubes. These

| $M_1$ | 48854 | 111478 | 400452 | 901543 |
| $M_2$ | 31113 | 73088 | 221545 | 707646 |

Table 2: Timings of the WAP matrix multiply algorithm.

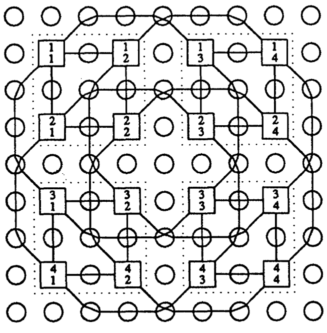

Figure 7: An order 4 binary n-cube.

order 2 cubes use the order 1 and $k+1$ edges. Each matrix multiply sends 1 message each way giving $w(e) = \frac{n}{2}$, where $e$ is a order 1 or $k+1$ edge. Since this is the largest value, $K(CMM) = \frac{n}{2}$.

Consider any contraction, $M(CMM,p)$ where $p = 2^m$ for some $m \leq 2k$. $M(CMM,p)$ will map $\frac{n^2}{p}$ logical processes to every processor. This allows us to put a cube of order $\log \left\lceil \frac{n^2}{p} \right\rceil = 2k-m$ into each processor. The processor-to-processor connection graph is also a cube and is of order $m$. Each processor-to-processor connection supports $\frac{n^2}{p}$ communication paths in the original graph. The real question is which sub-cube do we map to each processor. The cost of the contraction, $K(M(CMM,p))$ will be $\frac{n^2}{p}$ times the maximum $w(e)$, where $e$ is mapped to a physical edge. If $e$ is order 1 or $2k+1$ from the original cube, $K(M(CMM,p)) = \frac{n^3}{2p}$.

Consider the contraction that maps the edges of order 1 through $\left\lfloor \frac{2k-m}{2} \right\rfloor$ and order $k+1$ through $k+\left\lfloor \frac{2k-m}{2} \right\rfloor$ into internal edges. This makes the edge of order $k+\left\lfloor \frac{2k-m}{2} \right\rfloor+1$ the edge with the most messages. This edge is used by level $k-\left\lfloor \frac{2k-m}{2} \right\rfloor$ of the recursion. From before we know that $w(e) = 2^{k-\left\lfloor \frac{2k-m}{2} \right\rfloor-1} = \frac{\sqrt{p}}{2}$. Therefore $K(M(CMM,p)) = \frac{n^2\sqrt{p}}{2p}$. Clearly, this contraction is better in terms of the number of messages over the busiest physical edge than any contraction that does not keep the high traffic logical edges internal to a processor.

By contrast, let us consider the Batcher bitonic merge sort. This sort runs on a order $k$ cube to sort $n = 2^k$ elements. The final sorting will have the smallest element in the first processor and the largest element in the last processor. Figure 8 shows a graphical representation of the algorithm. The arrows represent a data exchange and a compare, leaving the larger number at the end with the arrow and the smaller at the other end. It is obvious from the figure that the order 1 edge has the most messages. Therefore, $K(SORT) = \log n$.

Again, to contract this algorithm, we see that we want to assign a sub-cube into a processor. Consider the contraction $M(SORT,p)$ where the edges of order 1 through order $\log p$ are mapped to internal edges. We are assuming that $p = 2^m$, for some $m \leq \log n$. This contraction assigns the busiest logical edges to be internal edges. These edges carry $\log n - \log p$ messages. Since each processor contains $\frac{n}{p}$ logical processors, $K(M(SORT,p)) = \frac{n(\log n - \log p)}{p}$. Any contraction that does not map these first $\log p$ edges to internal edges will have a higher communication cost. These results agree with and explain the results of Hsiao[7], even though his final algorithm was embedded in a grid instead of another cube.

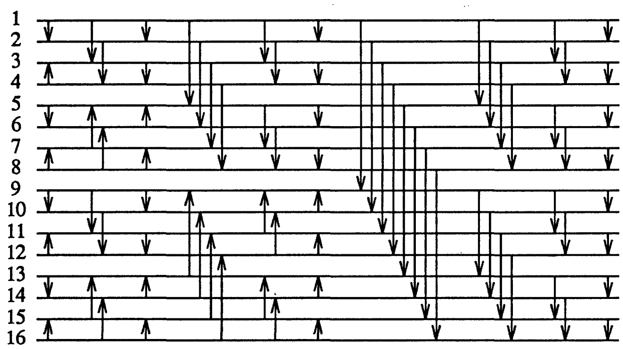

Figure 8: Batcher's bitonic merge sort.

In comparing the contractions for matrix multiply and Batcher's sort, we see that the same size cube is mapped in a different way when mapped to the same number of processors. The busiest edges are different for the two algorithms, thus, the contractions are different.

## Conclusion

The algorithm contraction problem is an important problem for parallel programmers. The way in which an algorithm is contracted can have a significant affect on performance. Processor-to-processor communication can be used as a lower bound on the execution time for an algorithm. It is the processor-to-processor communication that is affected by different contractions.

We have looked at algorithms for the tree, grid, and binary n-cube interconnections. For each algorithm we have compared possible contractions of these algorithms. For trees, we proved that Leiserson's layout technique was the best for contracting tree algorithms such as minimum and sums. For grid algorithms, we conjectured that coalescing by maximizing the area for a given perimeter is optimal for the algorithms with balanced edge loadings. Finally, we showed two algorithms for binary n-cubes that required different contractions to produce the optimal results for the algorithm.

**Abstract:** Convolution is a basic operation of linear systems theory, and 2-D convolution is a frequently used operation in image processing. However, 2-D convolution is computationally intensive. For an $N$ by $N$ search area and an $M$ and $M$ window, the time complexity of a serial algorithm is $O(N^2M^2)$. This paper presents several parallel convolution algorithms for array processors with $N^2$ processing elements connected by various communication networks. By using inter-PE communication networks efficiently, each PE requires only a small local memory, many unnecessary data transmissions are eliminated, and the time complexity is reduced to $O(M^2)$.

## I. INTRODUCTION

Great efforts have been devoted to developing parallel processing architectures and associated algorithms for many popular mathematical operations [DuLe81, FuIc82, HwFu83, LiNi85, NiHw85, NiJa85]. *Convolution* is a very important operation in linear systems theory and image processing. The convolution of two functions **G** and **W** is a function $C$ of a displacement $y$ defined as

$$C(y) = \int \mathbf{G}(x)\mathbf{W}(x-y)dx.$$

We generalize it to the following form:

$$C(y) = \Omega[\mathbf{G}(x)\bullet\mathbf{W}(x-y)],$$

where $\bullet$ is a binary operator, which could be a multiplication (*), addition (+), inf, logical AND, etc.; and $\Omega$ is a function defined on all values of $[\mathbf{G}(x)\bullet\mathbf{W}(x-y)]$ over the entire region of $x$. $\Omega$ could be an integration (continuous case), summation (discrete case), sup, or maximum.

In two dimensions, one function is "rubbed over" the other [Ball82]. The value of the convolution at any displacement can be defined as the following general form:

$$C(i,j) = \Psi\Phi[\mathbf{G}(i+s,j+t)\bullet\mathbf{W}(s,t)]$$

where $\Phi$ is a function defined over the region of $t$, and $\Psi$ is a function defined over the region of $s$. In the finite discrete case, **G** is defined on a square grid array of size $N^2$ as

$$\mathbf{G} = \left\{ G_{ij} | i,j \in [0,N-1] \right\},$$

and **W** is defined on a finite rectangular grid of size $M$ by $M'$ $(M,M' < N)$,

$$\mathbf{W} = \left\{ W_{st} | s \in [0,M-1], t \in [0,M'-1] \right\}.$$

Hence, the 2-D digital convolution of **G** and **W** can be defined as:

$$C_{ij} = \sum_{s=0}^{M-1}\sum_{t=0}^{M'-1} G_{i+s,j+t} * W_{st}. \tag{1}$$

Equation (1) is also called *image correlation* or *image template matching.*

Many other applications, such as *object labeling* including fuzzy model, discrete model, and linear stochastic model and *morphological operations* including dilation and erosion, also require some forms of 2-D convolution. Their difference lies on the different choices of $\Psi$, $\Phi$, and $\bullet$ functions. For example, the linear stochastic model for object labeling in computer vision requires the computation of the probability that a label $y$ fits object $x$. Let $W_{st}$ denote the probability that label $t$ fits object $s$. Also let $G_{st}$ denote the conditional probability that label $y$ fits object $x$ given that $t$ is the correct label for object $s$. Then the probability that $y$ is the correct label for object $x$ of the $(k+1)th$ iteration is

$$C(i,j) = \Psi\Phi[\mathbf{G}(i+s,j+t)\bullet\mathbf{W}(s,t)],$$

where $i=j=0$, $\bullet$ defines a multiplication, $\Phi$ defines a summation over the range of $t$, and $\Psi$ defines a weighted summation over $s$ with weighting factors $\beta_{xs}$ for different values of $s$. That is,

$$\mathbf{W}^{(k+1)}(x,y) = \sum_s \beta_{xs} [\sum_t [\mathbf{G}(x,y;s,t) * \mathbf{W}^{(k)}(s,t)]],$$

or in a more familiar form [RoHB76]:

$$P_x^{(k+1)}(\lambda_y) = \sum_s c_{xs} [\sum_t [P_{xs}(\lambda_y|\lambda_t)P_s^{(k)}(\lambda_t)]].$$

We are concerned with the communication complexity of 2-D convolutions. Various definitions of $\Psi$, $\Phi$, and $\bullet$ only affect the computational complexity. Equation (1) will be used as a representative case to indicate the computational requirement for a wide variety of window-based image processing tasks. **G** is called the *search area* and **W** is called a *window.* 2-D digital convolution is used to find *sub-search-areas* (*subareas*) from **G** that match closely with **W**. For convenience, each $M$ by $M'$ subarea of **G** can be uniquely referenced by its upper left corner coordinate $(i,j)$. Let $SUB(i,j)$ denote the subarea at location $(i,j)$. There are $(N-M+1)(N-M'+1)$ such subareas for $i \in [0,N-M]$ and $j \in [0,N-M']$ as shown in Fig.1.

The window **W** is matched against every subarea $SUB(i,j)$ in **G**; and the convolution $C_{ij}$ is computed as the *proximity measure* between **W** and each subarea $SUB(i,j)$. This measure is also called *non-normalized correlation*, or cross correlation. The *normalized correlation* is discussed in Section VII. To simplify the discussion, we assume that $M=M'$ and $M$ is a power of 2. We also assume the cross correlation $C_{ij}$ is used. In Section IV, we discuss the general case for array processors where $M \neq M'$ and $M$ is not necessary to be power of 2.

During the convolution computation of all displacements, $(N-M+1)(N-M'+1)$ similarity values are generated, and one of

† This work was supported in part by the DARPA NIMM project

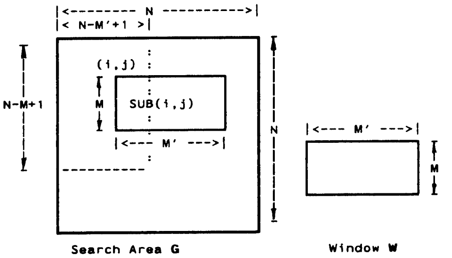

Fig. 1. An $N$ by $N$ search area **G** and an $M$ by $M'$ window **W**

the following results can be obtained:

1. another 2-D array, formed by the similarity values of all subarea locations;
2. all subareas with a similarity which exceeds a given threshold;
3. the subarea with the greatest similarity to a window; and
4. the first subarea whose similarity exceeds a predefined threshold.

Convolution can be used as a simple ***filtering*** method, for which option 1 above is desired. For ***edge detection***, the edge operator is a window and option 2 is produced [FrCh77]. ***Image registration***, or ***scene matching***, is another application of convolution where option 3 or 4 is used [WoHa78].

Our paper discusses parallel algorithms for 2-D convolution, as defined in Eq.(1), on array processors with three different types of interconnection networks. Usually, 2-D convolution operations are extremely time-consuming, involving the time required both to perform the calculations and for communication among the PEs. With a single processor and traditional algorithms, the number of steps for convolution operations is $(N-M+1)(N-M'+1)MM'$, approximately $N^2MM'$ for $M, M' << N$. With multiple processors and parallel processing algorithms, the total time can be significantly reduced. These algorithms can be easily modified for other applications of convolution, such as those listed in Table 1.

Different convolution applications have different computational complexities in their evaluation of different functions $\Phi$, $\Psi$ and $\bullet$. For each application, however, the time complexity of the computation performed in the PEs is exactly the same, regardless of the type of network. It is the time complexity for communication among the PEs that varies widely from network to network. We will compare the communication complexities of three different types of networks, independent of the forms of the functions $\Phi$, $\Psi$ and $\bullet$.

In this paper, parallel algorithms are developed and discussed for 2-D digital convolution on array processors with different types of interconnection networks. Section II introduces a model of an array processor and the three types of interconnection networks. Detailed algorithms for array processors with $N^2$ PEs with a mesh network, a hypercube network, and a shuffle-exchange network are given in Sections III, IV and V, respectively. Section VI provides an explanation of the modifications required to the algorithms for different size of array processors. Section VII discusses the computation of generalized convolution. Section VIII presents our conclusions, including a table comparing the network communication complexities.

## II. MODEL OF AN ARRAY PROCESSOR

An array processor is comprised of $Q=2^q$ processing elements (PEs), each having some local memory [HwBr84]. We assume that the PEs are indexed 0 through $Q-1$ and refer to the $p$th PE as PE($p$). The synchronized PEs execute instructions issued from a control unit. The control unit broadcasts an instruction to all PEs, and all enabled PEs simultaneously execute. the instruction. The enable/disable mask can be used to select a subset of the PEs that are to perform an instruction. The set of enabled PEs can be changed from instruction to instruction.

A network is needed to provide inter-PE communication. While several types of interconnection networks have been proposed [Sieg79], some are topologically equivalent and some are not [WuFe80]. The control transfer algorithm among the equivalent networks has been studied in [Fang84,FaDe85]. Three interconnection networks which are not topologically equivalent are considered in this paper -- the mesh, hypercube, and shuffle-exchange networks.

### Mesh Interconnection Network

In this model, the PEs may be thought of as being physically arranged in a k-dimensional array $A(n_{k-1}, n_{k-2}, \cdots, n_0)$, where $n_i$ is the size of the $i$th dimension and $Q=n_{k-1}*n_{k-2}*\ldots*n_0$. The PE at location $A(p_{k-1},\ldots,p_0)$ is connected to the PEs at locations $A(p_{k-1},\ldots,p_j\pm 1,\ldots,p_0)$, $0\leq j<k$, provided they exist. Data may be transmitted from one PE to another via this interconnection pattern only. The interconnection scheme for 16 PEs with $k=2$ is given in Fig. 2a.

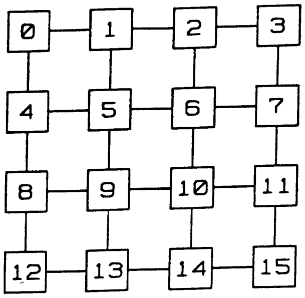

Fig. 2a. A mesh topology with 16 PEs

### Hypercube Interconnection Network

Let $p_{q-1}\ldots p_0$ be the binary representation of $p$, the index of PE($p$), for $p=0,1,\ldots,2^q-1$. Let $p^{(b)}$ be the number with binary representation $p_{q-1}\cdots p_{b+1}\overline{p}_b\, p_{b-1}\cdots p_0$, where $\overline{p}_b$ is the complement of $p_b$ and $0\leq b<q$. In the hypercube model, PE($p$) is directly connected to PE($p^{(b)}$) for $0\leq b<q$. A 4-cube (16 PEs) interconnection network is shown in Fig. 2b. The hypercube has been proposed and used in both SIMD and MIMD computer systems [PrVu79,Seit85].

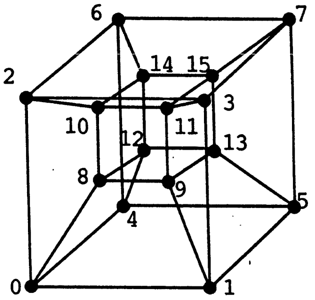

Fig. 2b. A hypercube topology with 16 PEs

### Shuffle-Exchange Interconnection Network

Let $q$, $p$ and $p^{(b)}$ be the same as in the hypercube model. Let $p_{q-1} \cdots p_0$ be the binary representation of $p$. Define SHUFFLE($p$) and UNSHUFFLE($p$) to be the integers with binary representation $p_{q-2}p_{q-3} \cdots p_0 p_{q-1}$ and $p_0 p_{q-1} \cdots p_1$, respectively. In the shuffle-exchange model, PE($p$) is connected to PE($p^{(0)}$), PE(SHUFFLE($p$)) and PE(UNSHUFFLE($p$)). These three connections are called *exchange, shuffle* and *unshuffle*, respectively. Once again, data transmission from one PE to another is possible only via the connection scheme. A shuffle-exchange network of 16 PEs is shown in Fig. 2c.

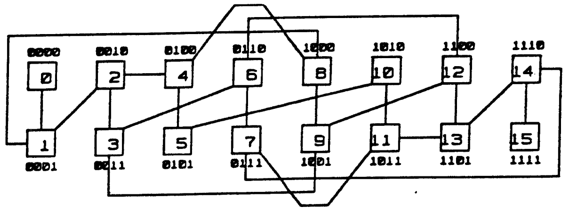

Fig. 2c. A shuffle-exchange topology with 16 PES

It should be noted that the shuffle-exchange model requires at most three connections per PE, while the mesh model requires $2k$ connections per PE, and the hypercube model requires $q$ connections per PE. It should also be emphasized that, in any time instance, only one unit of data can be transmitted along an interconnection line, although all lines can be busy at the same time.

To evaluate the efficiency of parallel algorithms on array processors, one must consider the amount of parallellism that can be exploited in order to fully utilize the large amount of PEs. Such a study on image correlation was conducted in [SiSF82]. In their approach, each PE has a large local memory to handle a number of subimages, and only neighboring pixels need be sent among PEs. In our approach, we use the interconnection networks efficiently to obtain an optimal solution. Each local memory is small, containing only $M$ locations.

In describing our algorithms, we follow the notations and assumptions used in [DeNS81] as stated below. PE($p$) denotes the PE with index $p$. $R(p)$, $A(p)$, $B(p)$, and $C(p)$ are registers in PE($p$). MAR($p$) denotes the local memory address register in PE($p$), and M[MAR($p$)] denotes the local memory location with address in MAR($p$). The symbol "$\leftarrow$" signals an assignment involving data routing between directly connected PEs, while the symbol ":=" indicates an assignment in which all variables in both sides of ":=" are local to the same PE. "$\Leftarrow$" indicates movement involving common data or constants from the control unit memory to the local memories whose address is specified in MAR($p$). For any integer $i$, $i_b$ will denote bit $b$ of the binary representation of $i$, and $i_{s:r}$ will signify the number whose binary representation is $i_s i_{s-1} \dots i_r$. PEs may be enabled by providing a *selectivity function* following a statement. For example, if we want to perform $R(p) := A(p) + B(p)$ for those PEs whose index has bit $b$ equal to 0, the statement will be

$$R(p) := A(p) + B(p),\ (p_b = 0).$$

The communication complexity of an algorithm includes both the time needed to route data from PE to PE, and the time needed to broadcast data from control unit memory to local memories. A *unit-route* is a data transmission from a PE to a directly connected PE. The following unit-route statements will be used in the three interconnection networks in this paper:

(1) In the 2-dimensional mesh model:
$R(p_1-1,p_2) \leftarrow R(p_1,p_2)$ (* go up *);
$R(p_1+1,p_2) \leftarrow R(p_1,p_2)$ (* go down *);
$R(p_1,p_2-1) \leftarrow R(p_1,p_2)$ (* go left *);
$R(p_1,p_2+1) \leftarrow R(p_1,p_2)$ (* go right *).

(2) In the hypercube model:
$R(p^{(b)}) \leftarrow R(p)$ where $0 \leq b < q$.

(3) In the shuffle-exchange model:
$R(p^{(0)}) \leftarrow R(p)$ (* go exchange connection *);
$R(SHUFFLE(p)) \leftarrow R(p)$ (* go shuffle connection *);
$R(UNSHUFFLE(p)) \leftarrow R(p)$ (* go unshuffle connection *).

The above notations will be frequently used in the algorithms in the upcoming sections. The following procedure ROTATE will be extensively used and is demonstrated below. Consider a 2-D search area, $\mathbf{G} = \{G_{ij},\ \text{for } i,j \in [0,N-1]\}$, and an array processor with $Q = 2^q = N^2$ PEs, where the element $G_{ij}$ is stored in register $R(p)$ of PE($p = iN + j$) and $N = 2^n$. For convenience, we may use PE($i,j$) or $R(i,j)$ to denote PE($iN + j$) or $R(iN + j)$. Thus, initially, we have $R(i,j) = G_{ij}$. We may wish to *rotate*, or *end-around shift*, the 2-D search area $2^k$ positions to either

right $(R(i,j) = G_{i,(j-2^k) \bmod N})$,
left $(R(i,j) = G_{i,(j+2^k) \bmod N})$,
up $(R(i,j) = G_{(i+2^k) \bmod N,j})$,
or down $(R(i,j) = G_{(i-2^k) \bmod N,j})$,

for $0 \leq k < n-1$. The rotation procedure for a 2-D mesh machine is straightforward. The procedure to perform a rotate operation in a hypercube array processor is shown below. The rotate procedure for a shuffle-exchange network is explained in Section V. In procedure ROTATE, $s$ indicates the bit position where the bit complement operation begins; $r$ is the bit position where the bit complement ends. Flag is set to 0 for left and up rotate operations; it is set to 1 for right and down rotate operations.

```
procedure ROTATE($R,s,r$,flag);
begin
  $R(p^{(s)}) \leftarrow R(p)$;
  for $b := s+1$ to $r$ do
    if flag=0 then
      $R(p^{(b)}) \leftarrow R(p),\ (p_{b-1}=1\ \&\ \cdots\ \&\ p_s=1)$
    else (* Note that & is a logical AND operator *)
      $R(p^{(b)}) \leftarrow R(p),\ (p_{b-1}=0\ \&\ \cdots\ \&\ p_s=0)$;
end;
```

In the following sections, we shall present detailed convolution algorithms for array processors with three different types of interconnection networks.

## III. MESH MODEL WITH $N^2$ PEs

In this section an $O(M^2)$ convolution algorithm MESH-N2 is developed for a two-dimensional mesh model with $N^2$ PEs, which can handle various sizes of windows. These $N^2$ PEs may be viewed as an $N$ by $N$ 2-D array. We assume that $N=2^n$ and $M=2^m$. Initially, the element $G_{ij}$ is stored in register $A(i,j)$ of PE$(i,j)$ for $i,j \in [0,N-1]$. The $M$ by $M$ window is stored in the control unit memory in column-major order with a starting address $\alpha$. The resulting similarity measures of $C_{ij}$ will be stored in register $C(i,j)$ of each PE.

This algorithm is designed to process one column of the window at a time. For a fixed column $t$, $M$ window elements, $W_{0t}, \cdots, W_{m-1,t}$ will be broadcast to all PEs. Thus, $M$ local memory locations are needed in each PE to hold these elements. If we rotate up the search area **G** one row per step, we can compute a partial sum of $M$ products for a given $t$. Therefore, PE$(i,j)$, which is responsible for evaluating $C_{ij}$, will accumulate the following $M$ products.

$$\sum_{s=0}^{M-1} G_{i+s,j+t} * W_{st} \qquad (2)$$

MESH-N2 matches an $M$ by $M$ window in an $N$ by $N$ search area on a mesh machine with $N^2$ PEs. The initial configuration is $A(i,j) = G_{ij}$.

```
procedure MESH-N2 ($A$, $C$)
begin
  $C(i,j)$ := 0; (*initialization*)
  for $t$ :=0 to $M$-1 do begin
    (*read one window column to local memory*)
    MAR($i,j$) := 0; (*initialize MAR*)
    for $s$ :=0 to $M$-1 do begin
      CMAR := $\alpha+t*M+s$;
      M[MAR($i,j$)] ⇐ CM[CMAR];
      MAR($i,j$) := MAR($i,j$) + 1;
    end; (*end loop $s$ *)
    (*Rotate-multiply-add on the search area segment*)
    MAR($i,j$) := 0;
    $C(i,j)$ := $C(i,j)$+$A(i,j)$*M[MAR($i,j$)];
    (*get first product*)
    for $k$ :=1 to $M$-1 do begin
      $A(i-1,j) \leftarrow A(i,j)$;
      MAR($i,j$) := MAR($i,j$) + 1;
      $C(i,j)$ := $C(i,j)$ + $A(i,j)$*M[MAR($i,j$)];
    end; (*partial summation of $M$ products*)
    for $k$ :=1 to $M$-1 do $A(i+1,j) \leftarrow A(i,j)$;
      (*recover the original value*)
    $A(i,j-1) \leftarrow A(i,j)$;
      (* rotate G left one position *)
  end; (*end loop $t$, process one window column*)
end;
```

Clearly, the communication time complexity of the MESH-N2 algorithm is

$$\sum_{t=0}^{M-1} 3M = 3M^2 = O(M^2)$$

It is trivial to extend MESH-N2 to the general case where either $M \neq M'$ or $M$ is not a power of 2.

## IV. HYPERCUBE MODEL WITH $N^2$ PEs

Now we turn to CUBE-N2, the convolution algorithm for a hypercube array processor with $N^2$ PEs. As with the mesh model, the $M$ by $M$ window is stored in the control unit memory in column-major order with a starting address $\alpha$; and each PE has $M$ locations in the local memory. We logically divide each column of the search area **G** into $N/M$ segments, where each segment has $M$ consecutive elements.

There are four phases involved in order to compute Eq.(2) for a given window column. In phase 1, all $M$ elements of the window column are sent to the local memory of all PEs. These $M$ elements are located in addresses from 0 to $M-1$. In phase 2, we permute the elements within each segment. Then, we multiply the element in register $A$ with the window element, which is stored in local memory. Finally, we add the product to register $C$. These permute-multiply-accumulate (PMA) steps are repeated so that every element of the segment appears exactly once in each position of the segment. Since we only permute elements within the same segment, some positions which need elements from the next segment cannot be satisfied. For instance, the last position of a segment needs $M-1$ elements of **G** from the segment below it. Thus, only half of the products are generated in phase 2 (this will be clear from the later example and discussion).

In phase 3, we first rotate **G** up $M$ positions. Then, we repeat the PMA steps in the same way as in phase 2 in order to generate the remaining half of the products needed in Eq.(2). Before we go to the next phase, we have to rotate **G** down $M$ positions to recover it to the original status. In phase 4, we rotate **G** left one position so that we can start to work on the next window column. After we have processed all $M$ window columns, the final result of $C_{ij}$ is stored in $C(i,j)$.

To simplify our description of the PMA steps, we omit the second subscripts of $j$ and $t$ for **G** and **W**. We use $G_0, G_1, \cdots, G_{m-1}$ to denote the $M$ elements of one segment. Initially, we have $A(i)=G_i$ and $C(i)=0$. After the execution of $C(i)=C(i)+A(i)$*M[MAR($i$)], we have $G_i * W_0$ in register $C$ of every PE.

Now we will discuss the PMA sequence. First, we exchange one element in each segment so that $A(i)=G_j$, where $j=i^{(0)}$. We assign MAR($i$)=1. Only the PE($i$) with $i_0=0$ can perform the multiplication to generate $G_{i+1} * W_1$.

In the second step, we exchange pairs of elements within each segment. If there is a valid local memory address (to be discussed later), only PE($i$) with $i_1=0$ can multiply $A(i)$*M[MAR($i$)]). The product will be added to $C(i)$. Since the second step should generate two terms in Eq.(2), $G_{i+2} * W_2$ and $G_{i+3} * W_3$, in PE($i$) with $i_1=0$, a procedure GRAY (to be defined later) is employed to exchange the elements in each pair within the segment. In the same way, the $(k+1)$th step exchanges $2^k$ element pieces within each segment. Using a valid address, we perform

$$C(i) := C(i) + A(i) * \text{M[MAR}(i)], \quad (i_k = 0).$$

Just as in the second step, the $(k+1)$th step generates $2^k$ terms in Eq.(2), and procedure GRAY executes a permutation subsequence. After executing the $m-1$ steps, each element in a segment should appear in any position of the segment once and only once.

We employ the GRAY sequence concept [Roth79] to generate the permutation subsequence for the small section of $2^k$ elements in each step. Given an integer $i$ in the range $[0,M-1]$, where $i=i_{m-1:0}$, and a given $k$ $(0 \le k < m-1)$, starting with integer $i$, we can change one bit of the binary expression at a time to generate a sequence of $2^k-1$ integers in the range $\{\lfloor i/2^k \rfloor * 2^k, \ldots, (\lfloor i/2^k \rfloor + 1) * 2^k - 1\}$ with $i$ excluded. Let $S_{k-1}$ denote the sequence of bit positions on which the GRAY sequence with $2^k-1$ integers will take a complement operation to generate the corresponding integers. $S_{k-1}$ can be recursively defined as follows:

$$S_0 = 0$$

$$S_{k-1} = S_{k-2},\ k-1,\ S_{k-2}.$$

The length of the GRAY sequence can be obtained by the recursive equation $L(S_{k-1})=2L(S_{k-2})+1$, where $L(S_0)=1$. The following lemmas are useful in developing our parallel algorithms and can be easily proved by induction on $k$.

**Lemma 1**: Given an integer $i=i_{m-1:k}\,i_{k-1}i_{k-2:0}$ in $[0,M-1]$, starting from $i$, the last number in the GRAY sequence of $2^k-1$ numbers is $i^{(k-1)}=i_{m-1:k}\,\bar{i}_{k-1}i_{k-2:0}$.

Let $F$ be a boolean variable, which is changed alternatively between true and false in the generation of numbers of a GRAY sequence. The initial value of $F$ is false. In the sequence of bit positions $S_{k-1}$, each bit position $b$ $(0 \le b < k-1)$ is involved in pairs of complement operations. In each pair, the first complement is from $i_b$ to $\bar{i}_b$ when $F$ is true. The second complement is from $i_b$ to $\bar{i}_b$ when $F$ is false.

**Lemma 2**: During the GRAY sequence, when $i_b$ is to be complemented to generate the next number, MAR($i$) is modified by the following formula.

$$\text{MAR}(i) := \text{MAR}(i)+2^b \text{ if } (F \& i_b=0) | (\bar{F} \& i_b=1)$$
$$\text{MAR}(i) := \text{MAR}(i)-2^b \text{ if } (F \& i_b=1) | (\bar{F} \& i_b=0)$$

**Lemma 3**: After executing $A(i^{(k)}) \leftarrow A(i)$, the MAR($i$) is incremented by $2^k$ if $i_{k-1}=0$. If $i_{k-1}=1$, then MAR($i$) is unchanged.

The recursive procedure GRAY($U$,$F$,phase) is designed to generate the GRAY sequence, modify MAR($i$), and execute the multiply-accumulate operation on $C(i)$.

```
recursive procedure GRAY($U$,$F$,phase)
begin
  if $U=0$ then return else
  begin
    flag:=true;
    GRAY($U-1$,flag,phase);
    $A(p^{(U+n-1)}) \leftarrow A(p)$;
    if $F$ then
      MAR($p$):=MAR($p$)+$2^{U-1}$, $(p_{U+n-1}=0)$;
      MAR($p$):=MAR($p$)-$2^{U-1}$, $(p_{U+n-1}=1)$;
    else
      MAR($p$):=MAR($p$)-$2^{U-1}$, $(p_{U+n-1}=0)$;
      MAR($p$):=MAR($p$)+$2^{U-1}$, $(p_{U+n-1}=1)$;
    end; (* end if-else *)
    if phase=2 then $C(p):=C(p)+A(p)*$M[MAR($p$)], $(p_k=0)$
      else $C(p):=C(p)+A(p)*$M[MAR($p$)], $(p_k=1)$;
    flag:=false;
    GRAY($U-1$,flag,phase);
  end; (* end if-else *)
end;
```

Finally we come to procedure CUBE-N2, a convolution algorithm for a hypercube array processor with $N^2$ PEs.

```
procedure CUBE-N2($A$, $C$)
begin
  $C(p)$:=0; (* initialization *)
  (* process one window column at a time *)
  for $t$:=0 to $M-1$ do begin
    (* Phase 1: read one window column to local memory *)
    MAR($p$):=0; (* initialize MAR *)
    for $s$:=0 to $M-1$ do begin
      CMAR := $\alpha+t*M+s$;
      M[MAR($p$)] $\Leftarrow$CM[CMAR];
      MAR($p$) := MAR($p$)+1;
    end;
    (* Phase 2: PMA on its own segment *)
    MAR($p$):=0;
    $C(p):=C(p)+A(p)*$M[MAR($p$)]; (* get first product *)
    for $k$:=$n$ to $n+m-1$ do begin
      $A(p^{(k)}) \leftarrow A(p)$;
      if $k=n$ then MAR($p$):=MAR($p$)+1
        else MAR($p$):=MAR($p$)+$2^{k-n}$, $(p_{k-1}=0)$;
      $C(p):=C(p)+A(p)*$M[MAR($p$)], $(p_k=0)$;
      $F$:=false;
      $U$:=$k-n$;
      GRAY($U$,$F$,2);
    end (* end loop $k$ *)
    (* Phase 3: PMA on the next segment *)
    (* rotate the image up one segment *)
    $A(p^{(n+m-1)}) \leftarrow A(p)$; (* recover original value *)
    ROTATE($A$,$n+m$,$2n-1$,0);
    (* PMA on the new segment *)
    MAR($p$):=$M$;
    for $k$:=$n$ to $n+m-1$ do begin
      $A(p^{(k)}) \leftarrow A(p)$;
      if $k=n$ then MAR($p$):=MAR($p$)-1
        else MAR($p$):=MAR($p$)-$2^{k-n}$, $(p_{k-1}=1)$;
      $C(p):=C(p)+A(p)*$M[MAR($p$)], $(p_k=1)$;
      $F$:=false;
      $U$:=$k-n$;
      GRAY($U$,$F$,3);
    end (* end loop $k$ *)
    (* rotate G down one segment *)
    $A(p^{(n+m-1)}) \leftarrow A(p)$; (* recover original value *)
    ROTATE($A$,$n+m$,$2n-1$,1);
    (* Phase 4: Rotate G left one position *)
    ROTATE($A$,0,$n-1$,0);
  end; (* end loop $t$ *)
end;
```

Algorithm CUBE-N2 uses $M$ local memory locations for each PE. The inter-PE communication time in procedure GRAY with parameter $U$ is $2^U-1$ unit routes. Therefore, the communication time in phase 2 or phase 3 requires $\sum_{k=0}^{m-1}(2^k-1) \approx M$ unit-routes. To rotate **G** up or down one segment takes $\log_2(N/M)$ unit-routes. Phase 4 takes $\log_2 N$ unit-routes to rotate **G** left one position. The communication complexity is

$$\sum_{t=0}^{M-1}(3M+2(log_2 N-\log_2 M)+\log_2 N)$$
$$= M(3M+\log_2 N-2\log_2 M) \le M*\max(3M,\log_2 N)=O(M^2).$$

Note that the complexity of the traditional computer is $O(N^2*M^2)$.

Fig. 3. An example shows the permutation and address generation sequences for 16 PEs, where $M=8$

To further illustrate our algorithm, Fig.3 shows an example of processing one window column where $M=8$. The first column of the figure gives the initial configuration, where we list 16 PEs (PE(0,$j$) to PE(15,$j$)). The first value, $D$, associated with each PE, is the value of its MAR, and the second value, $G$, is the index $i$ of $G_{ij}$. Again, subscripts $j$ and $t$ are omitted from Fig.3. The results of all enable operations are followed by the symbol *. The first column in phase 3 demonstrates the rotation of G up one segment (8 positions). The second to last column in both phase 2 and phase 3 shows the restoration of G to its original value (before permutation). The last column in phase 3 shows the effects of rotating G down one segment. Fig.3 demonstrates that, after phase 3, all eight products are available for the evaluation of Eq.(2).

In the general case, a window could be an $M$ by $M'$ rectangle ($M<M'$), and $M$ might not be a power of 2. Let $M=M_1+M_2+\cdots+M_q$, where $M_d$ is an integer power of 2, and $d=1,2,...,q$. Algorithm CUBE-N2 can be modified by looping $k$ from $n$ to $n+m-1$ inside another loop on $d$ from 1 to $q$. For each value of $d$, the variable $m$ takes the value $\log_2(M_d)$. In the outermost loop, $t$ increments from 0 to $M'-1$ to process columns in the window. It is clear that the time complexity of the modified CUBE-N2 algorihm is $O(M{*}M')$.

## V. SHUFFLE-EXCHANGE MODEL WITH N$^2$ PEs

An $O(M^2)$ convolution algorithm for a $N^2=2^q$ shuffle-exchange array processor can be arrived at by simulating the routes in procedure CUBE-N2, using the technique used in [DeNS81]. We shall use the same logically two-dimensional view of PEs and the same initial configuration described in Section III and Section IV. Initially, $A(i,j)=G_{ij}$ for $i,j\in[0,N-1]$, and the $M$ by $M$ window is stored in the control unit memory in column-major order with the starting address $\alpha$. The resulting similarity measures will be in the register $C$.

The basic steps in the shuffle-exchange model convolution algorithm are the same as those used in CUBE-N2. The only difference is the data routing. In the shuffle-exchange model, we have to employ EXCHANGE, SHUFFLE, and UNSHUFFLE to simulate data transmission in the hypercube model. In the hypercube model, PE($p$) is directly connected to PE($p^{(b)}$) and the fundamental data transmission is $R(p^{(b)})\leftarrow R(p)$ for $0\le b<q$. Clearly, the following subroutine in the shuffle-exchange model implements the basic data transmission in the hypercube model.

```
proceudre TRANSMIT ($R$ :register; $b$ :integer)
begin
  for $i$:=1 to $b$ do $R$(UNSHUFFLE($p$)) ← $R(p)$;
    $R(p^{(0)})$ ← $R(p)$;
  for $i$:=1 to $b$ do $R$(SHUFFLE($p$)) ← $R(p)$;
end;
```

Note that the SHUFFLE and UNSHUFFLE connections are complementary operations. If several UNSHUFFLE operations are followed by the same number of SHUFFLE operations, the result will recover the search area to its original value. Since SHUFFLE or UNSHUFFLE rotates the bit position in the binary representation of index $p$, the selectivity function should take the corresponding adjustment if it is necessary.

Procedure ROTATE($R,s,r,flag$), developed in Section II for the hypercube model, should be modified to perform rotation for the shuffle-exchange model. The paprameters in the new procedure PS-ROTATE retain the same meanings as in the procedure ROTATE.

```
procedure PS-ROTATE($R,s,r$,flag);
begin
  for $i$:=1 to $s$ do $R$(UNSHUFFLE($p$)) ← $R(p)$;
    $R(p^{(0)})$←$R(p)$;
  for $i$:=1 to $r-s$ do
    $R$(UNSHUFFLE($p$)) ← $R(p)$;
    if flag=0 then
      $R(p^{(0)})$←$R(p)$, $(p_{q-1}=1$ & $\cdots$ & $p_{q-i}=1)$
    else (* Note that & is a logical AND operator *)
      $R(p^{(0)})$←$R(p)$, $(p_{q-1}=0$ & $\cdots$ & $p_{q-i}=0)$;
    end; (* end of if-then-else *)
  end; (* end loop $i$ *)
  for $i$:=1 to $r$ do $R$(SHUFFLE($p$)) ← $R(p)$;
end;
```

It is important to note that PS-ROTATE requires only twice as many unit-routes as does ROTATE in the hypercube model. Recall that each PE in a shuffle-exchange is connected to up to three 3 PEs, while in a hypercube each PE is connected to $q$ other PEs.

The parallel convolution algorithm SHEX-N2 for a shuffle-exchange network with $N^2$ PEs is obtained by (i) replacing the data transmitting statement $R(p^{(b)})\leftarrow R(p)$ with procedure TRANSMIT; and (ii) substituting PS-ROTATE for ROTATE in both the recursive procedure GRAY and algorithm CUBE-N2 from Section IV. SHEX-N2 also requires $M$ local memory locations for each PE. As mentioned above, PS-ROTATE takes about twice as many unit-routes as does ROTATE in the hypercube model. Thus, it takes $2*log_2(N/M)$ unit-routes to rotate **G** up or down one segment. Similarly, rotating **G** left one column takes $2*\log_2 N$ unit-routes.

Now we need to investigate the number of unit-routes required by procedure GRAY with parameter $U$. By definition of the GRAY sequence in Section IV, $S_U=S_{U-1},U,S_{U-1}$ where $S_U$ represents the sequence of bit positions on which the GRAY sequence with $2^U-1$ integers will take a complement operation to generate the corresponding integers. It is clear that $S_U$ is the same as an inorder traversal list of a complete binary tree with its root labelled $U$, and every other node of level $x$ labelled $U-x+1$. From this fact, an interesting property of the GRAY sequence is described in the following lemma.

**Lemma 4:** In $S_U$, corresponding to the GRAY sequence with parameter $U$, the number of integer $r$ 's, $1\leq r\leq U$, is $2^{U-r}$.

Each integer $r$ in $S_U$ corresponding to a GRAY sequence involves a data transmission $A(p^{(r)})\leftarrow A(p)$ in algorithm CUBE-N2. Therefore, by procedure TRANSMIT, it will take $2r-1$ unit-routes in the shuffle-exchange model. The inter-PE communication time in procedure GRAY with parameter $U$ is

$$\sum_{r=1}^{U}(2r-1)*2^{U-r} = 3*2^U-2*U-3$$

Therefore, phase 2 takes

$$\sum_{k=0}^{m-1}(3*2^k-2*k-3)+\sum_{k=0}^{m-1}(2k+1) = 3*2^m-2m-3\approx 3M$$

unit-routes. The overall time complexity of the SHEX-N2 algorithm is

$$\sum_{t=0}^{M-1}(M+2((3M-2\log_2 M-3)+2\log_2(N/M))+2\log_2 N)$$

$$=M(7M+6\log_2 N)\leq M*max(7M,6log_2 N)=O(M^2).$$

Note that the complexity of algorithm CUBE-N2 is $O(2M^2)$, while SHEX-N2 uses only triple as many unit-routes as does CUBE-N2 in the hypercube model. Each PE in the shuffle-exchange model is connected to up to 3 PEs however, instead of $q$ PEs as is the hypercube model.

## VI. ARRAY PROCESSORS WITH DIFFERENT NUMBERS OF PEs

The algorithms in the previous sections were developed on array processors with the number of PEs same as the size of the search area. We now demonstrate the modification of algorithm CUBE-N2 so that it can be applied to other numbers of PEs. The modification of algorithms on other types of array processors would be similar to this example.

First, let us consider the case of $L^2$ PEs, where $M\leq L\leq N$. Again we assume that $L$ is an integer power of 2. The search area **G** can be partitioned into $(N/L)^2$ equal-sized *blocks*, where each block $\mathbf{G}_{xy}$ is $L$ by $L$ for $0\leq x,y<(N/L)$. For a fixed $y$, we call procedure CUBE-N2 for blocks from $\mathbf{G}_{0y}$ to $\mathbf{G}_{zy}$, where $z=(N/L)-1$. Then we repeat the procedure call from $y=0$ to $y=(N/L)-1$. The only modification we have to make is the procedure ROTATE. In algorithm CUBE-N2, there are three places to call ROTATE: one for rotate up, one for rotate down, and one for rotate left. Instead of performing a rotate or end-around shift for those boundary elements, we must instead shift **G** from the neighboring (either down, up, or left) blocks. ROTATE can be easily modified to add this feature by reading the neighboring elements before performing the rotation. For example, to shift a block left one position, we can add the following statement to the beginning of ROTATE.

```
read block[$x*L:(x+1)*L-1;(y+1)*L+t:(y+2)*L+t-1$]
      ($p_{n-1:0}$=0 · · · 0);
```

Note that the leftmost column of the block to the right of the current block is read. Here $n=\log_2 L$.

An alternative approach does not involve modifying ROTATE. We can read the neighboring elements into another register, for instance, $B$. Suppose that we want to shift **G** up 4 positions. The top four rows of PEs (or $B$s) will be loaded with the element values of the top four rows of the blocks below it. Before we perform the shift on $A$, we exchange the contents of $A$ and $B$. Then, we perform ROTATE to get the desired result.

Now we present algorithm CUBE-L2 for a hypercube with $L^2$ PEs. **G** is initially stored in the I/O system and can be read block by block. The window **W** is stored in the control unit memory in the same way as was specified in CUBE-N2. Once it is obtained, the resulting similarity measure **C** is sent to the I/O system block by block.

```
procedure CUBE-L2
begin
  for $y$:=0 to (N/L)-1 do
    for $x$:=0 to (N/L)-1 do begin
      read block[$x*L:(x+1)*L-1;y*L:(y+1)*L-1$];
      Modified-CUBE-N2($x,y$);
    end;
end;
```

It is simple to show that the time complexity of CUBE-L2 is $O(N^2M^2/L^2)$.

Algorithm CUBE-N2M2, developed in [FaLN85], is a parallel template matching algorithm for an array processor with $N^2M^2$ PEs. By combining algorithms CUBE-N2M2 and CUBE-N2, one can obtain an efficient parallel convolution algorithm, CUBE-N2K2, for a hypercube with $N^2K^2$ PEs, where $1\leq K\leq M$. Algorithm CUBE-N2M2 has a time complexity of $O(log_2 N*\log_2 M)$. Meanwhile, algorithm CUBE-N2K2 has a time complexity of $O(M^2/K^2+\log_2 N*\log_2 K)$. One readily sees that when $K=1$, CUBE-N2K2 works exactly like CUBE-N2, and when $K=M$, CUBE-N2K2 works as CUBE-N2M2. When $K=M/\log_2 M$ and there are $N^2M^2/(log_2 M)^2$ PEs, it is interesting to see that the complexity of the algorithm CUBE-N2K2 is still $O(log_2 N*\log_2 M)$.

## VII. COMPUTATION FOR GENERALIZED CONVOLUTION

For some applications we need to normalize both arrays (search area and window) before the computation of convolution so that the similarity measure is a generalized digital convolution, i.e., normalized correlation. First we define

$$H=\sum_{s=0}^{M-1}\sum_{t=0}^{M'-1} G_{i+s,j+t}$$

$$T=\sum_{s=0}^{M-1}\sum_{t=0}^{M'-1} W_{st}$$

$$Z=\sum_{s=0}^{M-1}\sum_{t=0}^{M'-1} G_{i+s,j+t}^2$$

$$D=\sum_{s=0}^{M-1}\sum_{t=0}^{M'-1} W_{st}^2$$

$$E=\sum_{s=0}^{M-1}\sum_{t=0}^{M'-1} G_{i+s,j+t} * W_{st}$$

The normalized coorelation is thus defined as

$$G_{ij} = \frac{E-\frac{HT}{MM'}}{\sqrt{\left(Z-\frac{H^2}{MM'}\right)\left(D-\frac{T^2}{MM'}\right)}}$$

In each PE($p$), we use four registers MSI($p$), MWD($p$), MSIS($p$) and MWDS($p$) to store $H$, $T$, $Z$, and $D$, respectively. The modifications to algorithm CUBE-N2 include the following:

1. After a window column is read to local memory, cumulate M[MAR($p$)] into MWD($p$), cumulate M[MAR($p$)]$^2$ into MWDS($p$).
2. During the execution of multiplication-addition in both the main loop body and in procedure GRAY, cumulate $A(p)$ and $A(p)^2$ into MSI($p$) and MSIS($p$), respectively.
3. Before exiting, calculate the final result from contents in $C(p)$ and the four new memory locations.

The complexity of the algorithm generating the normalized correlation coefficient is still $O(M*M')$.

## VIII. CONCLUSIONS

Two-dimensional digital convolution, a basic operation in image processing, is computationally time consuming in traditional machines. We have proposed several parallel algorithms on array processors with different types of interconnection networks. PE operations can be carried out between the data movement steps among PEs, eliminating many unnecessary data transmissions. Our approach employs a small local memory requiring only M locations for each PE.

With $N^2$ PEs and $M=M'=2^m$, the communication time complexity of all three networks has the same order of magnitude $O(M^2)$. The degree of communication (connection links) of each PE is 4, $q$, and 3, for mesh, hypercube, and shuffle-exchange, respectively. However, the mesh connection provides the smallest communication complexity as summarized in Table 1. This is due to the inherent topological matching between mesh network and 2-D search area.

Table 1. Communication Time Complexity

| | |
|---|---|
| mesh | $3M^2$ |
| hypercube | $3M^2+M\log_2N-2M\log_2M$ |
| shuffle-exchange | $M*max(7M,6log_2N)$ |

# Parallel Geometric Algorithms for Digitized Pictures on Mesh of Trees

( Preliminary Version )

V. K. Prasanna Kumar and Mehrnoosh Mary Eshaghian
Department of Electrical Engineering-Systems
University of Southern California
Los Angeles, CA 90089-0781

## Abstract

In this paper we consider the Mesh of Trees organization for several fundamental tasks in computer vision. We illustrate the suitability of this architecture by showing fast parallel algorithms for many tasks in low to medium level vision. We derive poly logarithmic algorithms for many problems on digitized pictures such as identifying and labeling figures in a 0/1 image, drawing digitized straight lines, computing convexity properties of digitized images, determining distances, etc. For all the above problems, the Mesh of Trees organization has superior time performance compared with the pyramid and mesh connected computer of corresponding size.

## I. INTRODUCTION

Mesh Connected Computers (MCC) and Cellular Arrays have been considered suitable for image processing, since images can be naturally mapped onto these so that neighboring pixels are mapped onto neighboring processing elements [MILL 85, ROSE 83]. But solving many image processing problems on a $N \times N$ 2-MCC requires as much as $O(N)$ time. An alternate parallel architecture is the pyramid organization which has logarithmic diameter [TANI 83, MILL 84]. The hierarchical organization of pyramid results in logarithmic time performance for many image processing tasks. However, many other problems require as much as $O(N^{1/2})$ time on a $N \times N$ base pyramid [MILL 84]. In this paper, we explore the suitability of the Mesh of Trees for image processing applications.

The Mesh of Trees organization has been introduced to solve several problems such as sorting, matrix multiplication and some graph problems [LGHT 81, NATH 83]. In this paper we propose this as an alternate architecture to the pyramid computer and evaluate its performance with respect to several fundamental tasks in image processing. For many problems on digitized images, the Mesh of Trees organization is shown to have superior performance compared to either the pyramid or 2-MCC of corresponding size.

The rest of this paper is organized as follows. In the next section, we define the structure of the Mesh of Trees and standard operations on it which will be used throughout the paper. In section III, we present $O(\log N)$ parallel algorithms for the following problems: determining the extreme points of the convex hull of a figure, enumerating and deciding the PEs within the convex hull of a figure, deciding if two sets of processors are linearly separable, finding the PEs along a digitized straight line, determining nearest neighboring figure to a figure, etc. We also derive poly logarithmic algorithms for several problems including labeling 0/1 images, estimating convexity properties for digitized pictures having multiple objects, etc. For several problems, the solution on the Mesh of Trees turns out to be considerably simpler than those on the pyramid. Due to space limitation proof sketches will be provided. Details appear elsewhere [PRAS 86b].

## II. MESH OF TREES

The Mesh of Trees network can be looked upon as an $N \times N$ matrix of processors in which each row and each column of processors forms the leaves of a binary tree [LGHT 81, NATH 83]. The root and the internal nodes of each binary tree are also processors. This structure is called an $(N \times N)$-MOT for short. The $N^2$ leaf processors form the base of the network and are called base processors (BPs). Most of the processing is done by the BPs. The internal processors (IPs) are used for communication between BPs. During the course of this communication, the IPs may also be required to carry out some simple operations such as summing and extracting the minimum on the data. A $(4 \times 4)$-MOT and its layout is shown in figure 1, where the BPs are represented by white circles and the IPs are represented by black circles. Any two adjacent rows or columns of the base are $O(\log N)$ distance apart. Since there are $N$ rows and $N$ columns, the total VLSI area of the layout is $O(N^2(\log N)^2)$, which can be shown to be optimal [LGHT 81]. Notice that, in the standard VLSI model, $(N \times N)$ 2-MCC and $(N \times N)$ pyramid have $O(N^2)$ area requirement.

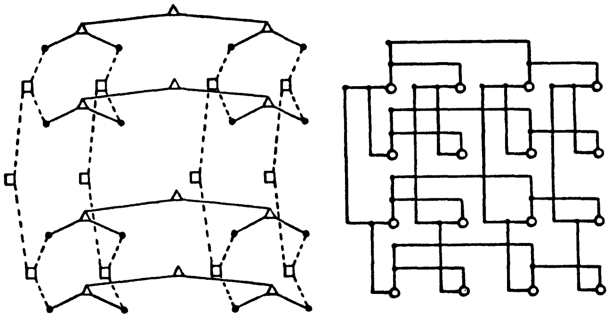

Fig. 1 (4×4)-MOT and it's layout

The following are some of the commonly used communication operations on the Mesh of Trees [NATH 83].

1) ROOTOLEAF-The contents of the data register of the root of the corresponding tree are broadcast to the leaves of the tree,

2) LEAFTOROOT-Selector specifies one BP whose register R contents are sent to the root of the corresponding tree.

3) LEAFTOLEAF-This can be expressed as a sequence of LEAFTOROOT and ROOTOLEAF operations.

The time required for the above operations is $O(\log N)$ which is the height of the tree.

## III. PARALLEL GEOMETRIC ALGORITHMS

In this section we consider several basic tasks on digitized images and derive fast parallel algorithms for these tasks. For all our algorithms the input is an $N \times N$ image with the base PE($i,j$) storing the pixel($i,j$).

### 3.1 Connected Components

Given a 0/1 image a fundamental task is to identify figures in the image. Figures correspond to connected 1's in the image. The labeling problem is to identify and associate an unique ID with the connected 1's in the image. An essential part of this algorithm is:

**Lemma 1:**[NATH 83] Given a $N \times N$ adjacency matrix of a $N$ vertex graph stored in the BPs of an $(N \times N)$-MOT, the connected components can be determined in $O((\log N)^3)$ time.

**Theorem 1:** Given a $N \times N$ 0/1 image, all figures can be labeled in $O((\log N)^4)$ time using an $(N \times N)$-MOT.

**Proof sketch:** The basic idea is to label blocks of size $k \times k$ and merge 4 adjacent blocks to form bigger size blocks. This is repeated until the block size becomes $N \times N$. To merge 4 blocks of size $k \times k$, we look at the boundary of the blocks as shown in figure 2. At the boundary between two blocks we can associate an *adjacency graph* as follows: each figure incident on the boundary corresponds to a vertex. Two figures adjacent to each other at the boundary has an edge between them. There can be $O(k)$ edges and $O(k)$ nodes across the boundary of two adjacent blocks. We then convert the $O(k)$ nodes and edges into adjacency matrix format using the basic data movement operations in $O(\log k)$ time. Now using lemma 1, the connected components of the *adjacency graph* is found in $O((\log k)^3)$ time. Repeating this along the horizontal boundary, we can determine the new labels within a block of size $2k \times 2k$. This information is propagated to the outer boundary of the block of size $2k \times 2k$ as shown in figure 2. Repeating this $\log N$ times, all the figure are labeled. By traversing the above steps in reverse, we can relabel all the figures. □

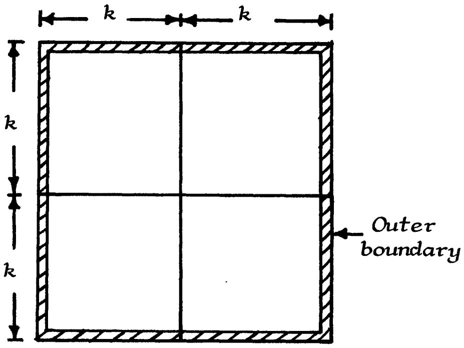

Fig. 2 Merging 4 blocks of size $k \times k$

### 3.2 Convexity Algorithms

Now we consider convexity problems. We use the following definition of convexity: A set of PEs is said to be convex if and only if the corresponding set of integer lattice points is convex. Given a set S of PEs, the convex hull of S, denoted Hull(S), is the smallest convex set of PEs containing S.

**Theorem 2:** In an $(N \times N)$-MOT, in $O(\log N)$ time one can identify the extreme points of 1's in a $N \times N$ image.

**Proof sketch:** The algorithm operates in two steps. It first finds the Right Most (RM) and the Left Most (LM) 1 in each row using the LEAFTOROOT and ROOTOLEAF operations. Then it verifies if these points are extreme points or not. The verification is done by having the $i$th column compute the enclosing angle made by the 1s in the image with the RM of the $i$th row ($RM_i$). This angle is defined to be the smallest angle $\phi_i$ such that all the 1s are enclosed inside the region X $RM_i$ Y as shown in figure 3. This can be easily computed in $O(\log N)$ time, using ROOTOLEAF and LEAFTOROOT operations. $RM_i$ is an extreme point if and only if $\phi_i < 180$ degrees. This step is repeated for LMs. □

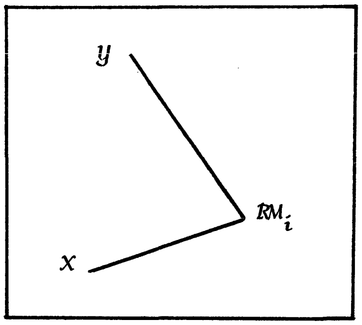

Fig. 3 Enclosing angle X $RM_i$ Y

**Lemma 2:** In an $(N \times N)$-MOT, suppose the extreme points of a set S have been marked. Then,

a. in $O(\log N)$ time the extreme points of S can be enumerated.

b. in $O(\log N)$ time the base PEs within the hull can be marked.

Using Lemma 2 we have:

**Corollary:** Using an $(N \times N)$-MOT , it can be decided if two sets of base processors are linearly separable in $O(\log N)$ time.

**Theorem 3:** Using an $(N \times N)$-MOT,

a. the diameter of a figure can be determined in $O(\log N)$ time.

b. a smallest enclosing box, a smallest enclosing circle for a figure can be determined in $O(\log N)$ time.

**Proof sketch:** a) The algorithm finds the diameter, by finding the maximum of distances between any two points on the boundary. The LM and the RM of each row having an extreme point is broadcast to all the BPs along that row. The $i$th column computes the distance between the extreme points in the $i$th row and the rest of the extreme points. In the next step, the maximum of those values is obtained in $O(\log N)$ time.

b) Given a set S of points in the plane, a smallest enclosing box is a rectangle of least area containing S. This rectangle must contain an extreme point of S on each side, and at least one of it's sides must contain two consecutive extreme points [FREE 75]. Therefore, after finding the extreme points of the convex hull enclosing the points, using theorem 2, each pair of consecutive extreme points is assumed to form the base of a rectangle. In $O(\log N)$ time, the extreme points of the convex hull of the figure lying on the other three sides can be found. Then the area of each of these rectangles is obtained. Using the data movement operations of section II, the rectangle with the minimum area is identified as the smallest enclosing box. Similarly, the smallest enclosing circle is a circle of least area containing S. This can also be computed in $O(\log N)$ time using a property of a smallest enclosing circle [FREE 75], and using the following fact [VOSS 82]: in a $N \times N$ digitized image, a figure can have at most $O(N^{2/3})$ extreme points. Details can be found in [PRAS 86b]. □

By combining adjacent convex hulls we can show:

**Theorem 4:** In an $(N \times N)$-MOT, one can determine and enumerate the extreme points of the convex hull of all figures simultaneously in $O((\log N)^4)$ time.

**Proof sketch:** The idea is to find convex hulls locally within blocks of size $k \times k$, merge the convex hulls within adjacent 4 blocks to construct convex hulls of figures within blocks of size $2k \times 2k$, $1 \leq k \leq \frac{N}{2}$. Notice that given two adjacent blocks of size $k \times k$, there can be at most $O(k)$ figures that run across the boundary between the blocks. Thus, $O(k)$ convex hulls need to be merged. Merging of convex hulls involves finding tangent lines $pq$ and $rs$ as shown in figure 4. This can be done by a binary search on the extreme points of A and B. Using suitable representation for the convex hulls and a basic technique in [OVER 80] we can show:

**Lemma 3:** Given convex hulls within blocks of size $k \times k$, the convex hulls can be merged to yield the convex hull of figures in block of size $2k \times 2k$, in $O((\log N)^3)$ time simultaneously for all the figures.

A basic step in the proof of the above lemma is to gather information about the relationship of a given line $xy$ (joining an extreme point of A with an extreme point of B) to the convex hulls A and B. If this line is tangential to both A and B, then we are done; otherwise we need to identify one of several cases [OVER 80]. A crucial step is to identify this information in parallel for all the $O(k)$ figures. By recursively representing information about the convex hulls and using efficient data movement this can be done in $O((\log k)^2)$ time [PRAS 86b]. □

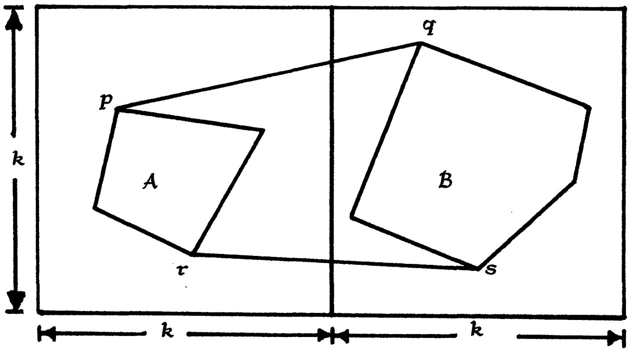

Fig. 4 Merging of convex hulls

### 3.3 Distance Problems

Now we consider several distance problems. In the following discussion we use the $l_1$ metric. However, it can be modified to operate for any $l_k$ metric.

**Theorem 5:** Using an $(N \times N)$-MOT,

a. the nearest neighbor 1 to each PE having a 1 can be found in $O(\log N)$ time.

b. the nearest neighboring figure to a given figure can be found in $O(\log N)$ time.

**Proof Sketch:** a) The algorithm starts by finding the nearest neighboring 1, along the X and Y axis, to each BP. This can be easily implemented by traversing the row and column trees. At the end of this step, each PE has the coordinates of the nearest PE with a 1, along the X and Y axis. Then each PE having a 1 broadcasts it's coordinates to all the PEs within it's nearest neighbor 1 in each direction. Each PE calculates the minimum distance between the broadcast address and it's nearest neighbor 1 along X and Y axis. In the return movement, the minimum of all these distances is sent back to the PE having a 1 which sets its nearest neighbor.

b) The idea of the algorithm is to first find the nearest neighbor for all the boundary PEs of the figure, and then to find the nearest figure, by finding the minimum among all those values obtained for the PEs at the boundaries. Details will appear in the full paper. □

A related problem is the closest pair problem for which efficient solutions are known on the pyramid computer [STOU 85]. This can be easily solved on the Mesh of Trees:

**Corollary:** Given an $(N \times N)$-MOT, the closest pair problem can be solved in $O(\log N)$ time.

## IV. CONCLUSION

In this paper we showed that many of the image processing tasks which required $O(N)$ computation time on an $(N \times N)$ mesh connected computer, can be computed in logarithmic time using a $(N \times N)$ Mesh of Trees. Indeed for several problems on digitized images, Mesh of Trees organization seems to be a natural candidate as opposed to the pyramid organization. This is illustrated by simple and elegant parallel algorithms for these problems.

# PARALLEL $A^*$ AND $AO^*$ ALGORITHMS: AN OPTIMALITY CRITERION AND PERFORMANCE EVALUATION

Keki B. Irani and Yi-fong Shih

Computing Research Laboratory
Department of Electrical Engineering and Computer Science
University of Michigan
Ann Arbor, MI 48109

Abstract-- A criterion is presented for validating the optimality of solutions acquired by parallel $A^*$ and $AO^*$ algorithms using multiple processors and a global *OPEN* queue or local best solution graph selection. It is shown analytically that the parallel $A^*$ algorithm with an *OPEN* queue can achieve linear speedups for up to a large number of processors when processor contention to access the queue is small. For the parallel $AO^*$ algorithm, utilizing Nilsson's solution graph cost revision in every processor gives a much higher performance than ordering solution graphs in a global queue.

## Introduction

The introduction of Very Large Scale Integration has enabled the construction of massively parallel systems[1,2]. In the field of Artificial Intelligence, parallel processing has been recognized belately as a powerful tool for accelerating the execution of search algorithms. In this paper we concentrate on both the state-space search and the AND-OR search. An optimality termination criterion for the parallel versions of the $A^*$ and $AO^*$ algorithms is presented and its correctness demonstrated. The solution that has the best merit at the time the criterion is first satisfied is the optimal solution.

In the past, research on performance evaluation of search algorithms concentrated on Branch-and-Bound search. Wah and Ma [3] have proposed an architecture, called MANIP, that uses a global register to hold the current best heuristic value. Wah has also given the performance speedups for Branch-and-Bound search[4,5]. Lai and Sahni [6] find that when using multiple processors it is possible to be trapped in an anamoly where the speedup dips below 1.0. Our emphasis, however, is on the state-space search and the AND-OR search algorithms that utilize admissable heuristic evaluation functions.

## Algorithm $E^*$

Throughout this paper we will use the same notations for heuristic evaluation functions (HEFs) as given in Nilsson[7]. We will refer to a heuristic evaluation function (HEF) as being *admissable* if the cost estimate function $h(n)$ of the HEF $f(n)$ satisfies the relation $h(n) \leq h^*(n)$ for all nodes $n$. A HEF $f(n)$ is also said to be *monotonic* if $f(n_1) \leq f(n_2)$ for any pair of nodes $(n_1,n_2)$ such that $n_1$ is a predecessor of $n_2$. We will call our parallel version of the $A^*$ algorithm $E^*$ algorithm. The algorithm $E^*$ runs on every PE in a system consisting of $p$ processors(PEs), a global OPEN queue for ordering unexpanded nodes, and a shared variable $\alpha$ which is initially set to $\infty$. The algorithm $E^*$ is identical to $A^*$ except that everytime a solution is found by the system, $\alpha$ is updated to contain the cost of the least costly solution found thus far. The purpose of $\alpha$ is explained in the next section.

## Proofs for the Alpha Criterion

Since our multiprocessor system is not synchronized, it is possible to obtain a suboptimal solution before an optimal one is found. It is therefore essential to derive a sufficient condition, called the $\alpha$-criterion in this paper, for determining the optimality of a solution that has been acquired. We will omit the proofs of the following sequence of propositions that shows the condition does indeed exist which optimally terminates the $E^*$ algorithm. For the derivations of all the expressions in this paper the reader shall refer to [8].

*Lemma 1:* If an optimal solution exists, $E^*$, without the $\alpha$-criterion, will acquire it.

*Lemma 2:* Before algorithm $E^*$ acquires the optimal solution there exists at least one node $n$ on the OPEN queue such that its heuristic merit $f(n) \leq \alpha$.

*Theorem 1:* If for every node $n_j$ on the OPEN queue the condition $f(n_j) > \alpha$ holds for all $j$, then the least costly solution that has been found by $E^*$ is the optimal solution.

The condition $f(n_j) > \alpha$ for all $j$ is referred to as the $\alpha$-*criterion*.

## Performance Evaluation

### Assumptions for A* and E*

Our purpose in analyzing the $E^*$ algorithm is primarily to derive an upper bound for the number of nodes that $E^*$ needs to expand in order to acquire the optimal solution. If the contention by the PEs to access the global queue is minimal, then this upper bound becomes indicative of the potential speedup possible for $E^*$. Therefore, in the analysis of the $E^*$ algorithm we will assume the amount of contention is negligible for one of two reasons: (1) $p$ is small so there is little contention or (2) hardware support for queue management is available for reducing the processor idle time due to contention caused by queue management overhead. Moreover, we make the following assumptions to simplify the evaluation of algorithms $A^*$ and $E^*$.

(1) There exists a unique optimal solution of cost $N$ $(=N_\gamma)$. There are $\gamma-1$ other suboptimal solutions with costs $N_1, N_2, \ldots, N_{\gamma-1}$. The heuristic merit $f(n)$, where node $n$ lies on the $i^{th}$ solution path, lies in the range between 0 and $N_i$. If node $n$ is on a path that does not lead to any goal, then $f(n)$ lies between 0 and $\infty$. The cost of each arc in the search graph is assumed to be 1.

(2) The search graph is acyclic and every node except the root $s$ has exactly one parent.

(3) The heuristic evaluation function $f$ is admissable and monotonic.

(4) $N_i \leq 2N$ for all $i$. The probability density of $f(n)$, where $n$ is on the $i^{th}$ solution path, at any point before reaching its goal is $\dfrac{1}{N_i - g(n)}$, where the end points of the density function are $g(n)$ and $N_i$.

(5) For evaluation, $E^*$ is assumed to execute on a cycle-synchronized multiprocessor.

The assumption of admissability implies that $A^*$ will expand a path from $s$ up to a node $n$ such that $n$ is the last node on this path to have $f(n) \leq f^*(s)$. Probabilistically, $f(n)$ of the final node $n$ expanded along a suboptimal path is equally likely to be less than $N$ as to be greater than $N$. Therefore,

$$N_i - N = N - g(n)$$

### Expansion Cost for A*

From Nilsson [7] if a HEF is admissable and monotonic then a node on OPEN, excluding the optimal goal node, will be expanded by $A^*$ if and only if $f(n) < N$. Henceforth, a node expanded by $A^*$ will be referred to as a *critical node*, and $E_I(z)$ will denote the expected number of nodes expanded by algorithm $I$ before the optimal solution is obtained.

$$E_{A^*}(z) = N + \sum_{i=1}^{\gamma-1} E(L_i)$$

where $E(L_i)$ is the expected length of a suboptimal solution path before the search stops for that path. To compute $E(L_i)$ we note that the expected length is at the point on the density function where the probability of $f(n) \leq N$ equals the probability that $f(n) > N$. Therefore,

$$E_{A^*}(z) = N + \sum_{i=1}^{\gamma-1} (2N-N_i)$$

### Expansion Cost for E*

Assume that all $p$ processors are used for every expansion cycle. Then there is a distinct possibility that some of the nodes expanded during a cycle may not be critical. We call these cycles *mixed cycles*. A cycle during which only critical nodes are expanded is called a *perfect cycle*. It can be shown that every node expanded by $A^*$ will also be expanded by $E^*$. When the monotonicity is considered as an additional constraint on the HEF, any non-critical nodes expanded by $E^*$ in mixed cycles cannot produce critical successors that may rank ahead of the nodes on the optimal path and slow down search. This leads to the following theorem.

*Theorem 2:* If a HEF is admissable and monotonic, then the critical nodes expanded by $A^*$ are exactly those critical nodes expanded by $E^*$.

Li and Wah [4] has shown that the number of mixed cycles $y$ in an $E^*$ search is less than or equal to $N$. Then $E_{E^*}(z)$ is

$$E_{E^*}(z) \leq E_{A^*}(z) + \left( yp - \sum_{i=1}^{y} m_i \right)$$

where $m_i$ is the number of critical nodes expanded during the $i^{th}$ mixed cycle. Knowing $y \leq N$ and $m_i \geq 1$ for all $i$ and using the uniform density assumption for all the nodes and letting all suboptimal solutions have the same depth $N_n$, we have

$$E_{E^*}(z) \leq pN + (\gamma-1)(2N-N_n)$$

Now we can estimate the speedup $U_p$ for a p-processor $E^*$ algorithm:

$$U_p = \frac{E_{A^*}(z)p}{E_{E^*}(z)}$$

$$\approx \frac{p\left(N + \left(\gamma-1\right)\left(2N-N_n\right)\right)}{pN + \left(\gamma-1\right)\left(2N-N_n\right)}$$

From the equations above we can see that the search speedup is at its best when we have a bushy search graph where the values of $N$, $N_n$ and $\gamma$ are large. To define the range of processors in which the speedup is almost $p$, we rearrange the speedup equation into

$$U_p \approx p - \frac{p^2 N - pN}{pN + \left(\gamma-1\right)\left(2N-N_n\right)}$$

For the speedup in the above equation to be approximately $p-1$, $p$ must be greater than 1 and less than $1 + \sqrt{1+\frac{1}{N}\left(\gamma-1\right)\left(2N-N_n\right)}$. As we can see this range increases for a larger and/or deeper search graph.

### Algorithm AO*

The $AO^*$ algorithm is the equivalent version of $A^*$ algorithm for the AND_OR problem reduction search. The purpose of $AO^*$ and its parallel counterparts is to find a solution graph from $s$ to the terminal set $T$ that has the minimum cost. The algorithm consists of two major operations (see Nilsson [7]): (1) a top-down graph-growing operation to find the best partial solution graph (PSG) and (2) a bottom-up, cost revising, connector-marking operation called *upward cost revision* (UCR). Starting with the node $n$ just expanded, this step revises its cost using newly computed costs of its successors, and marks the outgoing connector from $n$ on the estimated best path to the terminals. This revision process is repeated for every node in the PSG from the parent of $n$ to the start node $s$.

### Assumptions for AND-OR Algorithms

All the assumptions pertaining to the search graph for state-space search are assumed valid for the PSG in AND-OR search. In addition, every node in a PSG has $l$ connectors and every connector is a $k$-connector. The cost of every connector is exactly $k$. The probability density for the cost estimation function $f_i(s)$ ( the estimated cost of the $i^{th}$ PSG $G_i$ ) is uniformly distributed between its known arc cost and the actual total cost $N_i$.

### Total Cycle Time for AO*

From our assumptions it is obvious the algebraic expressions for $E_{AO^*}(z)$ and $E_{EO^*}(z)$ are identical to those for $E_{A^*}(z)$ and $E_{E^*}(z)$ respectively if the parameters are properly interpreted. Unlike the cases for $A^*$ and $E^*$, however, the speedup performance for $AO^*$ is different because the comparison cost in UCR must be taken into account. Similarily, the speedup expression for $EO^*$ will also be different because of the comparison costs in queue management and processor idle time waiting for PSG insertion into the global OPEN queue.

For the calculations that follow, let $\omega$ be the unit cost for a node expansion, and let

$$\epsilon = \frac{\textit{unit comparison cost}}{\textit{unit expansion cost}}$$

where the unit comparison cost is the time taken to compare two numerical values in a given computer system. The unit comparison cost is used in computing the UCR comparison cost, and in the search for a place in the OPEN queue when ordering a PSG. The unit expansion cost is the cost of expanding a node in a PSG.

The $AO^*$ cycle time in the $i^{th}$ cycle varies with the cycle number, the height of the PSG being expanded in the $i^{th}$ cycle, the unit expansion cost and the unit comparison cost. In our calculation, the height of the expanded PSG will be taken to be the height of an uniform search graph that has been expanded breadth-first.

The average height is

$$height_{avg}(i) = \lceil \log_{lk}(ilk) \rceil$$

where $i$(cycle number ) = 1,2,3,.... The total execution time over all cycles is

$$TCT_{AO^*} = \omega \sum_{i=1}^{E_{AO^*}(z)} \left(1+\epsilon(l-1)\lceil height_{avg}(i)\rceil\right)$$

$$\approx \omega\left(E_{AO^*}(z)\left(1+\frac{\epsilon(l-1)\ln(lk\ E_{AO^*}(z))}{\ln lk} - \frac{\epsilon(l-1)}{\ln lk}\right)\right.$$

$$\left. + \frac{\epsilon(l-1)}{\ln lk}(\ln lk + 1) - 1\right)$$

### Algorithm EO* and Its Total Cycle Time

To execute AND-OR search in parallel, Algorithm $EO^*$ employs a global queue to order PSGs. Since its implementation is virtually identical to that of $E^*$, $EO^*$ will also terminate when $\alpha$-criterion is satisfied. However, in computing the performance of $EO^*$ we will include the cost of comparison intrinsic to the insertion operations in queue management, and show that the comparison cost causes an unacceptable bottleneck at the OPEN queue. The average number of comparisons needed to locate a place to insert in OPEN will be taken to be $\frac{|OPEN_i|}{2}$, where $|OPEN_i|$ is the size of the OPEN queue in the $i^{th}$ cycle. The expansion process is partitioned into two phases: the initial phase in which $|OPEN_i| < p$, and the second phase in which $|OPEN_i| \geq p$. Then

$$TCT_{EO^*} \approx \omega\left(\frac{E_{EO^*}(z)}{p} + \frac{\epsilon}{2}\left(E^2_{EO^*}(z)(l^2-l)\right.\right.$$

$$\left.\left. + E_{EO^*}(z)\left(2\lceil \log_l p\rceil pl + 2l^{\lceil \log_l \rceil+1} - pl - 2pl^2\lceil \log_l p\rceil - l\right)\right)\right)$$

The $E^2_{EO^*}(z)$ term is the dominant term in the whole equation. The speedup for $EO^*$ is tabulated in Table 1 where the increasing size of the OPEN queue apparently increases the ordering cost, which in turn increases the $EO^*$ single cycle cost dramatically over that of $AO^*$ as the cycle number increases.

Table 1

$EO^*$ Speedup $(=\frac{TCT_{AO^*}}{TCT_{EO^*}})$

$l=3, k=2, \epsilon=0.1,$

$\gamma=100, N=50, N_n=75$

| $p$ | $U_p$ |
|---|---|

## Distributed Queueing AND-OR Search: The FO* Algorithm

An algorithm that is more "distributed" than $EO^*$ is needed to eliminate the global bottleneck. Such an algorithm, called $FO^*$, assumes that an interconnection network connects all PEs to enable PSGs to be passed during the execution of $FO^*$. However, for the performance evaluation that follows, we assume that every PE has one or more PSGs and that no communciation between PEs takes place. Every PE does UCR to determine the next best PSG to expand. To terminate optimally, the system periodically checks if $f^j(s) > \alpha$ is satisfied for all $j$, where $f^j(s)$ is the cost of the best PSG in the $j^{th}$ processor.

### Cycle Types

Unlike $E^*$ and $EO^*$, $FO^*$ contains five distinct cycle types classified according to the patterns with which critical PSGs ( those having $f_i(s) \leq N$ ) and non-critical PSGs $(f_i(s) > N)$ appear in the PEs. Let $Q$ be the total number of critical PSGs in all the PEs at an instant during execution. Then the five cycle types can be described as:

(1) $PB$ $(p \leq Q)$

The $p$-best type $a$ cycle. Cycles belonging to this type has a critical PSG as the local best PSG in every PE, and every local best PSG is among the global $p$-best in the system. $PB_a$ is identical to the perfect cycle type in $EO^*$.

(2) $PB$ $(p > Q)$

The $p$-best type $b$ cycle. This type corresponds to the mixed cycle in $EO^*$. This cycle expands not only all the critical PSGs in the system but also some of the non-critical ones as well.

(3) $NPB_a$ ( $p \leq Q$)

The Not-$p$-best type $a$ cycle. Every OPEN has a critical PSG as its local best PSG, although not every one is global $p$-best.

(4) $NPB_b$ $(p \leq Q)$

The Not-$p$-best type $b$ cycle with $p \leq Q$. At least one PE in this cycle has a non-critical PSG, and therefore a non-global best PSG, as its local best PSG.

(5) $NPB$ $(p > Q)$.

The Not-$p$-best type $b$ cycle with $p > Q$. At least one PE in this cycle contains at least two globally best PSGs.

We may now define two probability parameters and a parameter for measuring the relative expansion power of an algorithm. First, the *existential probability* $P^i_e(I)$ is defined to be the probability of occurrence of cycle type $i$ in algorithm $I$ during execution. The *expansion probability* $P^i_{\exp}(I)$ is the probability of expanding the optimal solution in a cycle type $i$ of algorithm $I$. The product $P^i_e(I) \cdot P^i_{\exp}(I)$ gives us the *expansion power* of cycle type $i$ in algorithm $I$, where expansion power of a cycle type is the probability that it is that cycle type that will expand the optimal solution when given a random cycle. Using these two parameters we may define a new parameter, the power ratio $PR$, which measures the ratio of expansion powers of certain cycle types $M$ and $N$ in algorithms $C$ and $D$, respectively.

$$PR(C_M, D_N) = \frac{\sum\limits_{i \in M} P^i_e(C)\, P^i_{\exp}(C)}{\sum\limits_{j \in N} P^j_e(D)\, P^j_{\exp}(D)} = \frac{E_{DN}(z)}{E_{CM}(z)}$$

where $E_{DN}(z)$ and $E_{CM}(z)$ are the expected numbers of nodes expanded by cycle set $N$ in algorithm $D$ and cycle set $M$ in algorithm $C$ respectively.

### Expected number of nodes for FO*

Let cycle type 1 and type 2 be the perfect cycle and the mixed cycle in $EO^*$ respectively. Then

$$E_{FO^*}(z) = \frac{E_{EO^*}(z)}{PR(FO^*_{1,2,3,4,5}, EO^*_{1,2})}$$

$$\leq E_{EO^*}(z) \cdot \left( \frac{P^1_{\exp}(EO^*)P^1_e(EO^*)}{\sum\limits_{i=1,3,4} P^i_{\exp}(FO^*)P^i_e(FO^*)} + \frac{P^2_{\exp}(EO^*)P^2_e(EO^*)}{\sum\limits_{i=2,4} P^i_{\exp}(FO^*)P^i_e(FO^*)} \right)$$

We will denote the first term inside the parentheses power ratio $PR_1$, and the second term $PR_2$.

### Assumptions for FO*

If the number of critical PSGs in a $EO^*$ cycle is taken to be $Q$, then we can assume that the probability of expanding the optimal PSG in this cycle to be $\frac{p}{Q}$ if all $p \leq Q$. Thus $P^1_{\exp}(EO^*) = \frac{p}{Q}$ and $P^2_{\exp}(EO^*) = 1.0$ for the perfect and the mixed cycles of $EO^*$ respectively. For the cycle types of algorithm $FO^*$ we have:

(1) Type 1.

Same as the perfect cycle of $EO^*$. That is, $P^1_{\exp}(FO^*) = \frac{p}{Q}$.

(2) Type 2.

Same as the mixed cycle of $EO^*$. That is, $P^i_{\exp}(FO^*) = 1.0$.

(3) Type 3.

In this cycle type every local best PSG is a critical PSG, but not every local best PSG is also global best. Again w estimate the expansion probability to be $P^3_{\exp}(FO^*) = \frac{p}{Q}$.

(4) Type 4.

In this cycle there is at least one PE that has a non-critical, non-global best as its local best PSG. Letting the number of local best PSGs that are also global best be $r$, then $P^4_{\exp}(FO^*) = \frac{r}{Q}$, where $r \leq p$.

(5) Type 5.

In this cycle there exists at least one PE that has at least two critical PSGs as its top two PSGs. We use a lower bound $\frac{1}{G_1}$ for $P^5_{\exp}(FO^*)$, where $G_1$ is the number of global best PSGs in the PE that has the largest number of global best PSGs in the system. To understand this lower bound see [8].

Since we are only interested in an upper bound of $E_{FO^*}(z)$, we will assume that $P^1_e(EO^*) = P^2_e(EO^*) = 1.0$. The existential probabilities of all five cycle types of $FO^*$ is computed in the following section by using combinatorial analysis.

## The Power Ratio and Combinatorial Analysis

The existential probabilities can be determined by examining how $p$-best PSGs rank among other PSGs in heuristic merit in every processor. The number of combinations of $p$-best PSG rankings in different PEs, given the number of local queues that do not possess any $p$-best PSGs (known as the *bad queues*), is known as an *i-combination* (denoted by $BQ_i$ ), where $i$ is the number of local queues lacking $p$-best PSGs. For example, if $p=5$ and $i=2$, a possible configuration in the 2-combination is

queue 1: 1,4
queue 2: none
queue 3: 3
queue 4: 2,5
queue 5: none

where the numbers 1,4 in queue 1 indicates that queue 1 has the first and the fourth best PSGs in the system. We also define a *pattern* to be a set of numbers where each number corresponds to the number of $p$-best PSGs in an unspecified queue. For instance, if $i=2$, then there are two possible patterns: 3-1-1 and 2-2-1, where each number separated by a dash denotes the number of $p$-best PSGs queued up at a local OPEN queue without considering which processor this queue belongs. Every such number in the pattern is referred to as a *digit*. The number of combinations in $BQ_i$ ( combinations with $i$ number of bad queues ) can be written as:

$$BQ_i = \binom{p}{i}\sum_{all\ j}\left(\frac{\left(p-i\right)!\prod_{n=0}^{m}\binom{p-\sum_{l=0}^{n}c_l^j k_l^j}{c_{n+1}^j}}{\prod_{l=1}^{m}k_l^j!}\right)$$

where $c_0^j=0$ for all $j$, $1 \le i \le p-1$, and $j$ is the total number of patterns possible for $i$ bad queues, $p$ is the number of PE's, $c_l^j$ is the $l^{th}$ digit of the $j^{th}$ pattern, $k_l^j$ is the number of times the $l^{th}$ digit appears in the $j^{th}$ pattern and $m$ is the total number of distinct digits in the $j^{th}$ pattern. The existential probability of a cycle type $i$ can be expressed as

$$P_e^i(FO^*) = \frac{\sum_{m\in M} BQ_m}{\sum_{n=0}^{p-1} BQ_n}$$

Since every OPEN queue in $FO^*$ determines its best PSG by using local UCR, the equation for total cycle cost for $FO^*$ is identical to that of $AO^*$ except for a substitution of $\frac{E_{FO^*}(z)}{p}$ for $E_{AO^*}(z)$. Therefore,

$$TCT_{FO^*} \le \omega\left(\frac{E_{FO^*}(z)}{p}\left(1 + \frac{\epsilon(l-1)\ln\frac{(lkE_{FO^*}(z)}{p})}{\ln lk} - \frac{\epsilon(l-1)}{\ln lk}\right)\right.$$
$$\left. + \frac{\epsilon(l-1)}{\ln lk}\left(1+\ln lk\right)-1\right)$$

The Table 2 shows a decreasing trend for processor efficiency. However, the rate of decrease is relatively small, and the speedup is large enough to justify the use of local queueing over global queueing for small $p$.

Table 2
$FO^*$ Measurements
$l=3,k=2,\epsilon=0.1,\gamma=100,N=50,N_n=75$

| $p$ | $PR_1$ | $PR_2$ | speedup | efficiency | $E_{FO^*}(z)$ |
|---|---|---|---|---|---|
| 2 | 0.75 | 0.75 | 0.75 | 0.38 | 6867 |
| 3 | 0.70 | 0.59 | 0.96 | 0.32 | 8199 |
| 4 | 0.68 | 0.51 | 1.17 | 0.29 | 9179 |
| 5 | 0.67 | 0.51 | 1.38 | 0.28 | 9865 |
| 6 | 0.67 | 0.44 | 1.59 | 0.27 | 10449 |
| 7 | 0.66 | 0.42 | 1.80 | 0.26 | 11006 |
| 8 | 0.66 | 0.41 | 2.02 | 0.25 | 11368 |
| 9 | 0.66 | 0.40 | 2.24 | 0.25 | 11744 |
| 10 | 0.65 | 0.40 | 2.48 | 0.25 | 12014 |

## Conclusion

In this paper we have examined the performances of two parallel search algorithms. When only the number of nodes expanded is taken into account, we show that the speedup is linear for a large number of processors. However, when one also considers ths cost of managing a global queue, especially in the context of AND-OR search, then the availability of more processors in $EO^*$ actually slows down execution. Finally, it has been shown that algorithm $FO^*$, which uses local UCR, performs much better than $EO^*$.

**ABSTRACT** This paper presents an algorithm to perform the parallel prefix operation on a linked list of items. Let $N$ be the length of the list, and let $P$ be the number of processors. The algorithm described here runs on a fully connected direct connection machine (DCM) in time $O(N/P + P^2)$. It attains linear speedup for $N=\Omega(P^3)$. Previously, linear speedup has only been attained on shared memory models.

## 1. Introduction

Graph algorithms for sequential machines have received intensive study, and by now the basics, at least, are well understood. In contrast, the study of parallel algorithms began fairly recently; even for some seemingly simple problems, efficient parallel algorithms are hard to find. Two fundamental problems are product computation and initial prefix computation. The *product computation* problem is to compute the product $a_0 o\, a_1 o \cdots o\, a_{N-1}$, given $N$ elements $a_0, a_1, ..., a_{N-1}$, and a binary, associative operation, denoted $o$. The *initial prefix* problem is to compute all $N$ initial prefixes $a_0$, $a_0 o\, a_1$, The initial prefix problem when solved in parallel is known as *parallel prefix*. In this paper, we present efficient parallel algorithms for product computation and initial prefix computation, when the elements are stored in a linked list. As shown in [8], these results can be used to obtain efficient parallel algorithms for other graph theoretic problems.

Since parallel processors will be built with a fixed number of processors, and since users tend to push the limits of their machine, it is important to consider the situation in which there are fewer processors than data elements. In such cases, the user wishes to use all the processors efficiently. We assume that there are $p \leq N$ processors cooperating (to solve a problem of size $N$). We desire parallel algorithms that solve a problem in $\Theta(t(N)/p)$ time, where $t(N)$ is the sequential time to solve the problem; this is called *linear speedup* and is always optimal.

Various models of parallel computations have been studied. In the *PRAM* model, a set of processors can all concurrently access shared memory. Three variants are distinguished depending on the type of simultaneous action permitted to each memory cell: The most powerful model, the *CRCW*, allows concurrent reading and writing to any cell by any number of processors. The *CREW* model requires that no two processors simultaneously write to the same cell; however, simultaneous reading is allowed. The *EREW* model restricts reading and writing so that no two processors can simultaneously access (read or write) the same cell. In contrast to the PRAM model, a somewhat more realistic model is the *Direct Connection Machine (DCM)*: Memory is divided into memory modules with an equal number of processors and memory modules. Any processor can access any cell in any module; however, simultaneous access to any module is prohibited (even if the accesses are to different cells).

The product and prefix problems have been extensively studied for the case that the memory layout of the input is *data independent*, i.e. the location of $x_i$ is determined by the index $i$ [3],[5],[6],[9],[11],[14]. In the *data dependent* versions of the product and initial prefix problems, the locations of the elements are given but it is not known which element is which. Only the location of the first element is given along with a map from the $i$th element to the $(i+1)$st element. In practice, the mapping will be represented as a linked list, so that if element $i$ is contained in $A[j]$ then element $i+1$ is contained in $A[Next[j]]$. It is easy to solve the product and initial prefix problems sequentially in $O(N)$ time by starting at the first element and following the links. Examples of such problems are that of computing the rank of each element on a linked list, or that of labeling each element of a linked list with the name of the first element of the list.

The *parallel prefix operation* may be described as follows. We are given a set $S$ of items, together with an associative binary operation $o$ on these items. Let

$$(x_1, x_2, \ldots, x_N)$$

be a list of items, $x_i \in S$, $1 \leq i \leq N$. The parallel prefix operation produces the list of items

$$(x_1, x_1 o x_2, \ldots, x_1 o x_2 o \cdots o x_N),$$

i.e. the $i$th item is the $i$th partial product $x_1 o x_2 o \cdots o x_i$. Parallel prefix is an extremely important operation on parallel machines. For example, it is used in efficient parallel algorithms to solve the following problems (see [1],[2],[4],[10],[12],[15]):

(1) summing, i.e. the operation is ordinary addition;

(2) broadcast a value to all processors;

(3) packing data items;

(4) preorder and postorder traversal of trees;

(5) graph problems, such as finding connected components.

In general, the efficiency of the known algorithms to implement parallel prefix depends upon the data structure used to represent the list of items. When the items are stored in contiguous memory locations, i.e. in an array, we have the following previous results. Let $P$ denote the

Part of this work was done while the first author was at the University of Illinois and the third author was at Carnegie-Mellon University. The first author was supported in part by a grant from IBM.

0190-3918/86/0000/0278 $01.00 © 1986 IEEE

number of processors. There is an $O(N/P + \log P)$ algorithm for parallel prefix on the Shuffle Exchange Machine (see [12]). This readily yields an algorithm of the same time complexity for a fully connected Direct Connection Machine (DCM) and for the (EREW) PRAM (exclusive-read, exclusive-write parallel RAM). Parallel prefix when the data items are stored in a linked list was first discussed in [18]. There is an $O(\frac{N \log N}{P \log(2N/P)})$ algorithm for the EREW [7]. It attains linear speedup for $N = \Omega(P^{1+\epsilon})$, $\epsilon > 0$ any constant. See [17] for randomized shared memory algorithms.

This paper describes an algorithm for parallel prefix on a linked list that runs in time $O(N/P + P^2)$ on a fully connected DCM. It attains linear speedup for $N = \Omega(P^3)$.

Recently, researchers have become interested in finding good models of parallel computation, and studying the differences between the models. Upfal and Wigderson [16] show that any on-line simulation of $T$ steps of a PRAM takes at least $\Omega(T\frac{\log P}{\log \log P})$ steps on a DCM. Furthermore, they show that a fully-connected DCM can simulate any computation of an EREW PRAM at the cost of a factor of $O(\log P(\log \log P)^2)$ in running time (assuming that the size of memory is only polynomial in the number of processors). Together, the two results say that PRAM's are, in some sense, more powerful than DCM's, but not much more powerful.

To really prove that PRAM's are more powerful than DCM's, one should produce a (natural) problem that can be solved faster on a PRAM than on a DCM — not merely an algorithm that cannot be simulated efficiently step by step. While it certainly may be the case that such problems exist and may even be common, it is not easy to think of reasonable candidates — much less actually prove that some problem is hard on a fully connected DCM. Very small problems will not separate the models, because, if the problem is small enough, every data item can be placed in a separate memory module. (Depending on the exact rules for accessing common locations in a memory module, a fully connected DCM with at most one data item in each memory module will be equivalent to some PRAM model.) Intuitively, large graph problems would seem to be plausible candidates because of the difficulty in following pointers in parallel when there is more than one concurrent reference to the same memory module. The techniques in this paper coupled with some recently discovered techniques [8], will produce efficient DCM algorithms for many graph problems; thus, perhaps surprisingly, large graph problems do not separate (the power of) the two models. Our results, however, leave open the possibility that intermediate sized problems separate the models.

## 2. Preliminaries

The model of parallel computation that we will be primarily concerned with in this paper is the *fully connected* DCM. There are $P$ processing elements (PEs), each of which has a (large) local memory. We denote the $i$th processor by $\mathrm{PE}_i$, $1 \le i \le P$, and will refer to its local memory by $\mathrm{M}_i$. Each pair of processors is connected by a data link. During one cycle of the machine clock a processor may access its own or any other processors local memory. However, only one processor may gain access to the same local memory during any single cycle. So if $k$ processors attempt to access the same local memory at the same time, then it will take $k$ cycles before all of their requests are satisfied. In particular, during a single cycle, a set of memory cells may be simultaneously accessed only if they are all in different local memories. This is in contrast with the EREW PRAM, where any set of $k \le P$ distinct memory cells can be accessed simultaneously.

## 3. The Parallel Prefix Algorithm: An Outline

### 3.1. The Algorithm

The main idea of our parallel prefix algorithm is to reduce efficiently the size of the list by a constant factor, call the algorithm recursively, and then obtain the parallel prefix for the whole list from the parallel prefix for the collapsed list. Each of the nodes in the list consists of two parts: a *data item* and a *next link* pointing to the next item in the list. The data items are stored in arrays *Value[ ]*, and the next links are in arrays *Next[ ]*. We reduce the size of the list by *pairing* adjacent nodes, as illustrated in Fig. 1.

We assume that the $N$ data items are distributed evenly among the processors, i.e. about $N/P$ items in each local memory. If $N \le P$, there is at most one item per processor, and we can use the usual parallel prefix algorithm, which is given below. We assume without loss of generality that the data items are located in the first $N$ local memories.

```
for $j \leftarrow 1$ to $\log N$ do
    forall $i$, $1 \le i \le N$, in parallel do
        if $Next[i] \ne NIL$ then
            $Value[Next[i]] \leftarrow Value[i] \mathbin{o} Value[Next[i]]$;
            $Next[i] \leftarrow Next[Next[i]]$;
        end if
    end forall
end for
```

Now we consider the case when $N > P$. The following is a general scheme for solving this problem. We assume the existence of a predecessor map *Pred*, which is easy to construct in $O(N/P)$ time.

```
General Parallel Prefix Algorithm
    if the list contains more than one element then
        pick a set S of nonadjacent elements in the list;
        for each $x \in S$ do
            {replace a pair of adjacent elements by one
              element}
            $Value[Succ[x]] :=$
                $Value[x] \mathbin{o} Value[Succ[x]]$;
            $Succ[Pred[x]] := Succ[x]$;
            $Pred[Succ[x]] := Pred[x]$
        end for;
        execute algorithm recursively;
        for each $\mathrm{A} \in \mathrm{S}$ do
            {expand element back into a pair}
            $Value[x] := Value[Pred[x]] \mathbin{o} Value[x]$;
            $Succ[Pred[x]] := x$;
            $Pred[Succ[x]] := x$
        end for
    end if
```

The first part of the algorithm solves the product problem, successively compacting the list until only one item is left; the second part, where the recursion unfolds, expands the list back, and computes the missing partial products. Any parallel algorithm that solves the product problem by successive compaction can be used to create a parallel prefix algorithm that expands the list back, by matching step by step the compression operations done by the parallel product algorithm. The resulting algorithm will have about twice the running time of the original algorithm. We shall henceforth consider only the product part.

At the outermost level of the recursion, each processor will process its $N/P$ elements one at a time (replacing a pair of adjacent elements by one element). An efficient parallel implementation will process $O(P)$ elements at each time step. This must be done while avoiding two potential conflicts: First, no two adjacent elements can be processed at the same time (which would destroy the linked list). Second, no two processors can access the same memory module at the same time. The first type of conflict must be avoided when one is implementing this algorithm on a shared memory machine; the second type of conflict is unique to DCM machines. We ensure that neither type of conflict occurs by using a memory access routine described below. After pairing elements at the outermost level of the recursion, the elements are packed so that there are approximately an equal number of elements in each processor. The algorithm is then called recursively.

### 4. A Memory Access Technique

In this section we will describe and analyze a method for organizing memory references on a DCM. This is essentially a refinement of an idea due to Gottlieb and Kruskal [4]. It will allow us to obtain efficient parallel algorithms on the DCM (for $N >> P$). This section is organized as follows. One of the components of the main algorithm is a distributed maximal matching algorithm, which is discussed in the first subsection. The next subsection describes the memory access method itself, which is actually an algorithm schema intended to be used as a procedure in other algorithms. In the third subsection we analyze the parallel time required by our algorithm, under natural assumptions that will hold in all of our applications.

#### 4.1. Maximal Matching Algorithm

A *matching* in a graph is a set edges in the graph, no two of which share the same vertex. A matching is *maximal* if no edge from the graph can be added to it and still obtain a matching. There is an obvious sequential algorithm for finding a maximal matching in $O(E)$ time: start with the empty matching, and iterate through the edges one at a time, adding the edge to the matching if neither of its endpoints is already covered. Here we informally describe an $O(V^2)$ sequential algorithm that is easy to parallelize.

Let $N$ be the number of vertices, and number them 0 to $N$-1. For convenience we assume that $N$ is a power of two. We use a Boolean array *Matched* [0..$N$-1]. We initialize *Matched* $[i] \leftarrow$ **false** for all $i$, $0 \leq i < N$. The basic idea of the algorithm is as follows. We try to match the first $N/2$ vertices with the last $N/2$ simply by checking each possible pair of vertices $(i,j)$, with $0 \leq i < N/2$ and $n/2 \leq j < N$. We then call the algorithm recursively, trying to match up the first $N/2$ vertices among themselves, and the last $N/2$ among themselves. Here is a program describing the first level of recursion.

```
for $k \leftarrow 0$ to $N/2 - 1$ do
    for $i \leftarrow 0$ to $N/2 - 1$ do
        $j \leftarrow N/2 + (i+k) \bmod (N/2)$;
        if not Matched[$i$] and not Matched[$j$]
                and $\{i, j\} \in E$ then
            add edge $\{i, j\}$ to $M$;
            Matched[$i$]$\leftarrow$true ; Matched[$j$]$\leftarrow$true ;
        end if
    end for $i$
end for $k$
```

Assume that we have a fully connected DCM with $N$ processors. This algorithm is trivially converted to a parallel algorithm by simply performing the inner loop in parallel with $N/2$ processors on each level of the recursion. It is easy to see that the active processors (e.g. the first $N/2$ at the first level, the first $N/4$ and the third $N/4$ at the second level, etc.) do not have any memory conflicts among themselves. Moreover, since active processors only try to match with inactive ones, we avoid the undesirable situation where $\text{PE}_{i_1}$ is trying to match with $\text{PE}_{i_2}$, which in turn is trying to match with $\text{PE}_{i_3}$. Note that the algorithm is truly distributed in the sense that each processor only needs to know the identities of those other processors that it wants to match up with.

The recurrence relation for the parallel time required by the algorithm is

$$T(N) = cN/2 + T(N/2)$$

where $c$ is some constant. The first term arises because the inner loop (the **for** $i$) can be carried out in constant time using $N/2$ processors, and the second term is the time needed for the recursive calls. These calls are carried out independently in parallel. This is easily solved to obtain $T(N) = O(N)$.

#### 4.2. Memory Access Algorithm

During a computation there will be times when each processor wishes to access several (possibly many) locations and at each access process the data therein. Often it does not matter in what order the accesses occur or in what order the data is processed. Each processor will have a list of locations it wishes to access, and therefore a list of memory modules along with the locations in each module it wishes to access. An efficient parallel program will arrange the accesses so that no two processors conflict at a module.

Formally, a *memory access map* is a directed graph $G = (V, E)$ with $|V| = P$. Associated with each directed edge $e \in E$ there is an integer *weight* $w_e > 0$. There are no multiple edges; however, loops (i.e. edges of the form $(v,v)$) are permitted. Each vertex $v \in V$ represents a processor. There is an edge $e = (i, j) \in E$ if $\text{PE}_i$ needs to access $\text{M}_j$ $w_e$ times. In addition we associate a set $X_{ij}$ of elements, $|X_{ij}| = w_e$, with the edge $e = (i, j)$. These sets are not really a part of the memory access map, but are kept locally in each processor. They represent items that $\mathrm{PE}_i$ needs to process. As part of the processing of these items it is necessary for $\mathrm{PE}_i$ to access $\mathrm{M}_j$. The order in which the items are processed is irrelevant to the overall algorithm. That is, there do not exist processors $\mathrm{PE}_i$ and $\mathrm{PE}_j$ and items $x \in X_{im}$, $y \in X_{jn}$, such that $\mathrm{PE}_i$ must process $x$ before $\mathrm{PE}_j$ can process $y$.

If the set of edges $E'$ represents a set of accesses to memory modules, then the domain($E'$) is the set of processors involved in those accesses. Formally, if $E' \subseteq E$, where $G = (V, E)$ is a directed graph, then the *domain* of $E'$ is defined by

$$\mathrm{domain}(E') = \{i \in V \mid \text{there exists } j \in V \text{ such that } (i,j) \in E'\} .$$

We are now ready to describe the memory access procedure. Each of the steps is executed in parallel by each processor. Throughout the algorithm only one processor is ever active in a given local memory at the same time. The only information that each processor $\mathrm{PE}_i$ initially needs is the sets $X_{ij}$ for $j \neq i$.

Let $\tau$ be a threshold. We will determine its exact value later.

PROCEDURE: ACCESS MEMORY.

[A1] Considering only edges whose weights are larger than the threshold $\tau$, find a maximal matching $M$ in the current memory access map.

[A2] Find the minimum weight $w$ of any edge in the matching. Broadcast $w$ to all of the processors.

[A3] Each $\mathrm{PE}_i$ with $i \in \mathrm{domain}(M)$ executes the following code. (If $i$ is not in domain($M$) then $\mathrm{PE}_i$ is idle.)

```
let $j \in V$ be such that $(i, j) \in M$;
for $k \leftarrow 1$ to $w$ do
    choose an item $x \in X_{ij}$;
    $X_{ij} \leftarrow X_{ij} - \{x\}$;
    process $x$;
end for
```

[A4] Each processor now updates the part of the memory access map contained in its local memory. To do this, set $w_e \leftarrow w_e - w$ for each edge $e \in M$.

[A5] Repeat steps [A2]-[A5] until the weight of every edge is less than the threshold $\tau$.

[A6] Each $\mathrm{PE}_i$ executes the following code.

```
for $j \leftarrow 0$ to $P-1$ do
    for $k \leftarrow 1$ to $s$ do
        choose an item $x \in X_{i,i+j \bmod P}$
            (if there is one);
        $X_{i,i+j \bmod P} \leftarrow X_{i,i+j \bmod P} - x$;
        process $x$
    end for
end for
```

### 4.3. Analysis

We now analyze the ACCESS MEMORY algorithm. In order to calculate how many iterations there are of steps [A1]-[A5], consider any vertex $v$ in the memory access map. Since we always have a maximal matching of the memory access map for edges whose weights are greater than $\tau$, during an iteration either a vertex $v$ is matched, all of $v$'s neighbors are matched, or $v$ has no incident edge with weight greater than $\tau$. In the first case, the weight of $v$ will be reduced by $w > \tau$; in the second case, the weight of all its neighbors is reduced by $w > \tau$. Thus the total number of iterations of steps [A1]-[A5] involving vertex $v$ is at most the sum of its weight and the maximum weight of any of its neighbors, divided by $\tau$. Since each processor has weight at most $\lceil N/P \rceil$, there are are at most $2 \lceil N/P \rceil / \tau$ iterations.

Step [A1] is the maximal matching algorithm discussed above, and each invocation takes time $O(P)$. So all together, step [A1] takes $O(N/\tau)$ time. Step [A2] involves the standard minimizations and broadcast operations, and at each iteration takes time $O(\log P)$; hence, the total time required for [A2] is $O((N \log P)/(P\tau))$.

Reasoning as above, the total number of iterations of the **for** loop in step [A3] involving vertex $v$ is at most the sum of its weight and the maximum weight of any of its neighbors. This is $O(N/P)$ iterations.

Step [A4] takes constant time at each iteration.

Step [A6] iterates through all the memory modules, spending $O(\tau)$ time at each module. Thus step [A5] takes $O(P\tau)$ time.

By summing the costs of all of the steps, we find that the parallel running time of the entire ACCESS MEMORY algorithm is $O(N/P + N/\tau + P\tau)$. This is minimized for $\tau = \Theta(\sqrt{N/P})$, making the total time $O(N/P + \sqrt{NP})$.

## 5. The Parallel Prefix Algorithm: Details

### 5.1. The Algorithm

We now give a detailed description of the fully connected DCM parallel prefix algorithm outlined in Section 3.

ALGORITHM: PARALLEL PREFIX ON A LINKED LIST (DCM)

[P1] First we construct the memory access map as follows. Each processor partitions its $N/P$ data items into $P$ groups. The items in group $j$ are those whose next links reference local memory $\mathrm{M}_j$ of processor $\mathrm{PE}_j$. Group $j$ for $\mathrm{PE}_i$ is denoted by $X_{ij}$. Put $w_{ij} = |X_{ij}|$. Module $i$ will contain $w_{ij}$ for all $0 \leq j < p$.

[P2] Each processor now calls the procedure ACCESS MEMORY defined in the preceding section. To process an item $x \in X_{ij}$, the following code is used to pair the item with the next item. All of the items are initially undeleted (i.e. *Delete* $[x]$ = False).

```
$Value[Succ[x]] := Value[x] \; o \; Value[Succ[x]]$;
$Succ[Pred[x]] := Succ[x]$;
$Pred[Succ[x]] := Pred[x]$;
$Deleted[x] :=$ True;
```

Note that a second invocation of ACCESS MEMORY is required to adjust the *A.Pred* values. The matching automatically ensures that two adjacent elements will not both be updated at the same time.

[P3] For each item in the original linked list, either it has been paired with another item, or its predecessor and successor have been paired. Thus the size of the collapsed list is no more than $2N/3 + O(1)$. Now repack the undeleted items in order to ensure that the items of the collapsed list are distributed evenly among the processors. The repacking procedure is discussed separately below. Then call the algorithm recursively on the collapsed list.

[P4] Upon return from the recursive call, we must unpack the list, "unpair" the items that were paired in step [P2], and correctly compute the parallel prefix for the original list. In order to do this we will need to keep a record of the items that are paired together in step [P2] and where they are moved in step [P3]. An easy modification of the repacking algorithm itself can be used to do the unpacking. Using our additional information, it is straightforward to obtain the parallel prefix for the original list from the parallel prefix for the collapsed list.

Next we describe an algorithm to accomplish the repacking needed in step [P3]. The similarity of the repacking routine to the entire parallel prefix algorithm should be apparent.

### 5.2. Repacking a Linked List

ALGORITHM: REPACK A LINKED LIST (DCM).

[R1] Construct a memory access map as follows. Each processor counts the number of list items in its local memory. For $PE_i$ we denote this quantity by $N_i$. Each processor then sends to every other one a message indicating the number of items that it has. Now compute the sum $N' = \sum_{i=1}^{P} N_i$. If $N_i > N'/P$ then $PE_i$ will be a *sender*. If $N_i < N'/P$ then $PE_i$ will be a *receiver*. Let $S$ denote the set of senders, $R$ the set of receivers. Order the sets $S$ and $R$ arbitrarily but deterministically, e.g. by processor index. A sender $PE_i$ has an *excess* of items, defined by $e_i = N_i - N'/P$; a receiver has a *deficit*, $d_i = N'/P - N_i$. We now define the bipartite digraph that will serve as the memory access map. The set of vertices will be $S \cup R$. A directed edge will always go from a vertex in $S$ to a vertex in $R$. Each edge is labeled with a weight. We determine the edges and their weights as follows. Let $PE_i$ be the first sender, and let $PE_j$ be the first receiver. Add the edge $(i, j)$ to the digraph. Label it with the weight $w = \min\{e_i, d_j\}$. We now readjust the excess $e_i \leftarrow e_i - w$ and also readjust the deficit $d_j \leftarrow d_j - w$. If $e_i = 0$ then $PE_i$ is not considered further. Similarly, if $d_j = 0$ then $PE_j$ is not considered further. We repeat this process with the remaining senders and receivers until there are no more processors to consider. Each $PE_i$ that is a sender will select $w_{ij}$ items arbitrarily and put them in the set $X_{ij}$, for each edge $(i, j)$ in the digraph. (Note: The sets $X_{ij}$ constructed here are distinct from the ones in step [P1].)

[R2] Now call the procedure ACCESS MEMORY to move list items from the senders to the receivers. To process an item $x \in X_{ij}$, $PE_i$ does the following:

```
let $y$ denote a new location in $M_j$;
$A[y] \leftarrow A[x]$;
$Next[y] \leftarrow Next[x]$;
$Next[x] \leftarrow y$;
mark $x$ as "moved";
```

[R3] We must now readjust the next links. To do this we follow the links in parallel. This actually involves another application of the ACCESS MEMORY procedure; however, it is exactly the same as used before where every processor had to examine the successor of each node. When we follow a link and find that $Next[x]$ is marked as moved, then we set $Next[x] \leftarrow Next[Next[x]]$. This is done for all of the data items, including the newly created copies, but excluding those items marked as moved. Fig. 2 illustrates how a list item is moved, and how the next links are then readjusted.

### 5.3. Analysis

In this section we will obtain the time bound for our parallel prefix algorithm. First note that step [P1] of the algorithm can easily be accomplished in time $O(N/P + P)$. Each next link may be viewed as an ordered pair $(i, \alpha)$, where $i$ designates a local memory $M_i$ and $\alpha$ specifies an address within $M_i$. Each processor sorts on the $i$ coordinate of the next links. This takes time $O(N/P + P)$ using a bucket sort with $P$ buckets. Construction of the first maximal matching requires $O(P)$ time as describe previously.

Step [P2], the ACCESS MEMORY routine, takes time $O(N/P + \sqrt{NP})$.

Let $N'$ denote the number of items in the new (collapsed) list. The purpose of the repacking in step [P3] is to ensure that the items of the new list are distributed evenly across the processors, i.e. $N'/P$ per processor. The repacking routine takes time $O(N/P + \sqrt{NP})$. To prove this, first note that it is easy to see that the memory access map defined in step [R1] has at most $P$ vertices and $P$ edges, and the method of construction clearly takes time $O(P)$. For step [R2], a maximal matching can be found in time $O(P)$ and at least one edge is (effectively) eliminated at each iteration of steps [A1]-[A5] of ACCESS MEMORY. So the total time spent finding maximal matchings is $O(P^2)$. Now we can apply our theorem again. In this case the weight of each node is its excess or deficit, which must be at most $N/(2P)$. Thus the total time spent moving items is $O(N/P)$, and so steps [R1] and [R2] of the repacking take time $O(N/P + \sqrt{NP})$. Finally, by a similar analysis it can be shown that step [R3] of the repacking takes time $O(N/P + \sqrt{NP})$. The memory access map needed for that step is similar to the one constructed in step [P1] of the parallel prefix algorithm.

It is readily seen that after step [P2], all of the links in the list will have been considered. It follows that for every node in the list, either it has been paired with its predecessor or its successor, or else both its predecessor and its successor (with the obvious exception for the head and tail of the list) have been paired. Thus the length of the collapsed list is no more than $2N/3 + O(1)$. Let $T_P(N)$ denote the time required by the entire parallel prefix algorithm on a list of size $N$. Then we have the recurrence relation

$$T_P(N) \leq c\,(\frac{N}{P} + \sqrt{NP}\,) + T_P(\frac{2N}{3})$$

for some constant $c$. We stop the recurrence when the number of items is less than $P$. At this point, the algorithm for one item per processor can be used to solve the problem in $O(\log P)$ time. The solution to the recurrence thus becomes:

$$T_P(N) = O(\frac{N}{P} + \sqrt{NP}\,)).$$

For $N >> P$ we have that $T_P(N) = O(N/P)$, so that the algorithm is totally efficient for $N$ large relative to $P$. In fact it is easy to see that the algorithm is totally efficient for $N = \Omega(P^3)$.

**6. Remarks**

For large $P$ a fully connected DCM is not feasible. It is well known, however, that some bounded degree connection machines, e.g. the Shuffle-Exchange machine, can simulate a fully-connected DCM at the cost of only an $O(\log P)$ factor in the running time. Nevertheless, due to the $P^2$ term in the running time, our algorithm as it stands is not practical for large $P$. Thus the obvious open problem is to find an efficient parallel algorithm for parallel prefix on a linked list that will run on a DCM and that is totally efficient for $N$ smaller than $\Theta(P^3)$.

# REPLICATION AND PIPELINING IN MULTIPLE-INSTANCE ALGORITHMS

Jaime H. Moreno, Tomás Lang

Computer Science Department
University of California, Los Angeles
Los Angeles, Ca. 90024

**Abstract.** An algorithmic model and a methodology to evaluate the effectiveness of replication, pipelining, and local parallelism in the implementation of multiple-instance algorithms are presented. In the class of algorithms considered, instances are divided into groups with dependences between corresponding instances of consecutive groups. The implementations use a variable number of identical operation units, and the methodology permits the selection of the most efficient combination of concurrency techniques for a given execution time. The methodology is illustrated with an example, and has been used to obtain implementations for the Singular Value Decomposition computation.

## 1.- Introduction

Replication, pipelining, and local parallelism are well-recognized methods used, separately or in combination, to improve the speed of execution of digital systems. For a given computation, there are many alternatives in the use of these concurrency techniques to satisfy performance and cost constraints. In this paper, we study the effectiveness of those techniques for a class of computations encountered in a variety of important applications. This class has the following characteristics:

- The overall computation corresponds to the **execution of many instances** of a certain algorithm. This characteristic is the basis for the use of replication and pipelining. The **instances are not totally independent** but can be divided into groups of independent instances. This property limits the degree of replication and pipelining that can be used in an implementation, and complicates the tradeoffs between these techniques.

- An instance of the algorithm is described by a **directed graph** (where nodes represent subcomputations and arcs correspond to precedences among the subfunctions), without loops nor conditionals excepting those required to detect the end of the computation.

- The class of implementations we consider uses only **one type of operation unit.** This unit can be single function or multiple function.

As an example of computations that belong to the class outlined above, we can mention those that are described by expressions of the form

$$A_x^y = A_x^{y-1} \, (+,*) \, B^{y-1}$$

where $A$ and $B$ are terms of any complexity, usually involving matrices. This includes, for instance, matrix multiplication, LU-decomposition, transitive closure, and singular value decomposition[a] (SVD), which are frequently used in signal processing applications [1,2,3]. The main recurrences in these algorithms are procedures to update the values of a matrix using a modifier term that may depend on the current value of the matrix. These algorithms have been considered suitable for systolic array implementations [4,5,6].

Our goal for the class of computations described is to reduce the execution time for a given number of operation units. We are interested in identifying those implementations that offer better efficiency in terms of speed/cost. Since the algorithms of interest are compute bound and have implementations with negligible communication delay [4,5,6], only the computation time and the cost of the operation units are the relevant parameters for the design.

Our design methodology consists of top-down decomposition and bottom-up grouping of the nodes in the graph of an algorithm. Our results show that:

- for low throughput (or equivalently, up to a speed-up equal to the number of independent instances), replicated or pipelined implementations with efficiency equal to 1 can be achieved.

- for larger throughput, it is necessary to use combinations of the concurrency techniques, including the local parallelism in the graph of the algorithm. If portions of the graph have varying degrees of parallelism, pipelined implementations can be more effective because they require the addition of operation units only to those stages that exhibit greater local parallelism.

We have used this methodology to evaluate implementation alternatives for the singular value decomposition (SVD). It is shown in [7] that significant improvement in efficiency is possible by using a combination of pipelining and local parallelism, with respect to what is achieved in the replicated implementation (i.e. a linear systolic array) proposed in [5].

Previous research in the evaluation and selection of concurrency techniques includes [8] and [9]. However, these works deal with particular implementations (two-dimensional arrays, general purpose architectures, respectively), which are different from the ones sought here. Other related researches present formal models for the analysis of algorithms and ar-

[a] In the SVD, data dependencies are with two instances of the previous group instead of one. However, the model can be easily adapted to account for such situation.

chitectures [10, 11]. These approaches provide formal descriptions of hardware structures and algorithms, but assume the existence of an array of processors and attempt to map algorithms onto it, without evaluating other possible concurrent implementations. A combination of concurrency techniques is described in [12], which presents a two-level pipelined systolic array to perform convolutions. Such scheme deals with one specific algorithm and does not provide a methodology to select, among the alternatives for concurrency, an implementation for any given algorithm.

This paper is organized as follows. In Section 2, we present an algorithmic model for the class of computations of interest and a methodology for the design and evaluation of implementation alternatives. In Section 3 and 4 we discuss the characteristics of the concurrency techniques when applied to this class of algorithms, and we evaluate different implementation alternatives using only one or a combination of the techniques.

## 2.- Algorithmic Model and Methodology

In this section, we formalize a model for the class of algorithms considered, and define a set a performance and cost measures for implementations using concurrency. We also describe the methodology for the design and evaluation of such alternatives.

To design the system for a given computation it is necessary to describe the algorithm in a suitable form. Several models have been used to represent the dependences between subfunctions, including conditionals and loops [13, 14]. We use a directed graph in which nodes correspond to subcomputations and arcs indicate the precedences between these subcomputations. For the class of algorithms considered here, it is sufficient to use AND conditions as shown in Figure 1.

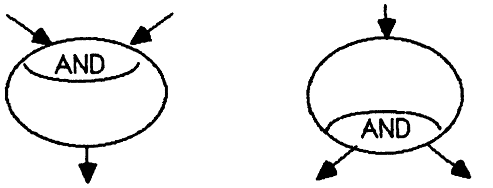

Figure 1 - Dependence Graph Elements

The primitive subcomputations used in the algorithm can have any level of complexity. Depending on this level (also called the **granularity** of the algorithm), implementations with different degrees of concurrency can be obtained. It is clear that larger concurrency can be obtained for finer granularity, which would indicate that it is always convenient to consider the representation with the finest granularity. However, this can lead to descriptions with large number of nodes, making the design of the system complex and unstructured. Therefore, it is convenient to resort to a structured design, in which one begins with the algorithm consisting of a relatively small number of nodes and then refines each of the nodes into subalgorithms. This top-down approach has the limitations that it is possible to loose some potential concurrency. The bottom-up approach is not totally satisfactory either, because the use of concurrency in the implementation of the node depends on how critical its execution time is in the overall algorithm. Consequently, the design process consists of several iterations until a satisfactory solution is found.

### Model of the Algorithm and the Implementation

From the considerations in Section 1, we can formalize the following model:

- The overall computation requires that an algorithm be executed for $M$ instances. These instances are divided into groups of $r$ each, where instance $x$ of group $y$ depends on instance $x$ of group $y-1$, as shown in Figure 2.

- The algorithm is described by a directed graph, in which the nodes are indivisible for a level of the implementation (i.e. the implementation of a node cannot be split across different processors or stages within a processor). Each node corresponds to a subfunction of the algorithm, and may exploit its internal concurrency using more than one operation unit. Therefore, for each node there might be more than one alternative implementation. To reflect this, the node is specified by a set of values $t_i(j)$ corresponding to its time of execution in an implementation with $j$ operation units.

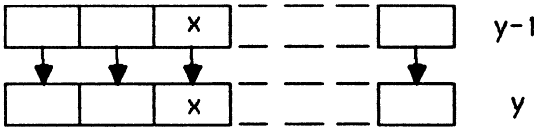

Figure 2 - Dependences between Groups of Instances

- Only one type of operation unit is used to execute all nodes. These operation units may be single function or multiple function and are considered indivisible. The use of a single type has implications in the design, since in such a case pipelining a sequential implementation of an algorithm requires additional units. (In contrast, if each node of the algorithm used a different type of unit, pipelining would not increase the number of those units).

- An increase in the number of operation units used to compute a node reduces its computation time at most proportionally to the number of units. Therefore,

$$t_i(j) \geq t_i(k) \geq \frac{j}{k} t_i(j) \quad , \quad k > j$$

For example, if a node corresponds to five independent operations as shown in Figure 3, then three or four operation units require two time units to compute the node, and the implementation with four units is not advantageous; however, the use of five units reduces the computation time to one.

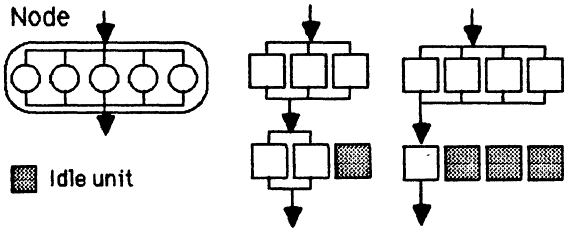

Figure 3 - Tradeoffs in Computation Time and Number of Operation Units

## Performance, Cost Measures, and Design Objective

Alternative implementations are compared using the following performance and cost measures:

- $t$: Time of execution of the computation (all $M$ instances of the algorithm).
- $N$: Total number of operation units.
- $SU = t_{cs} / t$ : Speedup of the concurrent implementation with respect to a **completely-sequential implementation** (with time $t_{cs}$), which uses only one operation unit to execute all nodes.
- $E = (t_{cs}\ N_{cs})/(t\ N)$ : Efficiency in a concurrent implementation with respect to the reference system. For our case, $N_{cs} = 1$.

Since we assume that there is only one type of operation unit, and since the computation time decreases at most proportionally to the number of units, **the speedup of any alternative is less or equal to $N$ and its efficiency is less or equal to 1.**

In terms of these measures, the main objective of the design can be described as selecting the implementation that for a given speedup (or computation time) has the largest efficiency (or uses the minimum number of operation units).

## 3.- Characteristics of Replicated, Parallel, and Pipelined Systems

We apply now the concepts of replication, pipelining and local parallelism to the class of algorithms described earlier. We evaluate the characteristics, performance, and cost measures for different implementations, using only one of the concurrency approaches in a given system, and provide a comparison of the resulting measures. In the next section, we will look at systems which use a combination of approaches.

To illustrate the choices that can be made we use the following example. We consider an algorithm that is executed for $M = 104$ instances and with dependences in groups of $r = 8$. At the topmost level in the design methodology, this algorithm appears as one node which requires only one operation unit and its computation time is $20M$ (completely - sequential implementation), as shown in Figure 4a. If higher throughput in the computation is desired, it is possible to decompose the node into subcomputations and then study the effectiveness of the concurrency techniques in the implementations of the decomposed algorithm. This process is repeated until a desired throughput is achieved.

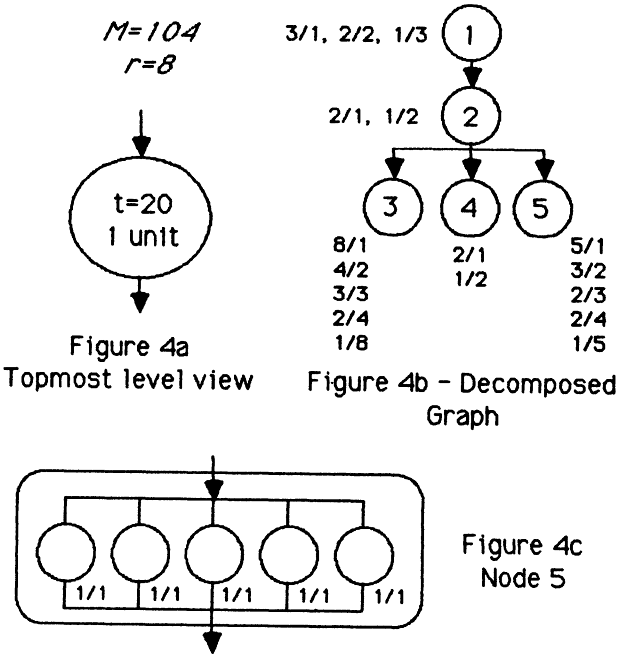

Figure 4a
Topmost level view

Figure 4b - Decomposed Graph

Figure 4c
Node 5

Figure 4 - Example Algorithm with Concurrent Capabilites

Consider now that the algorithm is described by Figure 4b. In this decomposed graph, each node has several alternative implementations with different number of operation units. This data was obtained from an analysis of each node, searching for internal parallelism and devising possible implementations for them. Figure 4c shows the structure of node 5 resulting from such analysis. The alternative implementations are indicated by the descriptors $t/n$ next to each node ($t$: computation time, $n$: number of units).

## Sequential Implementations

The sequential implementations are considered first, since they form the basis for some of the others. **An implementation of an algorithm is sequential if only one node (subfunction) is executed at a time.** To obtain this type of implementation the graph of the algorithm must have a total ordering of the nodes, which can be obtained by adding precedences. Since nodes may use more than one operation unit, we call $t_{seq}(j)$ the computation time of the sequential implementation that uses $j$ operation units. The following expressions describe the performance and cost measures for the sequential implementations:

$$\text{Comput. Time} \quad t_{seq}(j) = M \sum_i t_i(j)$$

$$\text{Speedup} \quad SU_{seq}(j) = \frac{t_{cs}}{t_{seq}(j)}$$

$$\text{Efficiency} \quad E_{seq}(j) = \frac{t_{cs}}{t_{seq}(j)\, j}$$

Table 1 includes the performance achievable with this scheme for the algorithm used as example.

### Replicated Systems

For our purposes, **a replicated implementation of an algorithm performs several instances of the computation simultaneously, using identical and separate hardware resources (processors) for each of the simultaneous instances.** Figure 5 shows an example of a replicated implementation of an algorithm. Due to the dependencies between instances in the class of algorithms considered, the number of instances executing simultaneously should be less or equal to $r$, the number of instances in a group. However, instances $x+1, x+2, ..., r$ in a group may be computed simultaneously with instances $1, 2, ..., x-1$ in the following group.

Consequently, if the hardware required to process an instance (a processor) is replicated $P$ times, the execution time of the $M$ instances, for $P \leq r$, is

$$t_{rep}(j,P) = \lceil M/P \rceil \frac{t_{seq}(j)}{M}$$

since the instances are performed in sets of $P$, excepting the last set which might be smaller than $P$. In particular, if $P = r$ then all instances in a group are processed at once and

$$t_{rep}(j,r) = \frac{t_{seq}(j)}{r}$$

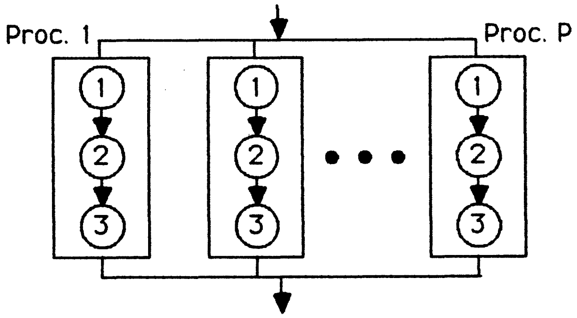

Figure 5 - Replicated Implementation of an Algorithm

The speedup and efficiency with respect to the completely-sequential implementation are

$$SU_{rep}(j,P) = \frac{t_{cs}}{t_{rep}(j,P)} = \frac{M}{\lceil M/P \rceil} SU_{seq}(j)$$

$$E_{rep}(j,P) = \frac{t_{cs}}{t_{rep}(j,P)\, jP} = \frac{M/P}{\lceil M/P \rceil} E_{seq}(j)$$

For the important case in which $M \gg r \geq P$, these expressions become

$$SU_{rep}(j,P) = P \; SU_{seq}(j)$$

$$E_{rep}(j,P) = E_{seq}(j)$$

Consequently, the maximum speedup is $r \; SU_{seq}(j)$ and the efficiency is the same as that of the sequential implementation that is being replicated. Therefore, **replication of the completely-sequential implementation is an optimal solution for speedup less or equal to $r$,** since efficiency $E = 1$ is preserved. For larger speedup, it is necessary to replicate a sequential implementation with $j$ units, which has lower efficiency.

| $j$ | $SU_{seq}$ $(j)$ | $SU_{rep}$ $(j,2)$ | | $SU_{rep}$ $(j,8)$ | $E_{rep}$ $(j,P)$ |
|---|---|---|---|---|---|
| 1 | 1.00 | 2.00 | -- | 8.00 | 1.00 |
| 2 | 1.82 | 3.64 | -- | 14.56 | 0.91 |
| 3 | 2.50 | 5.00 | -- | 20.00 | 0.83 |
| 4 | 2.86 | 5.72 | -- | 22.88 | 0.71 |
| 5 | 3.33 | 6.66 | -- | 26.64 | 0.67 |
| 6 | 3.33 | 6.66 | -- | 26.64 | 0.55 |
| 7 | 3.33 | 6.66 | -- | 26.64 | 0.48 |
| 8 | 4.00 | 8.00 | -- | 32.00 | 0.50 |

Table 1 - Replication of Sequential Implementations

Table 1 depicts this alternative for the algorithm in Figure 4, for different values of $j$ and $P$, up to the maximum replication $P = r = 8$.

### Pipelined Systems

In a pipelined implementation, **an algorithm is divided into stages and different instances are executed simultaneously at different stages** [15]. To perform the partitioning into stages, the algorithm should be sequential (i.e. precedences among nodes are such that a total ordering of nodes exists). Since each of the nodes in the graph is viewed as indivisible, two restrictions arise:

- A stage is composed of one node or a set of consecutive nodes. This partitioning is done (adding delays if necessary) so that the resulting stages have an (approximately) uniform delay.

- The maximum possible number of stages in the pipeline is equal to the number of nodes in the graph.

The number of stages $S$ is also limited by the number of independent instances, such that $S \leq r$. In terms of the number of stages $S$ and the stage delay $t_S$, the pipelined implementations are described by

$$\text{Comput. Time:} \quad t_{pipe} = [S + (M-1)]\, t_S$$

Speedup: $SU_{pipe} = \dfrac{t_{cs}}{[S + (M-1)]\, t_S}$

Assuming that the implementation that uses $j$ operation units is pipelined, then the stage delay with $j$ units is

$$t_S(j) \geq \frac{t_{seq}(j)}{M\, S}$$

Therefore,

$$SU_{pipe}\,(j,S) \leq \frac{M\, S}{S + (M-1)}\, \frac{t_{cs}}{t_{seq}(j)} = \frac{M\, S}{S + (M-1)}\, SU_{seq}(j)$$

In these expressions, the equality is achieved when the partitioning of the sequential implementation can be done perfectly, that is, into stages of uniform delay.

The total number of operation units is the sum of the units used in each stage. Since we are pipelining the sequential implementation with $j$ units, $j$ units per stage are used, which results in an efficiency with respect to the completely - sequential implementation of

$$E_{pipe}(j,S) \leq \frac{t_{cs}}{t_{pipe}(j,S)\, j\, S} = \frac{M}{S + (M-1)}\, E_{seq}(j)$$

In this case, the efficiency of the sequential implementation is reduced as a result of the startup time of the pipeline.

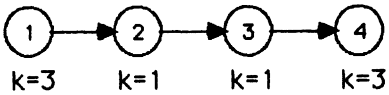
Of special interest is the situation in which $M \gg S$. In such case, the speedup and the efficiency tend to

$$SU_{pipe}(j,S) \leq S\ SU_{seq}(j)$$

$$E_{pipe}(j,S) \leq E_{seq}(j)$$

For perfect pipelining (no delay added to the stages) these expressions are identical to those obtained for replicated systems. Consequently, this alternative would be preferred to replication when the latter has implementation problems (such has interconnection complexity), since pipelining only requires communications between stages. However, pipelining is limited by the number of nodes in the graph of the algorithm.

Larger efficiency using pipelining can be obtained if all stages do not need the same number of units. Consider for example the algorithm shown in Figure 6, in a sequential implementation which uses three units. If such algorithm is pipelined, the stages in the middle do not need three units but only one (since fewer operations are involved), without affecting the computation time. As a consequence, the resulting efficiency is higher than what was obtained when all stages had the same number of units.



k: number of independent operations in a node

Figure 6 - Saving Operation Units in a Pipelined Implementation

| $j$ | $S$ | $SU_{pipe}$ $(j,S)$ | $E_{pipe}$ $(j,S)$ | $N_{saved}$ |
|---|---|---|---|---|
| 1 | 2 | 1.98 | 0.99 | 0 |
|  | 3 | 2.45 | 0.82 | 0 |
| 2 | 2 | 3.30 | 0.83 | 0 |

|  | 4 | 9.71 | 0.88 | 5 |
| 5 | 2 | 6.60 | 0.83 | 2 |
|  | 3 | 9.80 | 0.82 | 3 |
| 8 | 2 | 6.60 | 0.83 | 8 |
|  | 3 | 9.80 | 0.82 | 12 |
|  | 5 | 19.20 | 0.96 | 20 |

Table 2 - Pipelining of Sequential Implementations

Table 2 shows what is achievable with this approach in the algorithm described in Figure 4. The last column in this table indicates the number of units which are not needed for each one of the implementations.

The pipelined implementations require registers between stages. The addition to the cost and to the execution time that these registers produce is assumed to be negligible. This is true if the cost and delay of the stages are much larger than those of the registers. Also, the control of the system becomes somewhat more complex since each stage has to be controlled independently and the delays of the stages have to be made equal.

## Systems with Local Parallelism

We consider that **an implementation of an algorithm has local parallelism when it exploits the parallelism present in the graph to perform independent nodes concurrently.** Consequently, the time of execution of the sequential implementation might be reduced, but this may require additional operation units.

The speedup depends on the characteristics of the graph and on the scheduling of the nodes. An optimal schedule has to be devised to obtain the maximum speedup for a given number of operation units. In general, the determination of this schedule requires an exhaustive search, so several suboptimal heuristics and upper and lower bounds have been developed [16]. However, for algorithms with few nodes the exhaustive search is possible and convenient.

Since the improvements in computation time are, in the best case, proportional to the number of units, the speedup and the efficiency are bounded by

$$SU_{par}(j) \leq j \quad , \quad E_{par}(j) \leq 1$$

Without performing the actual scheduling it is not possible to know whether the parallel implementation (with $j$ operation units) is more efficient than the corresponding sequential one. That might be the case in computations with few instances or algorithms with dependences between groups of few instances.

This scheme is described in Table 3 for the example. A scheduling was performed for each value of $j$, which resulted in some implementations where nodes are executed in parallel (marked with *). The table also indicates the implementation chosen for each node.

In this section we have evaluated implementation alternatives for a given algorithm, using only one concurrency technique. The results obtained for the example algorithm are presented in Figure 7, where they are also compared with implementations using combinations of concurrency approaches, which are discussed in the next section.

| $j$ | $SU_{par}$ $(j)$ | $E_{par}$ $(j)$ | Implementation of Nodes 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|---|---|
| 2 | 1.82 | 0.91 | 2/2 | 1/2 | 4/2 | 1/2 | 3/2 |
| 3 | 2.50 | 0.83 | 1/3 | 1/2 | 3/3 | 1/2 | 2/3 |
| 4 | 3.33 | 0.83 | 1/3 | 1/2 | 2/4 | 2/1* | 2/3* |
| 5 | 4.00 | 0.80 | 1/3 | 1/2 | 2/4* | 2/1* | 1/5 |

** : nodes in parallel*

Table 3 - Implementations Using Local Parallelism

## 4.- Combinations of Replication, Local Parallelism and Pipelining.

In an implementation it is possible to combine two or all three of the approaches discussed previously. The characteristics of these combinations are described now and the corresponding performance and cost measures are evaluated.

### Replication and pipelining

In this case **the pipelined processor is replicated.** Because of the necessity of having enough independent instances, for the class of algorithms considered here the total number of processors and stages combined is limited so that $PS \leq r$. The following two possibilities exist:

- Replication of the pipelined completely-sequential implementation. This alternative produces a speedup of $PS$ and has efficiency 1 for large $M$ and values of $S$ that result in perfect pipelining. In such a case, this is equivalent in speedup and efficiency to the implementation that uses only replication. Therefore, its only advantage is that it requires fewer processors than the replicated implementation (which may replicate processors up to $r$, eventually creating realization problems such as a complex interconnection among the processors).

- Replication of the pipelined implementations that use more than one operation unit in some stages. These implementations increase the speedup of the single pipelined processor and maintain its efficiency. They are therefore suitable for higher speedups than that available with replication of the completely-sequential implementation.

For the example discussed, this scheme corresponds to implementations that are replications of the alternatives in Table 2, with $PS \leq 8$. Table 4 shows, for each possible number of stages, the configuration that offers the highest efficiency with that many stages.

| $S$ | Units per PE | $SU_{rep/pipe}(S,P)$ $P=1$ | $P=2$ | $P=3$ | $P=4$ | $E_{rep/pipe}$ $(S,P)$ |
|---|---|---|---|---|---|---|
| 2 | 4 | 3.30 | 6.60 | 9.90 | 13.20 | 0.83 |
| 3 | 8 | 6.54 | 13.08 | - | - | 0.82 |
| 4 | 11 | 9.71 | 19.42 | - | - | 0.88 |
| 5 | 20 | 19.20 | - | - | - | 0.96 |

Table 4 - Replication of Pipelined Processor with more than one Unit per Stage

### Replication and graph parallelism

**A processor which uses graph parallelism is replicated** in this implementation. It provides an increase of speedup with an efficiency equal to that of the implementation using only graph parallelism. Usually this efficiency will be significantly smaller than 1. Consequently, this scheme is only effective if the speedup cannot be achieved using a more efficient technique.

For the example discussed, this approach corresponds to implementations which are replications of the alternatives in Table 3. The maximum speedup achievable in the example with this scheme and the corresponding efficiency are

$$SU_{rep/par}(P=8, j=8) = 40.0$$

$$E_{rep/par}(P = 8, j = 8) = 0.63$$

Pipelining and graph parallelism

In this case, **one or more of the stages of the pipeline uses graph parallelism** (i.e. it executes more than one node concurrently). The partitioning into stages has to be modified (with respect to the implementation using pipelining only) to obtain stages of equal delay.

This scheme might be effective in increasing the efficiency of the pipeline, since it can help to get stages of equal delay and to tailor the number of operation units to the exact requirements of the stage. The number of stages is restricted by the number and the characteristics of the nodes. Nodes may be rearranged (preserving the dependences, of course) to achieve stages of (approximately) equal delay. The smallest stage delay possible is determined by the node with the longest computation time. The maximum number of stages is determined by the number of nodes in the critical path of the graph.

For the example discussed, Table 5 shows alternative implementation for different stage delays. Since the critical path in the graph traverses three nodes, up to three stages are possible.

| $t_S$ | $S$ | Total Units | $SU_{pipe/graph}$ $(j,S)$ | $E_{pipe/graph}$ $(j,S)$ |
|---|---|---|---|---|
| 7 | 2 | 3 | 2.83 | 0.94 |
| 5 | 3 | 4 | 3.92 | 0.98 |
| 4 | 2 | 6 | 4.95 | 0.83 |
| 3 | 2 | 8 | 6.60 | 0.83 |
| 2 | 2 | 11 | 9.90 | 0.90 |
| 1 | 3 | 20 | 19.61 | 0.98 |

Table 5 - Pipelining with Parallelism from the Graph

All three approaches

A possible application of this alternative is to **replicate the processor obtained by the use of a combination of pipelining and graph parallelism.** For the analysis of its effectiveness the same considerations apply as those discussed in the section on pipelining and graph parallelism, and on replication and pipelining.

For the example under discussion, the pipelined implementations in Table 5 are replicated as long as $PS \leq 8$. Table 6 shows the possible implementations. This approach produces implementations with high speedup and high efficiency. The system with highest speedup has the following parameters:

$$SU(S = 3, P = 2, j_{tot} = 40) = 39.22$$

| $t_S$ | $S$ | Units per PE | $SU_{all}$ | | | | $E_{all}$ |
|---|---|---|---|---|---|---|---|
| | | | $P = 1$ | $P = 2$ | $P = 3$ | $P = 4$ | |
| 7 | 2 | 3 | 2.83 | 5.66 | 8.49 | 11.32 | 0.94 |
| 5 | 3 | 4 | 3.92 | 7.84 | - | - | 0.98 |
| 4 | 2 | 6 | 4.95 | 9.90 | 14.85 | 19.80 | 0.83 |
| 3 | 2 | 8 | 6.60 | 13.20 | 19.80 | 26.40 | 0.83 |
| 2 | 2 | 11 | 9.90 | 19.80 | 29.70 | 39.60 | 0.90 |
| 1 | 3 | 20 | 19.61 | 39.22 | - | - | 0.98 |

Table 6 - Implementations with All Techniques

$$E(S = 3, P = 2, j_{tot} = 40) = 0.98$$

where $j_{tot}$ is the total number of units in all processors and stages.

Figure 7 illustrates the largest speedup achievable for different number of operation units, using either one concurrency technique or a combination of them. From the figure we infer that the selection of a particular implementation depends heavily on the characteristics of the algorithm and the number of operation units available. Depending on the characteristics of the algorithm, combinations of the different concurrency techniques might result more convenient than replication or pipelining of a completely-sequential processor. However, such conclusion is only possible after an evaluation of the alternative implementations of the algorithm.

Conclusions

We have identified replicated and pipelined implementations for computations that consist of multiple instances of a basic algorithm. We have concentrated on the case in which the multiple instances can be divided into groups, and there is a dependency between the corresponding instances of consecutive groups. Moreover, the implementations considered use only one type of operation unit.

We have devised a methodology to analyze such algorithms, using a dependence graph as the description tool. Such methodology leads to the evaluation of different implementations for an algorithm, at any level of decomposition. In this methodology, at a particular level one looks at all possible alternatives using either one or a combination of the concurrency techniques, searching for those cases which offer the highest efficiency. The analytical results obtained in this paper should be useful to facilitate the identification of those alternatives with higher efficiency. It might seem that this approach implies an exhaustive search for every possible implementation and is too costly in terms of the effort involved. However, that is not the case since the structured methodology allows to keep the number of nodes under evaluation at a given time restricted to a reasonable quantity. Therefore, it is possible to perform an intelligent search in the selection of the alternatives, which reduces the number of cases to evalu-

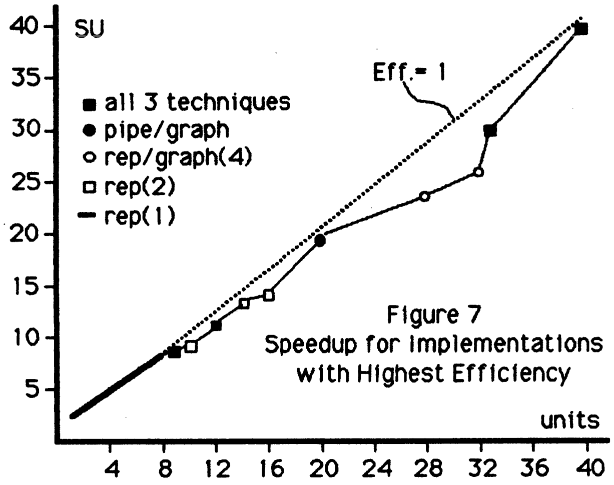

Figure 7
Speedup for Implementations with Highest Efficiency

ate.

Our results demonstrate that the selection of the most efficient implementation is strongly dependent on the algorithm that is implemented. This is particularly true when the dependence graph of the algorithm shows widely varying degrees of concurrency at different steps in the computation. Furthermore, we have been able to establish conditions for the concurrency techniques to be more effective in producing the highest speedup with a given number of operation units. Our results show that, for the class of algorithms considered, replication (or pipelining in some cases) alone is convenient up to a certain speedup value, with the limit imposed by the data dependences in the computation. For higher throughput, it is necessary to use combinations which include the local parallelism in the graph of the algorithm.

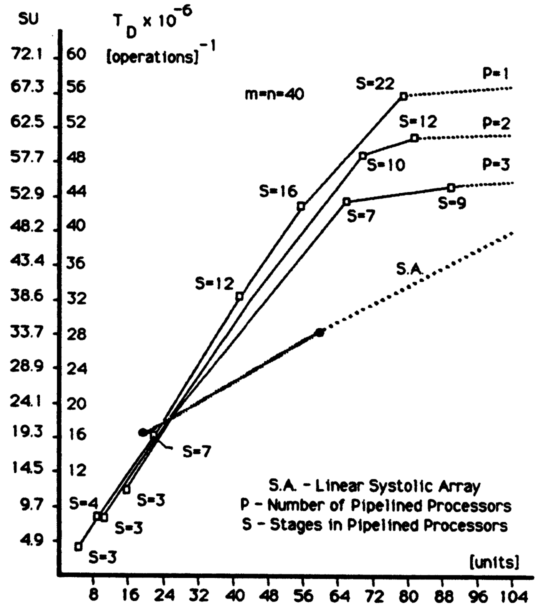

Figure 8 - Speedup and Throughput in Singular Value Decomposition for a 40 by 40 Matrix

We have applied this methodology to the analysis of alternatives for a Singular Value Decomposition (SVD) processor [7]. In particular, we have used it to compare pipelined implementations with graph-parallelism with respect to a linear systolic array (i.e. replication of a sequential implementation using graph parallelism) proposed for such computation [5]. Figure 8 depicts the difference in throughput obtained with those implementations. The plots show that the linear array is convenient only for lower throughput, but higher speedup is achieved with better efficiency in the pipelined architecture.

# HIERARCHICAL ARRAY PROCESSOR (HAP)
# FEATURING HIGH RELIABILITY AND HIGH SYSTEM PERFORMANCE

Tsutomu Ishikawa, Shigeharu Momoi, Shigeo Shimada, Yoshio Ogawa

Communications and Information Processing Laboratories
NTT Electrical Communications Laboratories
Musashino, Tokyo, Japan

Abstract--The HAP is a MIMD type highly parallel processor with 4096 PEs that basically uses NNM connection. It is capable of exceedingly high data transfer capability and reliability. Data transfer capability is upgraded by multi-layering PE arrays and utilizing its upper layer to transfer data in parallel to and from the lower layer, and also to reduce the inter-PE data transfer delay. For reliability upgrading, automatic high-speed system reconfiguration during failure is realized by a new fault-tolerant configuration and a new parallel diagnosis method that uses neighboring PEs. Thus, the HAP can be expected to gain high system performance in proportion to its number of PEs (max. 16 GIPS, 1.8 GFLOPS) and to realize the high reliability of nearly 1 availability and 1 year MTTF.

## 1. Introduction

Researches into parallel processors are being carried out on a worldwide scale [1]-[4], to meet the increasing needs for high performance computers. Especially approaches that use $10^3$-$10^4$ or more processing elements (PE) are receiving attention [5][6]. This is being stimulated by recent progress in LSI technology. In such a highly parallel processor, upgrading data transfer capability and reliability appear to hold the most promise for developing a practical machine, though, development of a parallel processing algorithm for each application is presupposed.

The system performance of a parallel processor is evaluated on the total time from initial data supply to processed data output. It is progressively limited by the data transfer time to and from all the PEs, rather than their processing time, as the number of PEs increases and therewith the overall processing power increases. Accordingly, the most important problem concerns data transfer to and from all PEs. The next important problem is the data transfer delay between PEs. This is because the maximum internode distance (1 + the number of PEs used as a relay) increases with the number of PEs in any network-type parallel processor [7], and the data transfer delay increases accordingly.

In considering reliability, imagine a system consisting of $10^4$PEs whose failure rate is $10^4$Fit. This means only a 10 hour mean time between failures (MTBF). In this case, one repair is needed on an average of every 10 hours, and if it is time consuming, the availability is lowered. Thus automatic failure recovery and shortening recovery time become important.

Conventional researches rarely touch on such problems. To cope with them, we researched the architecture of a system with the nearest neighbor mesh (NNM) connection selected to be suitable to a highly parallel structure. From those studies, we have developed a highly parallel processor, the hierarchical array processor (HAP). A small scale version is under trial at this time.

The HAP is a MIMD type processor with 4096 PEs designed for scientific calculation and speech, picture and other recognition processing applications. The previously mentioned problems are handled with a hierarchical PE array structure that utilizes its upper layer for data transfer, together with a new fault-tolerant configuration and parallel diagnosis of PEs.

## 2. System Architecture

### 2.1 System Configuration and Data Transfer

In order to cope with the data transfer problems, we adopted a hierarchical PE array structure similar to the EGPA [8], namely a large scale array with a small scale array above it. The number of PEs in the smaller array is approximately the square root of the large one's. By making use of the small array to accomplish data transfer to and from the large PE array and between PEs in the array, realization of a data transfer rate that matches the large array's processing power and reduction of the inter-PE data transfer delay are attempted. Hence, even if there is an increase in the number of PEs, a high system performance that is not limited by data transfer capability can be realized.

### 2.1.1 System Configuration

Figure 1 shows the system configuration of the HAP. In the HAP, multiple users are assumed in order to make full use of the processing power of all the PEs. Namely, it is properly used as the back-end processor for a number of user computers.

1) Configurations and Roles of Each Block

The PE array consists of a maximum of 4096 (64x64) PEs, and executes parallel tasks. The control PE array (cPE array) has a maximum of 64 (8x8) control PEs (cPE). Together with the data I/O mechanism, it performs the input-output of data to the PE array. It also relays the inter-PE data transfers. Besides these, hierarchical parallel tasks can also be executed. The PEs and the control PEs are basically microcomputers. A system management processor (SMP), using a general purpose computer, controls the whole system. The data I/O mechanism performs the input-output of data to user computers and cPEs, and also data buffering.

2) Physical Connection among PEs

PEs inside the PE array are both physically NNM

0190-3918/86/0000/0293 $01.00 © 1986 IEEE

and torus-connected, in consideration of the total data transfer capability / hardware quantities for connection between PEs, and the easy expansion to a physical structure. Therefore, each PE is connected with its four nearest neighbor (north, south, east and west) PEs. Although torus-connection slightly increases the inter-PE wiring length, it has the merit of reducing the maximum internode distance to half, compared to that of only an NNM, and is therefore applied. The cPE array also has the same connection scheme as the PE array. In inter-layer connection, such as the connection between PEs and cPEs, called lower PEs and upper PEs, respectively, a bus is used to reduce the amount of connecting hardware.

3) Logical Coupling between PEs

Logical coupling via memory is used between PEs, cPEs and both, in order to simplify program description and debugging (Fig. 2). Consequently, each PE can, as part of its own memory, directly access the memory contents of its neighboring PEs. Besides these, a cPE can also directly access the memory of the PEs to which it is connected. In this circumstance, when a particular PE is specified, only that memory can be accessed, but when not specified, the memories of all PEs can be accessed.

4) Bypass of the cPE Array

The cPE can be bypassed during the debugging of a PE program or during processing that does not require it. During such circumstances, the SMP and the PE array are directly logically-coupled.

2.1.2 Data Transfer

In the operation of a parallel processor, the program and the required initial data are supplied to the PEs in the first phase. Then, tasks expanded in parallel are executed in the PEs with necessary data transfer between the PEs. Finally, the processed data are collected by the user computer. That is, there are usually four types of data transfer in a parallel processor, namely, program load, initial data supply, inter-PE data transfer and result collecting. Since system performance is evaluated by the total processing time, which includes these data transfers, improvement in its transfer capabilities increases the value of a parallel processor. In the HAP, rapid data transfer is realized through the following approach.

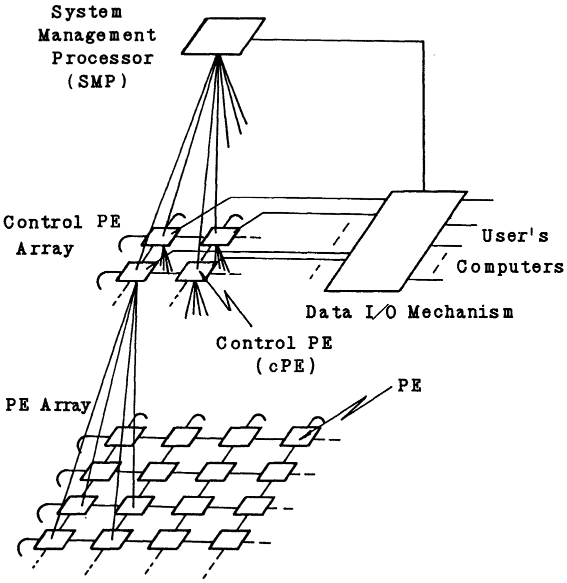

Fig. 1 Configuration of HAP System

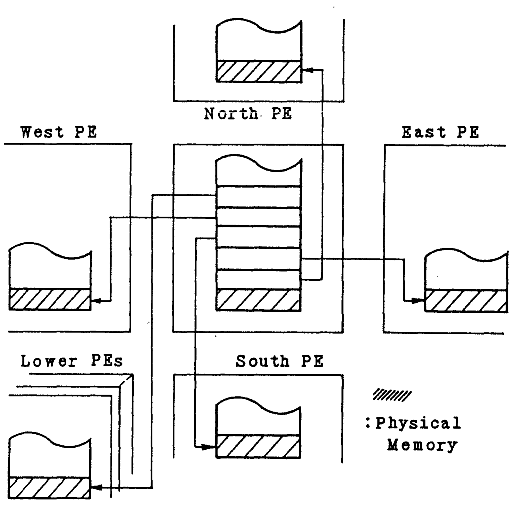

Fig. 2 Memory Sharing between PEs

1) Program Load

Load distribution, instead of function distribution, is used to improve the performance in highly parallel processors. The programs for all PEs are basically identical, so they are broadcast to all cPEs and PEs by the SMP. Moreover, independent program load to each PE is also possible, in consideration of occasions when the programs are different for part of the PEs. These are realized through memory accesses (write operations) to the lower PEs or PE by the upper PE.

2) Initial Data Supply and Result Collecting

Since the data to be processed by each PE is different, it is transferred from the SMP in serial fashion. This is a potential bottleneck in system performance. Therefore, in the HAP, data elements are supplied in parallel through the cPEs. Specifically the initial data buffered in the data I/O mechanism is transferred simultaneously to all the cPEs, then each cPE transfers it to the PEs that are coupled to it. Result collecting is basically similar, except the direction of data flow is reversed. These data transfers are DMA transfers by cPEs.

3) Inter-PE Data Transfer

A parallel processor with NNM connection is very suitable for processing problems where inter-PE data transfer occurs locally or regularly (e.g. solving Poisson's equation by the ODD-EVEN SOR method, or a Fast Fourier Transform (FFT))

Table 1 Inter-PE Data Transfer Method

| Method | Summary | Maximum Internode Distance | Maximum Transfer Parallelization |
|---|---|---|---|
| a) Routing | Same directional transfer in PE Array repeated by all PE's | $2\sqrt{N}-2$ | N |
| b) Array Relaying | Transfer relaying other PE's in PE Array | $\sqrt{N}$ | N |
| c) SMP Relaying | Transfer relaying the SMP (cPEs are bypassed) | 2 | 1 |
| d) Hierarchical Relaying | Transfer from PE to cPE, relaying in cPE array, and then from cPE to PE | $\sqrt{\frac{N}{Nc}}+2$ | Nc |

N : Number of PEs
Nc : Number of cPEs

[4][9]. However, it is not suitable for problems where transfers occur irregularly between PEs with large internode distances, e.g., logic simulation. This is because the maximum internode distance is still as large as $\sqrt{N}$ (N:the number of PEs) in this kind of parallel processor even if torus-connection is employed together with the NNM; therefore, much time is needed for these data transfers in such a problem.

To make it more suitable for the latter type of problem, a new data transfer mode utilizing the cPE (Table 1d) in addition to the usual mode (Tables 1a-1c) is provided to reduce the maximum internode distance and the inter-PE data transfer delay in the HAP. This mode is used for data transfer between PEs where the internode distance is greater than $\sqrt{N/Nc}$ (Nc:the number of cPEs). Hence, for the HAP, wherein N=4096 and Nc=64 (Fig. 1), the maximum internode distance is 10. This is shorter than that (equal to 12) of a hyper cube type [7] parallel processor with an equal number of PEs. Moreover, this mode can be used together with b), thus helping to improve the transfer rate. In the HAP, any of the several data transfer modes shown in Table 1 can be used, depending on the type of problem. These data transfers are realized through the repetition of memory access to the neighboring PE, memory accesses to the lower PE by the upper PE or both of them.

## 2.2 Fault-Tolerant Configuration

### 1) Redundancy Configuration and its Inter-PE Connection Network

There have been a number of proposals [10][11] for establishing redundancy in an NNM configuration. However, we use a new redundancy configuration that features simple inter-PE connection and easy switching control. Figure 3 shows its configuration schematically. One row and one column of spare PEs are provided for an n x n PE array. If the number of faulty PEs in the column does not exceed one, the column is considered good, thus n good PEs, out of n+1 PEs, are available. If there are more than 1 faulty PEs, the column is considered faulty, thus n good columns, out of n+1 columns, are available, forming an n x n good PE array.

With the fabrication of a switching circuit inside each PE, the switching of a faulty PE in this redundancy configuration is realized through the inter-PE connection network (called an IX network due to its shape) shown in Fig. 4 a). In the IX net, each PE is physically connected with 6 neighboring PEs. The switching of a faulty PE or a faulty column is done through bypassing them, as shown in Figs. 4 b) and c), respectively. That is, four connections are used out of a PE's six possible connections, and the IX net becomes functionally an NNM.

### 2) Effect of Application of Redundancy Configuration

The result of the application is shown in Fig. 5. Here [Degree of MTTF improvement G] = [MTTF of the redundantly configured system] / [MTTF of the nonredundantly configured system], where MTTF (Mean Time to Failure) is defined as the elapsed time from when all PEs are placed in good condition to when all spare PEs are used-up. Figure 5 shows that this redundancy configuration has a better effect than simply duplicating each PE, in spite of the smaller amount of redundancy, causing G to exceed $\sqrt{N}$ (N:the number of PEs), in the area where n is relatively small (<10). In the HAP, this configuration is used on each group

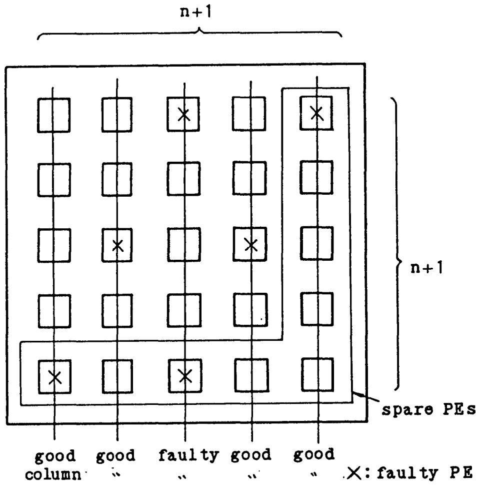

Fig. 3 Two-Level n-out-of-n+1 Fault-Tolerant Array

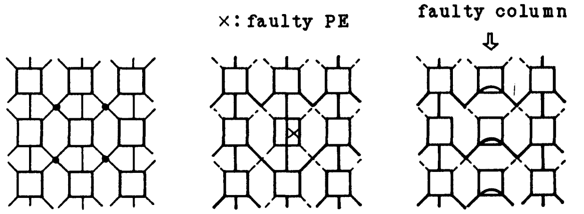

(a) IX-NET (b) Swithing Method for Faulty PE (c) Switching Method for Faulty Column

Fig. 4 IX-NET and Switching Methods for Faulty PE and Column

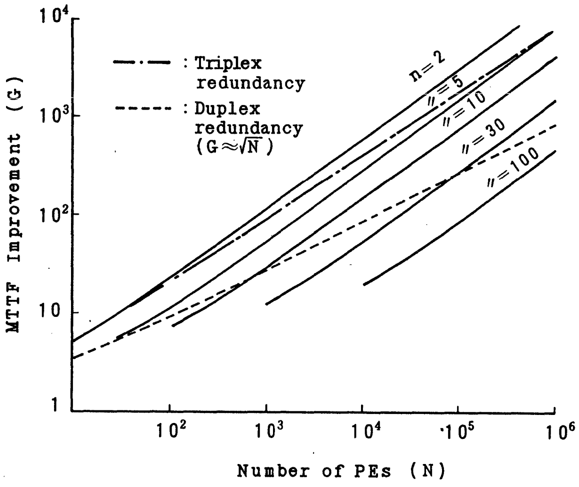

Fig. 5 MTTF improvement by Two-Level n-out-of-n+1 Fault-Tolerant Array

of PEs that are connected to a cPE. Hence, if the PE failure rate is $10^3$Fit, the MTTF of the HAP, excluding the SMP and the data I/O mechanism, would be about 1 year.

## 3. Processing Element (PE)

In the realization of a highly parallel processor with 4096 PEs, there is the necessity to miniaturize the PE. Though it would be ideal to fabricate the whole PE on a single LSI chip, market-available microprocessors, RAMs and gate arrays are used for the following reasons:

i) It is difficult to fabricate the PE for a MIMD machine, in which large memory is essential, on one LSI chip, even with the present advanced LSI technology.

ii) Fabrication of a memory-less PE on one LSI chip does not have much effect on miniaturization.

iii) Existing compilers and other software can be utilized without having to develop them when market-available microprocessors are used.

Moreover, PE and cPE have the same configuration thus reducing the number of LSI types that need to be developed for the HAP.

### 3.1 Configuration and Function

Figure 6 shows the configuration and table 2 shows the specification of the PE.

#### 1) Central Processing Unit (CPU)

Any of Intel's 80186, 80286, or 80386 processors can be used as the CPU. It executes fixed point arithmetic and controls the whole PE.

#### 2) Arithmetic Processing Unit (APU)

This is the co-processor for floating point arithmetic. Any of Intel's 8087, 80287 or 80387 processors can be used as the APU in a combination with the CPU shown in Table 2.

#### 3) Memory (MEM)

Besides the storage of PE programs and data, the MEM is used for various types of data transfer. From the point of view of upgrading PE performance, the MEM should be configured as two independent memory banks to avoid contention between CPU and APU memory accesses and data transfer memory accesses. However, in the PE of a MIMD machine, there are fewer of the latter type than the former (e.g. less than tenths in the ODD-EVEN SOR method). Accordingly, degradation of PE performance due to contention can be ignored and the MEM is configured as one bank. This makes miniaturization of the PE and expansion of the memory area used for data transfer possible.

#### 4) Memory Control Unit (MCU)

The MCU arbitrates the contention between memory accesses of the CPU and APU, and memory accesses due to data transfers, and it transmits data transfer requests and the several control requests to the CCU. In addition, it provides the interface between the microprocessors and the memory, namely the CPU and the APU and the MEM.

The MCU is configured so that it can be used by various types of microprocessors such as the CPU and the APU shown in Table 2. It is realized on a 1-chip gate array packaged in a pin grid array (PGA) case with 176 pins.

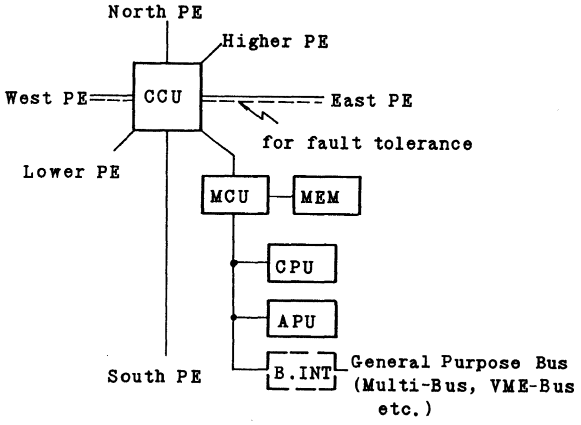

Fig. 6 Configuration of Processing Element (PE)

Table 2 PE Specification

| | | TYPE1 | TYPE2 | TYPE3 |
|---|---|---|---|---|

|---|---|---|---|---|

Fig. 7 Two Types of Packet Format for Data Transfer

5) Communication Control Unit (CCU)

The CCU performs the data transfers between PEs, cPEs and the SMP and provides the control that is needed for them. Packeted imformation (Fig. 7) is asynchronously, time-divided and bidirectionally transfered. Every interface, namely, north, south, east, west, upper and lower, has four data lines with bus structure. Moreover, all the interfaces between the PEs possess a bus-arbiter function so that any PE, cPE or SMP can operate as a master or as a slave. Additionally the CCU also performs the control concerning the synchronization of PEs and the start, stop or other relevant control (when used as a cPE). These controls will be discussed in the next section. The CCU is realized by the same type of gate array as the MCU.

6) Bus Interface (B.INT)

It is used for interfacing general busses such as the multi-bus, the VME bus and others. The cPE is connected to the data I/O mechanism through it.

3.2 Control Method

1) Fundamental Control Scheme

It is necessary to have controls for starting, stoping, data transfer and synchronization of PEs in a parallel processor. These controls are initiated by one instruction to ease program development, and are realized in hardware to provide high speed execution in the HAP. Figure 8 shows the fundamental control scheme where all the control requests of the controlling PE (including the SMP and the cPE) are done in the form of a label access to variables. These become pseudo-memory accesses during processor operation. Based on this access information, the control circuits recognize the control request and generate the necessary control information.

The control information is transfered to the controlled PE (or PEs) through a physical link such as data lines or control lines. The controled PE uses this control information to realize the various control operations through the generation of interrupt vectors, interrupt operations and execution of the required interruption handling routines.

However, controls that demand rapid execution, such as the synchronization of PEs (in this case, the controlling PE is also the controlled PE) are realized by controlling the "Ready" signal of the CPU. Specifically, when synchronization requests are generated by every PE, the CPU is in the wait condition for the "Ready" state. Once the concurrence of synchronization is detected, the "Ready" signal is generated and the CPU is shifted to the execution of the next instruction. With this control, the synchronization of all the PEs is realized in less than one microsecond in the HAP.

2) Flexible Synchronization Mechanism

A flexible synchronization mechanism utilizing the hierarchical structure is realized in the HAP (Fig. 9). It is the sync-mask-register specifying the return of the synchronous signal to its own layer or its propagation to the upper layer. The propagation of synchronous signals is controlled with this register, and the synchronization of all PEs including the cPEs and the SMP, local synchronization of PEs that are connected to the cPE, and other functions are possible. This mechanism is expected to be more useful in some recognition processings (especially pattern matching in their processings), such as character recognition, speech recognition and others where the hierarchical parallel algorithms are often used. Furthermore, the synchronization between neighboring PEs (or cPEs) can easily be realized through the setting and referring of shared varibles such as flags, semaphores and others, since the couplings are via memory, as shown in Fig. 2.

| Function Realized \ Control Level | (Controlling PE)<br>Control Request | PE Start or Stop | (Controlled PE)<br>Synchronization | Data Transfer * Control |
|---|---|---|---|---|
| Software | Label Access | Interruption Handling | Next Process | Interruption Handling |

## 4. Performance Estimation

The basic goal in developing the HAP is to realize a system having its performance proportional to the number of its PEs. System performance, $P_H$, is given by the expression,

$$P_H = PoN\alpha,$$

where Po is the processing capability of a single PE, N is the number of PEs and $\alpha$ is the operating efficiency of one PE. $\alpha$ is defined as the ratio of the performance per PE with N PEs operating in parallel to Po. $\alpha$ is dependent on the parallelization algorithm for the problem, with $\alpha = 1$ in the ideal case. The assumptions are that the total processing quantities do not vary with the parallel expansion, the overhead of the parallel processor, i.e., data transfer and synchronization, can be ignored, and the loads are equally divided among all PEs. Under such conditions, the peak system performance of the HAP, using an 80386 and an 80387 as the CPU and the APU respectively, is

$P_H = 4$ MIPS x 4096 x $1 \approx$ 16GIPS
(for fixed point arithemtic or general data processing)

$P_H = 0.45$ MFLOPS x 4096 x $1 \approx 1.8$ GFLOPS
(for floating point arithmetic).

However, $\alpha$ is usually not equal to 1. In the HAP, the factors that lower $\alpha$ from the hardware point of view are sufficiently coped with by the improvement in data transfer capability mentioned in 2.1.2 and by the speed-up in synchronization mentioned in 3.2. An example of this effect is shown in Fig. 10. This is for the case of solving first order simultaneous equations having M unknowns using Gauss' elimination method. The main factor in the lowering of $\alpha$ is the method of supplying initial data (i.e. coefficients of the equations) to the PEs. In the HAP, this is performed in parallel by the cPEs. This improves $\alpha$ up to the solid line shown in the same figure. Hence, the HAP can be expected to have a higher system performance than the usual NNM model on a number of problems, including the aforementioned ones.

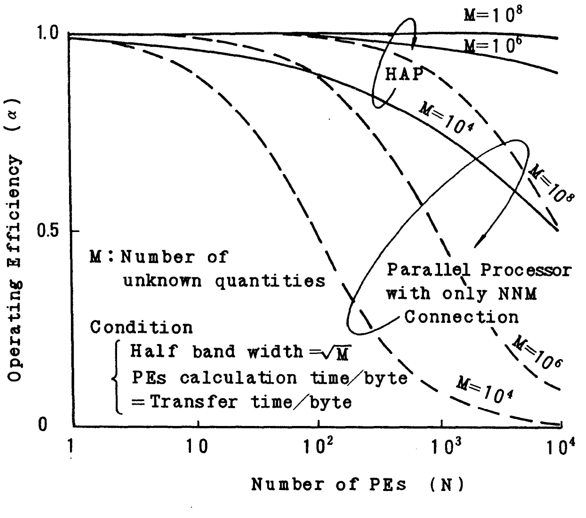

Fig. 10 Operating Efficiency of PE in Solving Simultaneous Equation by Gauss' Elimination Method

## 5. System Auto-Recofiguration

Automatic, speedy system reconfiguration is realized in the HAP to improve its availability and extend its maintenance period. That is, in the HAP, a faulty PE is promptly detected, and an NNM connected array excluding it is automatically reconfigured. This is realized through the use of the newly proposed parallel diagnosis and switching control methods.

### 1) Parallel Diagnosis of PEs

This method employs a decide-by-majority technique using the diagnosis results obtained from neighboring PEs to judge its own condition (called NV diagnosis). Figure 11 shows the concept of NV diagnosis. This diagnosis is carried out on all the PEs simultaneously using the following procedure:

i) The diagnosed PE runs the test program inside itself.

ii) The test result is sent to the 4 neighboring PEs. A comparison between the actual and the expected result is done in both the neighboring PEs and itself.

iii) The neighboring PEs send the compared results back to the diagnosed PE.

iv) Using the results for a decision by majority, the diagnosed PE judges its own condition.

A faulty condition of the diagnosed PE can be known through comparison between the actual and the expected result in the neighboring PEs since the test result will differ from the one expected. Moreover, even if one or two neighboring PEs are faulty, so long as 3 out of 5 (4 neighboring PEs and the diagnosed PE) are in good condition, the faulty condition of the diagnosed PE can be detected through these 3. Consequently, assuming that no more than 2 out of every 5 PEs are faulty, autonomous, parallel diagnosis is possible within the PE array.

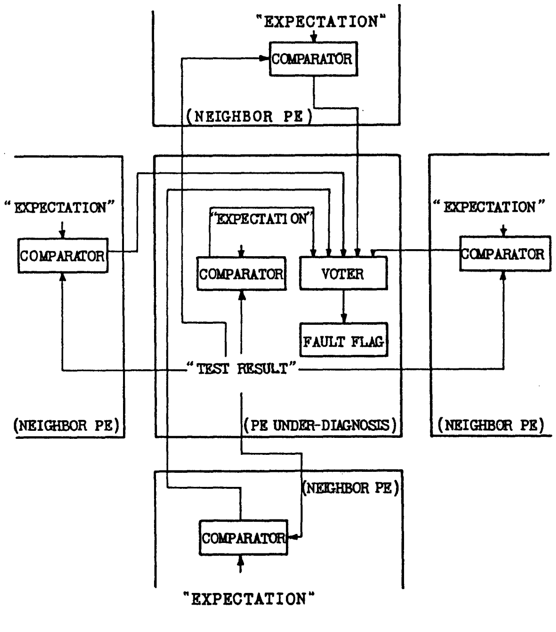

Fig. 11 NV (Neighbor Voting) Diagnosis

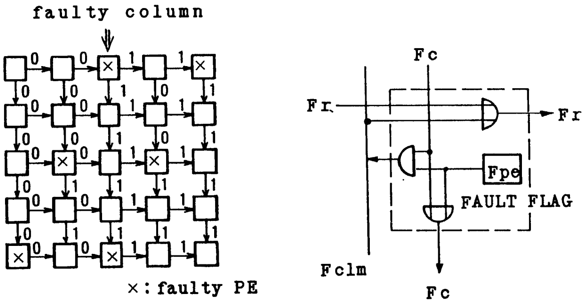
2) Switching Control Method

In the IX net in 2.2, a switching control to exclude the faulty PE and column is necessary (Figs. 4b and c). This control is done as follows:

i) The control signals, Fr and Fc for indicating the existence of a faulty column and a faulty PE, respectively, are transmitted in the manner shown in Fig. 12 a). Figure 12 b) shows the generation circuit for these signals.

ii) The interface direction and bypass of the PE are determined and then the switching is performed in each PE using these signals together with the condition of the PE itself (Fpe) and the condition of its own column (Fclm).

Once a faulty PE is detected, the switching is automatically done within the PE array.



(a) Propagation of Switching Control Signals

(a) Initial state

(b) State after 1st Test

(c) State after 2nd Test

(d) State after 3rd Test

Fig. 13 Auto-Reconfiguration Procedure

3) Auto-Reconfiguration Procedures

The system reconfiguration is done at the time of power on, or during system reset when a PE fails. Initially, all PEs are considered as good and diagnosis of all PEs, except spare ones, is carried out. As a result, if faulty PEs are detected, their flags are set (Fig. 11). Then an NNM connected array, excluding the faulty PEs, is automatically reconfigured by the method in 2). This procedure is executed three times at most before system reconfiguration is completed (Fig. 13). In the HAP, the maintenance period can be extended to the MTTF defined in 2.2 with an availability of nearly 1 by means of this system auto-reconfiguration.

## 6. Programming for HAP

A lot of research [12]-[14] has been done to develop a parallel processing oriented language that makes the abstraction of parallelism in the problem easy. However, the present automatic abstraction of parallelism tends to be at low levels, such as the instruction level or the DO loop level or others. We believe that to achieve an effective improvement in performance, which is the primary goal of a parallel processor, attention must be paid to the higher level of parallelism in the MIMD machine, but that the abstraction of these parallelisms still requires the involvement of man. Consequently, in the HAP, the programmer must be conscious of the parallel structure corresponding to the level of the program written.

1) Software Structure

In order to allow performance improvement' and ease-of-use, and also in consideration of the utilization of the HAP as a back-end processor, the software shown in Fig. 14 is provided. To the HAP user, only writing the program for his computer by utilizing the library program, not being conscious of the HAP hardware, is required. That is, the user's job is expanded to parallel tasks and subrouted at the library level.

Specifically, a parallel processing algorithm suitable to the job is developed at this level, and then the programs for executing the algorithm, divided into a PE program and an SMP program, are written. The main function of the PE program is the parallel alogrithm, and the SMP program is for program load, control of PEs and other functions. When assigning general processing to the cPE, aside from data transfer and synchronization, the writing of a cPE program is necessary too.

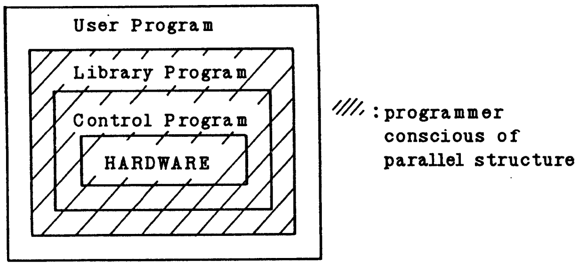

Fig. 14 Software Structure

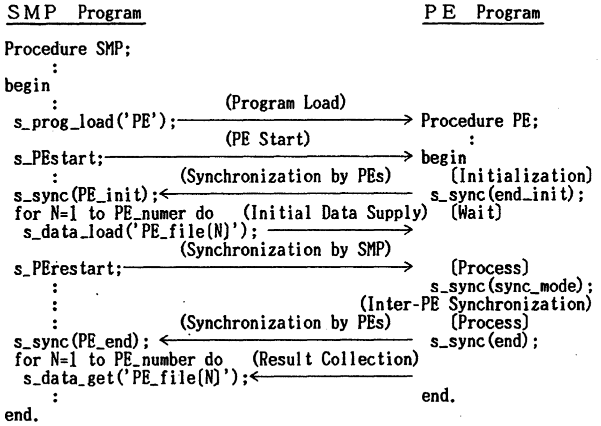

```

 for N=1 to PE_number do   (Result Collection)
  s_data_get('PE_file(N)');←─────────────────────
    :                                             end.
end.
```

Fig. 15 Example of Program Description (PASCAL)

However, these programmings are easy (Fig. 15) since these can use the subrouted control programs, and the fundamental controls are described by single instructions, as mentioned in 3.2. The control programs are written as to the various controls mentioned in 3.2.

2) Program Development Environment

In consideration of library program development using a general computer (not parallel), procedure calls and function calls are used instead of macro instructions in order to reduce dependency on the machine and language used.

For programming, high level languages such as PASCAL, C, Ada, FORTRAN and others can be used without any modification.

## 7. Conclusion

The configuration of a MIMD type highly parallel processor, the HAP, with 4096 PEs is discussed. The HAP appears capable of ensuring practical reliability and data transfer capability that matches the processing capability of its PEs, which are considered the main problems in high parallelization.

The problems of data transfer are solved by adopting a hierarchical PE array structure, namely, a large scale array with a small scale array above it, and utilizing the latter to transfer data. Specifically, the small PE array is used to parallel the data transfer to and from the large PE array and to reduce the inter-PE data transfer delay by relaying it. With these approaches, the HAP is expected to attain a system performance near the peak value of 16 GIPS, 1.8 GFLOPS (in the case of using 80386 and 80387 processors) over a broad range of applications.

Reliability problems are solved with the application of a fault-tolerant configuration where one row and one column of spare PEs are provided to each n x n PE array and automatic switching is done in PE and column units. Also, it applies a newly proposed parallel diagnosis method, called NV diagnosis, that uses neighboring PEs. Fast, automatic system reconfiguration is realized through these features, and thereby the maintenance period (equal to the MTTF) is about 1 year (with a PE failure rate of $10^3$ Fit) with an availability of approximately 1.

A small scale version with 256 PEs and 16 cPEs is under fabrication. Each PE consists of 13 LSIs, namely 80186 and 8087 type processors, 9 DRAMs (256kbits/chip) and 2 gate arrays (PE size 9cm x 6cm x 3cm). Testing of its capability for general scientific calculation and various types of recognition together with an overall evaluation is scheduled.

# MESH-CONNECTED COMPUTER ALGORITHMS FOR RECTANGLE-INTERSECTION PROBLEMS

**Mi Lu**
**Peter Varman**

Department of Electrical and Computer Engineering
Rice University

## Abstract

In this paper, Mesh-Connected Computer (MCC) algorithms for computing several properties of a set of, possibly intersecting rectangles are presented. Given a set of $n$ iso-oriented rectangles, we describe MCC algorithms for determining following properties: (i) The area of the logic "OR" of these rectangles (i.e. the area of the region covered by at least one rectangle). (ii) The area of the logic "AND" of the rectangles (i.e. the area of the region covered by two or more rectangles). (iii) The largest number of rectangles that overlap. This solves the fixed-size rectangle placement problem, i.e. given a set of plan points and a rectangle, find a placement of the rectangle in the plane so that the number of points covered by the rectangle is maximal. (iv) The minimum separation between any pair of a set of non-overlapping rectangles. All these algorithms can be implemented on a $\sqrt{n}\times\sqrt{n}$ MCC in $O(\sqrt{n})$ time. The best known algorithms for the above problems are sequential and have optimal $O(n \log n)$ time complexity.

## I. Introduction

A two-dimensional Mesh-Connected Computer (MCC) consists of a number of identical processors arranged in a two-dimensional array with interconnections between every pair of horizontally and vertically adjacent processors. Each processor has a fixed number of registers and is capable of performing arithmetic and boolean operations. The MCC operates as a single-instruction stream, multiple-data stream (SIMD) computer in which several processors execute the same instruction in parallel on different data items. The simplicity of the inter-processor communication pattern and the economical layout afforded by an MCC have resulted in actual implementations in recent years [1,2,3].

Several MCC algorithms for problems in diverse computational areas have been discovered. Thompson and Kung [4] and Nassimi and Sahni [5] presented fundamental MCC algorithms for sorting, which form the basis of data routing techniques [6]. Algorithms for solving matrix computations [7], solving graph-theoretic problems [8,9,10,11,12,13,14] and more recently for problems in computational geometry [15,16] have also been presented.

In this paper we present MCC algorithms for computing several interesting properties of a set of $n$, possibly overlapping, iso-oriented rectangles. (An iso-oriented rectangle is one whose sides are parallel to the coordinate axes). These problems belong to the class of rectangle intersection problems in computational geometry that has been widely studied for its applications in VLSI design [17], computer graphics and architectural data bases [18]. The specific problems that we cover are as follows.

Given a set of $n$ iso-oriented rectangles determine:
1. The area of the logic "OR" of these rectangles, that is the area of the region that is covered by at least one rectangle.
2. The area of the logic "AND" of these rectangles, that is the area of the region that is covered by two or more rectangles.
3. The maximal number of rectangles that overlap. This also solves the fixed rectangle placement problem, which asks one to determine the placement of a given rectangle in the plane so that it includes the largest number of a set of given planar points.
4. If the rectangles are non-intersecting, the distance between the closest pair of rectangles.

The algorithms presented in this paper employ a divide and conquer technique, based on the "separational principle" for planar objects proposed by Güting [19], and require $O(\sqrt{n})$ time on a $\sqrt{n}\times\sqrt{n}$ MCC. Upto constant factors, our algorithms are optimal on the "standard" MCC model being used, and compare favorably with the known sequential algorithms which have $O(n \log n)$ time complexity.

In sections II through V of the paper we present our algorithms for the problems mentioned earlier. In the discussion we assume familiarity with techniques for sorting a set of records distributed evenly among the processors (see [4]) and for performing parallel random access reads (RAR) or writes (RAW) on an MCC (see [6]).

## II. "OR" Area Reporting

A rectangle with its sides parallel to the coordinate axes is called an iso-oriented rectangle. Given a set of $n$ iso-oriented rectangles, the "OR" area reporting problem is to find the area of the region that is covered by one or more rectangles.

Consider the $2n$ vertical segments that make up the $n$ rectangles. The set of horizontal lines passing through the points at the bottom and the top of those segments partitions the plane into horizontal strips. Each strip is bounded in the vertical dimension by two horizontal rectangle edges (not necessarily belonging to the same rectangle), and each horizontal edge of a rectangle coincides with a strip's boundary. The area of the region covered by the logic "OR" of the set of rectangles is the sum of the covered area in each strip. The y-interval covered by each strip is simply the difference in the y-coordinates of the horizontal lines bounding the strip; so what we are interested in is only the x-interval covered by each strip. We solve the problem efficiently by using a divide-and-conquer approach as described below.

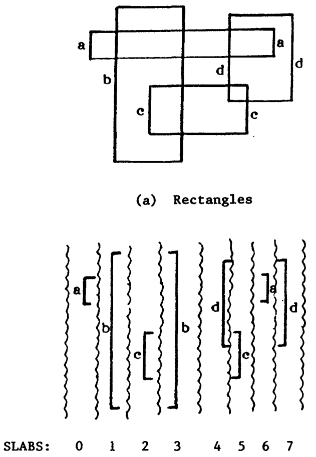
Sort all the vertical segments by their x-coordinates in non-decreasing order. Divide the plane into two slabs by a vertical line, $L$, that partitions the set of vertical segments into two equal-sized subsets so that every segment to the left (respectively right) of the dividing line $L$, has an x-coordinate less than (respectively greater than or equal to) the x-coordinate of $L$.

Iteratively partition each slab obtained into a left and right slab in a similar manner, until each slab finally contains one vertical segment. Each slab (except for the two at the end) is bounded by two dividing lines, which we refer to as the *left boundary* and *right boundary* of the slab. Assume that the *left boundary* of the leftmost slab to be a line passing through the left most segment

This research was partially supported by an IBM Faculty Development Award.

0190-3918/86/0000/0301 $01.00 © 1986 IEEE

and the *right boundary* of the rightmost slab to be a line passing through the rightmost segment. Figure 1 illustrates an example of the partitioning for eight vertical segments.



(a) Rectangles

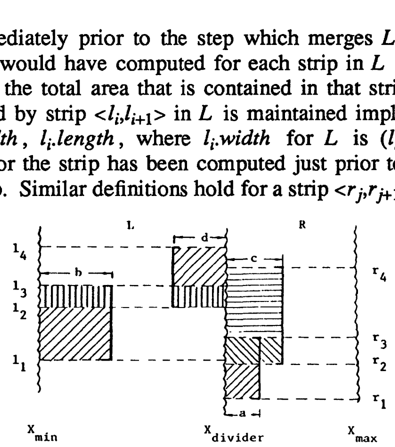
(b) Partitioning of Vertical Segments into Slabs.

Figure 1

The algorithm proceeds to merge together adjacent slabs in a binary tree fashion. All merges at a level of the computation tree are done in parallel, and the computation is completed after $\log_2 n$ iterations. Every merge step merges together slabs that lie to the left and right respectively of a common dividing line. Let us denote the left and right slabs being merged as $L$ and $R$ respectively. Let $l_1, l_2, ..., l_k, l_i \le l_{i+1}$, be the y-coordinates of the segments in $L$ and $r_1, r_2, ..., r_k, r_i \le r_{i+1}$, the y-coordinates of the segments in $R$.

The horizontal lines through $l_i$, $i$=1, ..., $k$, partition the slab $L$ into $k$ horizontal *strips*, where the $i$-th strip of $L$, $1 \le i \le k-1$, denoted by $<l_i, l_{i+1}>$ consists of the region between $l_i$ and $l_{i+1}$ and the $k$-th string (dummy) has width zero. In a similar fashion, the horizontal lines through $r_i$, $i$=1, ..., $k$, partition $R$ into $k$ horizontal strips.

Immediately prior to the step which merges $L$ and $R$, the algorithm would have computed for each strip in $L$ (and $R$), the portion of the total area that is contained in that strip. The area contributed by strip $<l_i, l_{i+1}>$ in $L$ is maintained implicitly by the pair $l_i$*.width*, $l_i$*.length*, where $l_i$*.width* for $L$ is $(l_{i+1} - l_i)$ and $l_i$*.length* for the strip has been computed just prior to the current merge step. Similar definitions hold for a strip $<r_j, r_{j+1}>$ in $R$.



Note: Shaded areas represent the area of the strip that is part of the total area.

Fig. 2(b) Following the merge of L and R into S.

Figure 2 illustrates a possible situation where $k$=4. The slabs $L$ and $R$ are merged to form a slab $S$, bounded on the left by the left boundary of $L$ with x-coordinate $x_{min}$ and on the right by the right boundary of $R$ with x-coordinate $x_{max}$.

Slab $S$ contains all the line segments in $L$ and $R$. Let $s_i$, $i$=1, ..., $2k$, $s_i \le s_{i+1}$, be the ordered list of y-coordinates of segments in $S$. Obviously, $s_1, ..., s_{2k}$ is obtained by merging together the ordered lists of points $l_1, ..., l_k$ and $r_1, ..., r_k$ corresponding to segments in $L$ and $R$ respectively. That is, the strips are *refined* in the merge step. To simplify the presentation of the merging algorithm, we present some definitions. The strip $<s_i, s_{i+1}>$ of $S$, which lies between the horizontal lines passing through $s_i$ and $s_{i+1}$, is called a *right_originating strip* (respectively *left_originating strip*) if $s_i = r_j$ (respectively $s_i = l_j$), for some $j$, $1 \le j \le k$. If $u$ and $v$ are vertical segments of the same rectangle, then $u$ ($v$) is a *partner* of $v$ ($u$). If the x-coordinate of $u$ is less (respectively greater) than that of its *partner* $v$, then $u$ is a left (respectively right) segment of the rectangle. A segment in $S$ is said to be a *left_open segment* if it is the right segment of a rectangle, lies in $R$ and does not have a left partner in $S$. A segment in $S$ is said to be a *right_open segment* if it is the left segment of a rectangle, lies in $L$ and does not have a right partner in $S$. A strip $<s_i, s_{i+1}>$ is a *left_open* (respectively *right_open*) *strip* if it is crossed by a *left_open* (respectively *right_open*) *segment.*

At the end of the step that merge $L$ and $R$, we should determine $s_i$*.length*, the length of the strip $<s_i, s_{i+1}>$ that is to be included in the overall area. This is computed by determining $(s_i.length)_L$ and $(s_i.length)_R$, which are the portions of $s_i$*.length* that lie to the left and right of the dividing line respectively, and then taking their sum.

The algorithm which computes $s_i$*.length* for each $s_i$, $i=1, ..., 2k$ is presented in Algorithm 1.

*Algorithm 1*:

```
for each strip $<s_i, s_{i+1}>$, $i=1, ..., 2k-1$, do
if $<s_i, s_{i+1}>$ is a left_originating strip, where $s_i = l_j$
  then
    begin
      if $<s_i, s_{i+1}>$ is a left_open strip, then
        /* the entire portion of the strip in L must be included */
          $(s_i.length)_L = x_{divider} - x_{min}$
      else /* no change in the portion covered in L */
```

```
          $(s_i.length)_L = l_j.length$
        if $<s_i,s_{i+1}>$ is a right_open strip, then
          /* the entire portion of the strip in $R$ must be included */
          $(s_i.length)_R = x_{max} - x_{divider}$
        else /* no change in the portion covered in $R$ */
(**)      /* Determine the strip $<r_p,r_{p+1}>$ in $R$ that previously
           covered the region now covered by $<s_i,s_{i+1}>$ */
        /* $r_p$ is the point in $r_1, ..., r_k$ such that
          $r_p < s_i < r_{p+1}$ */
          $(s_i.length)_R = r_p.length$
      end
  else /* $<s_i,s_{i+1}>$ is a right_originating strip, where
      $s_i = r_j$ */
      begin
        if $<s_i,s_{i+1}>$ is a right_open strip then
          $(s_i.length)_R = x_{max} - x_{divider}$
        else
          $(s_i.length)_R = r_j.length$
        if $<s_i,s_{i+1}>$ is a left_open strip then
          $(s_i.length)_L = x_{divider} - x_{min}$
        else
         /* let $l_p$ be the point in $l_1, ..., l_k$
          such that $l_p < s_i < l_{p+1}$ */
          $(s_i.length)_L = l_p.length$
      end
  $(s_i.length) = (s_i.lengh)_L + (s_i.length)_R$
end
```

We now describe the MCC algorithm for the OR-Area reporting problem. The PEs are assumed to be indexed in shuffled row-major order [4].

*MCC Algorithm*
/* Initialization */

1. Sort the vertical segments by their x-coordinates into non-decreasing order on the mesh in shuffled row-major order.

   Each PE contains one segment.

2. /* Determine left and right boundaries of current merge regions */

```
PE(i) executes:
if $i$ is even  $x_{max}$ = x-coordinate of segment in PE(i+1)
                $x_{min} = x$ /* x-coordinate of segment in PE(i) */
if $i$ is odd   $x_{min}$ = x-coordinate of segment in PE(i-1)
                $x_{max} = x$ /* x-coordinate of segment in PE(i) */
```

3. /* initialize length covered by each segment */

```
/* PE(i) maintains the strips corresponding to the top $y_t$ and
  bottom $y_b$ points of the segment it contains */
           $y_t.length = 0$ /* dummy strip */
if left segment then  $y_b.length = x_{max} - x$
                else  $y_b.length = x - x_{min}$
```

We now present details of the MCC implementation of the merge step corresponding to Algorithm 1.

Immediately prior to the merge step, points corresponding to segment in $L$ and $R$ are available in separate adjacent submeshes, two points per PE, sorted by y-coordinates.
Each point has with it the following information:

(i) the length of strip covered by it, in variable *length*;

(ii) a flag *bottom/top* indicating if it is the top or bottom point of a vertical segment;

(iii) a flag *left/right* indicating if it is the left or right segment of a rectangle;

(iv) a flag *full* indicating if the partner of the edge has been found or not;

(v) the co-ordinates of the point;

(vi) the id. of the rectangle to which the point belongs.

Each point also has the following global information:

(i) $x_{divider}$, $x_{min}$ and $x_{max}$.

(ii) the variable *local_rank* which is the position of the point in the sorted (by y-coordinates) list of points in its half.

Steps executed by a PE:

1. Merge the sorted lists of points in the two submeshes into a single sorted list, (using the y-coordinates as the key,) into non-decreasing row-major order. Ties are broken by the id. of the rectangle to which the point belongs. This ensures that points corresponding to segments that are partners will be adjacent in the sorted list. Let *global_rank* denote the position of a point in the merged list.

2. Each PE checks if the point adjacent to a point within it in the merged list has the same rectangle id. If so it sets *full* to 1.

3. Determine whether each strip in the merged list is *left_open* or *right_open*. We explain the steps needed to determine if it is *left_open* (symmetrical steps will determine if the strip is *right_open*). Basically, to determine if $<s_i,s_{i+1}>$ is *left_open* we count the number of right segments in $R$ whose bottom y-coordinate is less than $s_i$ and top y-coordinate exceeds $s_i$.

   Every point that is the top (respectively bottom) of a *left_open* segment (true *iff full* = 0, it belongs to $R$ and is a right segment) sets a local counter, count to 1 (respectively -1). By finding the sum of all "counts" that precede the point, every point can determine whether it lies in a *left_open* segment or not (if the sum is greater than 0, it does, else it does not).

   Since the points are sorted in row-major order, this is easily accomplished by a row-sweep that obtains the sum of counts within a row, followed by a column-sweep, which determines the sum up to the beginning of a row, followed by a final row-sweep, which distributes this partial sum to each PE in that row.

4. Execute the steps described in Algorithm 1.

   The only information that is not locally available to a PE corresponds to the case marked by a "**" in Algorithm 1. However, each PE can in constant time determine the index of the PE which contains the desired information as follows. Since *local_rank* is the position of the point among points only in its sorted list (say $A$) and *global_rank* is the position of the point in the list obtained by merging lists $A$ and $B$, the difference (actually *global_rank - local_rank - 1*) gives the position of the desired point in the sorted list $B$. By performing one RAR from the PE with index (*global_rank - local_rank - 1 + Base* address of the block of PEs containing the sorted list $B$), a PE can obtain the required information. (We presented a detailed description of such a scheme for other MCC algorithms earlier in [16].)

The time needed to find the area of the "OR" of a set of $n$ iso-oriented rectangles on a $\sqrt{n}\times\sqrt{n}$ MCC is $O(\sqrt{n})$. The sorting in the initialization step can be done in $O(\sqrt{n})$ time. Every merge of two sets of $k$ vertical segments takes place in a sub mesh of size no larger than $2\sqrt{k} \times 2\sqrt{k}$. Step 1, the mergings of two sorted lists, can be done in $O(\sqrt{k})$ time. Row and column sweeps required in Step 3 also take no more than $O(\sqrt{k})$ time. Finally, the RAR required in Step 4 also can be done in $O(\sqrt{k})$ time. The total time, $T(n)$ is therefore $T(n) \le c(\sqrt{n} + \sqrt{n}/2 + \sqrt{n}/4 + ... + 1)$

which is $O(\sqrt{n})$.

## III. "AND" Area Reporting

The "AND" of two rectangles $A$ and $B$ is a third rectangle which includes the region that is overlapped by $A$ and $B$. Given a set of $n$ iso-oriented rectangles, the "AND" area reporting problem is to find the area of the region which is covered by at least two rectangles.

We present an algorithm to solve this problem on a $\sqrt{n}\times\sqrt{n}$ MCC in $O(\sqrt{n})$ time. The algorithm follows the same general principle of the algorithm for reporting the OR-area detailed in section II, differing in the merge step which combines vertical segment on opposite sides of a dividing line. In fact, this algorithm may be considered a generalization of the "OR" problem, in that the solution to the latter is also obtained simultaneously.

Consider a strip $<l_i,l_{i+1}>$ in $L$, the region to the left of the dividing line currently being merged as in section II.

Assume that up to now the algorithm has computed the two quantities $l_i.length$ and $l_i.overlap$ for each strip $<l_i,l_{i+1}>$ in $L$. $l_i.length$ is the quantity computed by Algorithm 1 and represents the region in $<l_i,l_{i+1}>$ covered by at least one rectangle. $l_i.overlap$ represents the region in $<l_i,l_{i+1}>$ covered by two or more rectangles (i.e. the overlapped area) and has been computed in the previous iteration.

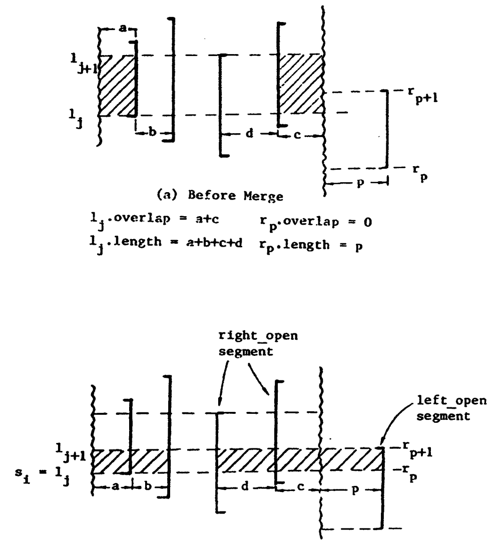
In a similar manner, the corresponding quantities $r_j.length$ and $r_j.overlap$ for all strips $<r_j,r_{j+1}>$ in $R$ have been computed.

The merging of regions $L$ and $R$ partitions the merged region $S$ into strips $<s_i,s_{i+1}>$. Algorithm 2 below presents the computation of $s_l.overlap$ using the values of $l_i.overlap$, $l_i.length$, $r_j.overlap$, $r_j.length$ already computed.

*Algorithm 2*

```
   for each <$s_i$,$s_{i+1}$> in parallel do
     if <$s_i$,$s_{i+1}$> is a left_originating strip where $s_i = l_j$
     then begin
          if <$s_i$,$s_{i+1}$> is a left_open strip then
            /* entire portion of strip <$l_j$,$l_{j+1}$> that was part
              of some rectangle is now in the overlapped area */
(1)            $(s_i.overlap)_L = l_j.length$
          else /* no change in overlapped area L */
(2)            $(s_i.overlap)_L = l_j.overlap$
          if <$s_i$,$s_{i+1}$> is a right_open strip then
            /* Let <$r_p$,$r_{p+1}$> be the segment in R that is now
              crossed by <$s_i$,$s_{i+1}$> */
(3)            $(s_i.overlap)_R = r_p.length$
          else
(4)            $(s_i.overlap)_R = r_p.overlap$
        end
     $s_i.overlap = (s_i.overlap)_L + (s_i.overlap)_R$
     else /* <$s_i$,$s_{i+1}$> is a right_originating strip */
       begin
          /* symmetrical code */
       end
end
```

Note that we also need to update $s_i.length$ during this merge step, using Algorithm 1. Fig. 3 shows the situation corresponding to (1) and (3) of Algorithm 2.



(a) Before Merge

$l_j.overlap = a+c$ $\quad$ $r_p.overlap = 0$

$l_j.length = a+b+c+d$ $\quad$ $r_p.length = p$

(b) After Merge

Case 1: $(s_i.overlap)_L = a+b+c+d$

Case 3: $(s_i.overlap)_R = p$

$(s_i.overlap) = a+b+c+d+p$

Figure 3

The MCC algorithm is similar to that in section II, and computes the AND-area in $O(\sqrt{n})$ time.

## IV. Maximum Overlap Problem

Given a set of $n$ iso-oriented rectangles, the maximum overlap problem is to determine the largest number of rectangles that overlap, i.e. include a common region. We present below an $O(\sqrt{n})$ time algorithm to solve the problem on a $\sqrt{n}\times\sqrt{n}$ MCC. At the expense of some additional book keeping, the algorithm can be modified to report a region of maximal overlap as well.

Just prior to the merge step that we are about to describe, each strip $<l_i,l_{i+1}>$ in $L$ has computed $l_r.max\_overlap$, equal to the maximum number of rectangles that overlap some region in strip $<l_i,l_{i+1}>$. Similarly, each strip $<r_j,r_{j+1}>$ in $R$ has computed $r_j.max\_overlap$. To determine the maximum number of overlapping rectangles that overlap a strip $<s_k,s_{k+1}>$ in the merged region $S$, we determine two quantities viz. $(s_k.max\_overlap)_L$ and $(s_k.max\_overlap)_R$ which are the maximum number of rectangles overlapping a point in strip $<s_k,s_{k+1}>$ that lies in $L$ or in $R$ respectively. $s_k.max\_overlap$ is then the larger of these two computed quantities.

Algorithm 3 below presents the details of the merge for a *left_originating strip* $<s_k,s_{k+1}>$. A symmetrical set of steps would apply if $<s_k,s_{k+1}>$ was a *right_originating strip.*

*Algorithm 3*

```
/* assuming <$s_k$,$s_{k+1}$> is a left_originating strip, $s_k$=$l_j$ */
1.   Find the number of left_open segments crossing <$s_k$,$s_{k+1}$>.
     Denote this by $n_L$
```

Each such *left_open segment* (which by definition belongs to $R$) must overlap all rectangles crossing $<l_j,l_{j+1}>$. Thus the maximum number of overlapping rectangles in the portion of $<s_k,s_{k+1}>$ that lies in $L$ is computed as follows.

2. $(s_i.max\_overlap)_L = (l_j.max\_overlap) + n_L$;
3. Find the number of *right_open* segments crossing $<s_k,s_{k+1}>$. Denote this by $n_R$. This region prior to the merge lay in strip $<r_p,r_{p+1}>$, where $r_p \leq l_j < r_{p+1}$.
4. $(s_i.max\_overlap)_R = (r_p.max\_overlap) + n_R$;
5. $s_i.max\_overlap = Max\,[(s_i.max\_overlap)_L,(s_i.max\_overlap)_R]$;

At the end of the last merge step, the algorithm has computed for each strip, the maximum number of rectangles overlapping within that strip. The algorithm is completed by finding the largest of these quantities over all the strips. As before the time complexity of the algorithm is $O(\sqrt{n})$ on $\sqrt{n}\times\sqrt{n}$ mesh.

An related problem in computational geometry is the fixed size rectangle placement problem. Given $n$ points in the plane, and an iso-oriented rectangle of fixed size, the problem is to find a placement of the rectangle in the plane so that the number of points covered by the rectangle is maximized. This problem is equivalent to the maximum overlap problem. Let the center of the rectangle be the intersection of its two diagonals. Generate $n$ iso-oriented rectangles of the size of the given rectangle and let each be centered at one of the given points. Find the region of maximum overlap for the rectangles, i.e. find the common region which is covered by the largest number of rectangles. Note that if a rectangle $A$ covers rectangle $B'$s center then rectangle $B$ can certainly cover $A'$s center since $A$ and $B$ are of the same size (see Fig. 4). The given rectangle should be placed centered at a region of maximal overlap.

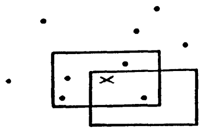


Figure 4

## V. Minimum Separation Between Rectangles

Given a set of $n$ non-overlapping iso-oriented rectangles, the minimum separation problem is to determine the distance between the closest pair of rectangles. The distance between two rectangles is defined to be the minimal (Euclidean) distance between all pairs of points, one belonging to each rectangle. If $p$ and $q$ are points on two non-overlapping rectangles $P$ and $Q$ respectively, then there are only three possibilities by which $p$ and $q$ can determine the distance between $P$ and $Q$, namely :

(i) $p$ lies on the left (right) vertical segment of $P$ and $q$ on the right (left) vertical segment of $Q$, and $p$ and $q$ have the same y-coordinate.

(ii) $p$ lies on the top (bottom) horizontal segment of $P$ and $q$ on the bottom (top) horizontal segment of $Q$, and $p$ and $q$ have the same x-coordinate.

(iii) $p$ is the northeast (northwest, southeast, southwest) corner of $P$ and $q$ is the southwest (southeast, northwest, northeast) corner of $Q$. In this case no points of $P$ and $Q$ have either a common x- or a common y-coordinate.

We refer to the distance between $P$ and $Q$ defined by the each of the three cases above as the horizontal, vertical and diagonal separation respectively. The minimum separation between the rectangles is the smallest of the horizontal, vertical and diagonal separations between all pairs of rectangles for which the corresponding separation is defined. Our algorithm to compute the minimum separation uses a divide-and-conquer strategy along the basic lines of the previous algorithms.

Assume inductively, that we have computed $\delta_L$ and $\delta_R$, the minimum separation between all pairs of rectangles (possibly incomplete) in the left and right regions, $L$ and $R$, being merged. In the merge step, we compute $\delta_S$, the minimum separation between rectangles in region $S$ as follows: Let $\delta = Min[\delta_L,\delta_R]$. We determine whether (a) the horizontal separation, (b) the vertical separation or (c) the diagonal separation between any pair of rectangles in $S$ is less than $\delta$. If so we update $\delta_S$ to the smallest of the three values computed above, else $\delta_S = \delta$. We outline the main steps in the algorithm.

### Horizontal Separation

We need to identify pairs of segments, one in $L$ and the other in $R$, which might have a horizontal separation less than $\delta$. Since the rectangles are non-overlapping, the only possibility for this occurs if a right vertical segment in $L$ and a left vertical segment in $R$ intersect a common horizontal strip, and the segment in $L$ (respectively $R$) is the rightmost (respectively leftmost) segment crossing that common strip. (See Fig. 5(a).)

To implement the merge step, we therefore need to maintain for each strip in $L$ (respectively $R$) information about the rightmost (respectively leftmost) edge in the strip. If in a refined strip we find that the rightmost segment in $L$ and the leftmost segment in $R$ crossing that strip are left-facing and right-facing respectively, we computes the horizontal separation between the two rectangles equal to the difference in the x-coordinates of the segment in $R$ and the segment in $L$. To complete the merge, the rightmost (respectively leftmost) segment in the refined strip is updated to be the rightmost (respectively leftmost) segment that crossed the strip in $R$ (respectively $L$). Finally, determine $\delta_h$, the minimum of the horizontal separations computed for each strip.

Set $\delta_S = Min[\delta,\delta_h]$. It is easy to see that these steps may be implemented on an MCC in a manner similar to the previous three algorithms.

### Vertical Separation

We need to identify pairs of segments one in $L$ and the other in $R$, which define two rectangles whose vertical separation is less than $\delta$.

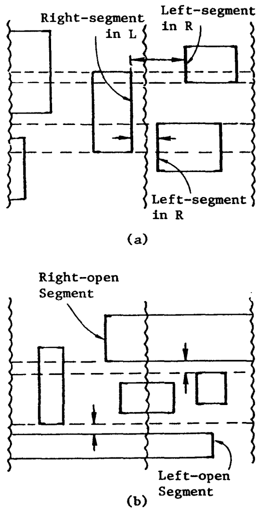

Figure 5

Observe first that, since the rectangles are non-overlapping any strip must be bounded by either the top and bottom horizontal edges of the same rectangle or by a pair consisting of the top and the bottom edges respectively of two different rectangles. A strip of the second type can influence the minimum vertical separation if and only if the horizontal edges of the two rectangles that bound the strip share a common x-coordinate. Consider a strip $<s_i,s_{i+1}>$ in the merged region $S$, where $s_i = l_j$ and $s_{i+1} = r_k$. The strip defines a vertical separation of $(s_{i+1}-s_i)$ between two rectangles if and only if either $l_j$ is a *right_open segment*, or $r_k$ is a *left_open segment* (see Fig. 5(b)). A symmetrical set of conditions holds if $s_i = r_j$ and $s_{i+1} = l_k$.

In the merge step of the algorithm, for each refined strip $<s_i,s_{i+1}>$ we determine whether it satisfies the conditions stated above. If so, we determine the vertical separation in the strip to be equal to $s_{i+1} - s_i$. Finally, update $\delta_S = Min[\delta_S,\delta_v]$. The implementation of this step on the MCC is simpler than all other cases considered so far, and does not require any random-access read. As before $\delta_v$ is the minimum of these computed values for all the strips.

Finally, we present the algorithm for examining the diagonal separation between the rectangles.

Diagonal Separation

We need to identify pairs of segments one in $L$ and the other in $R$, which define two rectangles whose diagonal separation is less than $\delta$.

In the merge step we check whether any northeast (respectively southeast) point in $L$ is within a distance $\delta$ of a southwest (respectively northwest) point of $R$. A crucial observation that enables efficient implementation of the step is that all the points of the same type (e.g. all the southwest points in $R$ or all the northeast points in $L$) obey the *sparsity* restriction, in that the distance between any two such points will be greater than $\delta$. This follows because the distance between two such points must always exceed the minimum separation between the rectangles computed so far which in turn is at least $\delta$ (see Fig. 6). Let us focus only on the northeast points in $L$ and the southwest points in $R$. (Similar considerations hold for southeast points in $L$ and northwest points in $R$.) We need to consider only those northeast points in $L$ and those southwest points in $R$ that lie within $\delta$ of the dividing line and determine if any such pairs of points one from $L$ and one from $R$, are closer than $\delta$ to each other. Since all the points under consideration in $R$ and $L$ are at least $\delta$ apart, for the density of planar point packing [20], it follows that for any northeast point in $L$, there can be at most a constant number (four in this case) of southwest points in $R$ which can be closer to the point in $L$ than the minimum separation between rectangles computed so far, i.e. $\delta$. Thus, for a northeast point in $L$ we only need to examine the distances between it and at most four southwest points in $R$ to determine if the pair from $L$ and $R$ are closer than the minimum distance between rectangles found so far. This step of the problem thus reduces to a variant of the closest pair problem for a set of planar points. We can use the merging step of the MCC algorithm presented in [16] to determine the closest pair of points consisting of a northeast point from $L$ and a southwest point from $R$. We very briefly outline the steps in the implementation. Sort all the northeast points in the left slab and all the southwest points in the right slab which are within a horizontal distance of $\delta$ from the boundary together. Record for each point, its *global_rank*, which is its position in the sorted list. Then sort the northeast and southwest points separately, and record for each point its *local_rank*, which is its position in its own sorted list. The index of a processor which contains one of the desired points on the other side is then obtained as described in Section II. The other three points are in processors immediately adjacent to this.

Find the minimum over all the diagonal distances computed above and set it equal to $\delta_d$. Finally set $\delta_S = Min[\delta_S,\delta_d]$.

Each of the three merging steps can be implemented in $O(\sqrt{k})$ time where $k$ is the number of segments being merged. The overall time complexity of the algorithm is therefore $O(\sqrt{n})$.

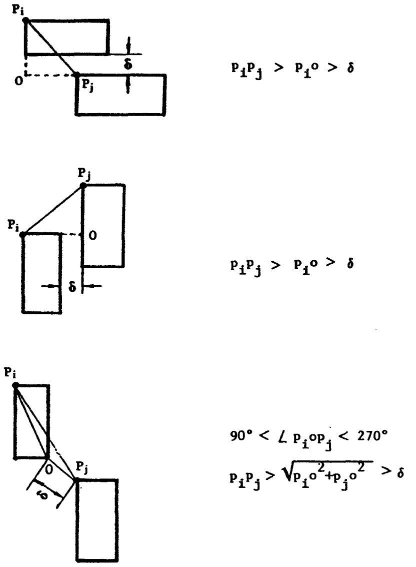

Figure 6

## VI. Summary

We have presented MCC algorithms for several rectangle intersection problems. Given a set of $n$ iso-oriented rectangles, we presented algorithms to determine the area of the logic "OR" and the logic "AND" of these rectangles. We then presented an algorithm for determining the maximum overlap for the set of rectangles, which also provides a solution for the fixed-size rectangle placement problem. Finally, we described an algorithm for computing the minimum separation of a set of non-overlapping iso-oriented rectangles. All the algorithms require an optimal $O(\sqrt{n})$ time on a $\sqrt{n}\times\sqrt{n}$ MCC with constant storage per processor.

In conclusion, we note that there are several other rectangle intersection problems similar to these considered in this paper (e.g. determining for each rectangle the number of rectangles that intersect it), that can be efficiently solved on an MCC using the "strip refinement" strategy. One interesting problem needing research is to determine an efficient means of *reporting* all pairs of intersecting rectangles using a Mesh-Connected Computer.

# M$^2$-Mesh: An augmented mesh architecture

Tsair-chin Lin and D. I. Moldovan

Dept. of Electrical Engineering/Systems
University of Southern California
Los Angeles, CA 90089-0781

**Abstract** An architecture called m$^2$-mesh is proposed here. This architecture augments mesh structure with shared memories and multiplexed multiple buses. The approach to the design of this architecture is presented. The routing capability of this architecture is discussed and its performance is analyzed. Routing algorithms for performing permutation, two point communication and broadcasting are proposed. It is shown that any permutation can be performed on m$^2$-mesh in $2N^{1/2}$ steps, as compared to $3(N^{1/2}-1)$ steps for mesh structure. Communication between any two processors, row broadcasting, column broadcasting can all be done in 2 steps on this architecture. We also compare the performance of m$^2$-mesh with mesh, mesh with single broadcasting, mesh with multiple broadcasting and tree structures. The applications of m$^2$-mesh to problems such as semi-group computations, algorithms with nested loops, linear algebra problems are discussed.

## 1. Introduction

A parallel computer achieves speedup over a uniprocessor system by executing several tasks on different processors simultaneously. The degree of speedup depends primarily on the parallelism of the program and the performance of the parallel computer. The communications between different problem tasks are performed by the interconnection network of the system. If the communication requirements of a problem "match" the system's interconnection structure, then the problem can be solved quickly. Otherwise, extra time has to be spent on data routing. Thus, often the performance of a parallel computer depends primarily on it's data routing capability. Several approaches can be taken to increase the performance of parallel computers. Most common are to design a system with a powerful interconnection network [19, 2], to design efficient parallel memories [9], and to design effective parallel algorithms for a particular architecture [21, 15]. Recently researchers proposed the use of small size systems to balance computation and communication [10, 12], or finding an efficient way to map algorithms to computers [1, 6, 11].

One of the most frequently mentioned parallel computers is the mesh-connected computer (MCC). An MCC has the advantages of simple topology and good scalability. Because of this, many results on the application of MCC have been reported, and among these are: sorting [22, 15], image processing [18], and graph algorithms [16]. However, previous researches showed that the communication time in MCC tends to dominate the total execution time. For example, the multiplication of two $N^{1/2}$ by $N^{1/2}$ matrices takes $O(N^{1/2})$ routing steps when executed on a $N^{1/2} \times N^{1/2}$ MCC [3]. Regarding the routing capability of MCC, it's shown that in general $3(N^{1/2}-1)$ steps are required to perform any permutation [17]. Therefore, for general application, mesh connected computers suffer from the limitation of their routing capability.

In this paper, we propose an architecture based on mesh structure, called multiplexed-multiple-bus mesh, or simply m$^2$-mesh. The system consists of both local and shared memory modules. We will show that by using this structure, many algorithms can be executed efficiently. The performance of this architecture is compared with mesh, mesh with broadcasting, tree structures. It can be seen that this structure performs more efficiently for a broader range of applications than MCC, with reasonable additional cost.

## 2. M$^2$-mesh Architecture

### 2.1. Comparision of two models of SIMD architectures

This research was supported by NSF grant ECS-8307258 and JSEP contract No. F49620-85-C0071

A mesh connected computer with N processors (N is a perfect square) is shown in figure 1.

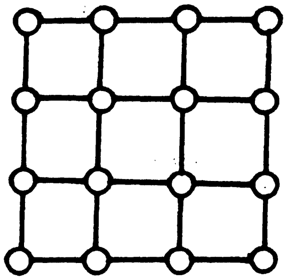

**Figure 1:** A mesh connected computer.

The processors are numbered in row major ordering. PE(i) is connected directly to PE(i±1), PE($i \pm N^{1/2}$), except the boundary PEs. The near neighbor interconnection is a simple but useful topology. Algorithms requiring frequent interactions between problem tasks can be mapped to this architecture naturally. The other feature of MCC is its good scalability, i.e., it's easy to expand from small size MCC to large size. However, for problems requiring global communication, mesh interconnection does not perform well. Considering the data routing time only, a permutation takes $3(N^{1/2}-1)$ steps on mesh. Broadcasting from one PE to any other PE takes $2(N^{1/2}-1)$ steps. In general, since the diameter of mesh is $2N^{1/2}$, normally $\Omega(N^{1/2})$ of routing steps are required for one routing function. So, if an algorithm takes O(f(N)) computation steps, and one routing function has to be performed between two computation steps, the worst case execution time could be $O(N^{1/2}f(N))$, instead of O(f(N)) (because $O(N^{1/2})$ routing steps are required for each of the $O(N^{1/2})$ data routing functions). Thus, the performance of an MCC could be greatly impaired by its communication capability. On way to overcome this problem without changing the system architecture is using mapping techniques. In [11] it was shown that any permutation can be performed on a MCC in at most four steps if the data are loaded properly. Thus, any algorithm which requires only a single type of permutation can always be achieved in constant data routing time. However, if the permutation requirement of the algorithm changes from time to time during execution, this mapping technique may not perform well.

The other way for overcoming the commnunication limitation of an MCC is to reconsider the original problem and to devise a better algorithm for the MCC. For example, the bitonic sorting algorithm on an MCC designed in [15] is achieved by this approach. This approach involves the design of parallel algorithms, which apparently is not an easy task for many users. Also, it suffers from lack of universality, because every algorithm has to be considered separately.

Our approach in this paper is to enhance the performance of MCC with reasonable additional cost. The idea of this newly proposed $m^2$-mesh architecture comes from the following observations. A mesh connected computer is really a multiprocessor system with local memory scheme. That is, every processor has its own private memory. Any two processors wishing to exchange information with each other have to use the mesh interconnection. This type of architecture can be modelled by the architecture shown in figure 2.

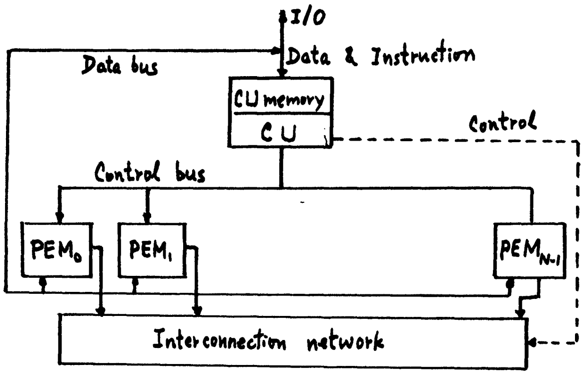

**Figure 2:** An SIMD machine with local memory scheme

However, since the longest path between any two processors is $2N^{1/2}$, long communication delay is inevitable. This problem is basically caused by the fact that local mamory scheme is used. Should two far-separated processors share the same memory module, then the communication time will not depend on their physical location. Since mesh structure has its merits, our strategy here is to include both local memory and shared memories. First consider the array processor model in figure 3 as used in [9]. In this architecture, both local memory and shared memory schemes are used here. Moreover, the interconnection between processors is separated from the inteconnection between memories.

**There are four interconnection networks in this architecture, each one may have different topology.**

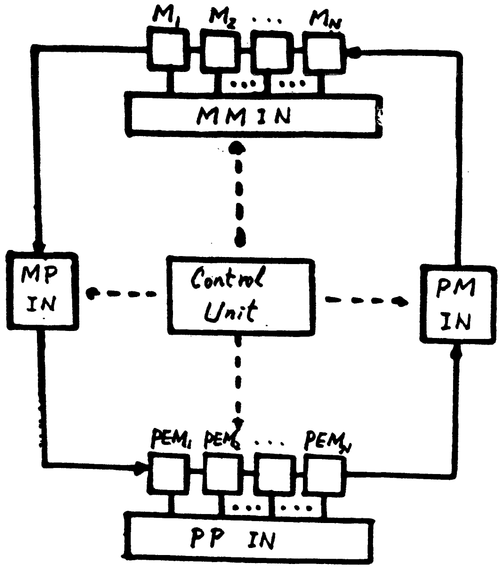

**Figure 3:** An SIMD with both local memory and shared memory system.

Every PEM contains a processor with its own local memory. The global memory modules M are shared by all processors. Thus interprocessor communication can be done either through processor-processor interconnection (PP), or through the shared memory. Compared to model shown in figure 2, this scheme is more powerful.

### 2.2. The $m^2$-mesh architecture

The idea in last section is adopted in our proposed architecture, which is shown in figure 4.

The system consists of N processors and N shared memory modules. Processors are interconnected by an $N^{1/2}$ by $N^{1/2}$ mesh, with local memory attached to each processor. Processors are identified by their two dimensional coordinates. Shared memory modules are numbered similarly. $M(i_1,j_1)$ and $M(i_2,j_2)$ share a row bus if $i_1 = i_2$, and similarly, $M(i_1,j_1)$, $M(i_2,j_2)$, $PE(i_3,j_3)$ share a column bus if $j_1=j_2=j_3$. In terms of the model from figure 3, our architecture uses mesh for processor-processor communication and processor-memory and memory-memory communications are done through buses.

The memories used here have special organization. Each memory module is divided into $N^{1/2}$ banks. The kth bank of M(i,j) is denoted as $M_k(i,j)$. Memory accesses work in the following fashion:

1. PE(i,j) can read every bank of every memory module in the jth column, i.e., PE(i,j) can read $M_k(l,j)$ $\forall k,l, 0 \leq k,l \leq N^{1/2}-1$.

2. PE(i,j) can only write to $M_i(j,j)$, the ith bank of M(j,j).

3. When a data item is written to $M_i(j,j)$ by PE(i,j), it's written through all the ith bank of the memories in the same row, i.e., $M_i(j,k)$ $\forall k, 0 \leq k \leq N^{1/2}-1$.

Since PE(i,j) can only write data to $M_i(j,j)$, only one of the processors in the same column can write at a particular time. From this point of view, the processors in the same column are time *multiplexed* on the column bus. However, processors in different columns can write to shared memory simultaneously. This means that the *multiple* column buses can be used concurrently. So, this architecture is called $m^2$-mesh. The write through scheme allows data to be transferred between processors efficiently, as will be explained in the next section.

## 3. Routing strategy and routing scheme

Since $m^2$-mesh contains mesh structure as a subset, the advantage of mesh is kept. Our routing stategy is that if communication is between near-neighbor processors, local communication through mesh is exploited. For long distance routing, buses and shared memory are used. This can be done by the implementation of two routing instructions: G(i,j) and L(i,j), where G(i,j) is global communication, and L(i,j) is local communication. In the following, we will show that many data routing functions which mesh cannot perform well can be achieved by $m^2$-mesh efficiently.

1. Two point communication: One way to evaluate the routing capability of an interconnection network is the communication time between any two processors. The communication from $PE(i_1,j_1)$ to $PE(i_2,j_2)$ requires $|i_1-i_2| + |j_1-j_2|$ steps on mesh, which is $2(N^{1/2}-1)$ in the worst case. By using $m^2$-mesh, this can always be achieved in two steps. First, $PE(i_1,j_1)$ writes to $M_{i_1}(j_1,j_1)$, then $PE(i_2,j_2)$ reads back from $M_{i_1}(j_1,j_2)$.

2.Column broadcasting: PE(i,j) sends data to PE(*,j)'s. This can be done by first writing data by PE(i,j) to $M_i(j,j)$, then by activating all PE's in the column, all the PE's in the same column read it back simultaneously. Two steps are sufficient.

3.Row broadcasting: PE(i,j) writes data to PE(i,*)s. This can be done in two steps: First, PE(i,j) writes to $M_i(j,j)$, then, every PE(i,k), $0 \leq k \leq N^{1/2}-1$, read data from $M_i(j,k)$.

4.Permutation: Any permutation can be done in $2N^{1/2}$ steps. Assume permutation P maps PE(i,j) to PE(p,q). We use the notation p = r(P(i,j)), q = c(P(i,j), where r and c indicate the row and the column number of a PE respectively.

Similarly, $i = r(P^{-1}(p,q))$, and $j = c(P^{-1}(p,q))$. The routing algorithm for permutation P is as following:

**Routing algorithm for permutations**

```
/* Permutation algorithm for P : PE(i,j) --> PE(p,q) *
    for n = 1 to $N^{1/2}$
      cobegin        /* row major loop */
        PE(n,i) --> $M_n(i,i)$    $0 \leq i \leq N^{1/2} - 1$
      coend
    for n = 1 to $N^{1/2}$
      cobegin        /* column major loop */
                     /* $j = r(P^{-1}(n,i))$, $k = c(P^{-1}(n,i))$*
        PE(n,i) <-- $M_j(k,i)$    $0 \leq i \leq N^{1/2} - 1$
      coend
```

Notice that if more than one column broadcastings occur concurrently, they can be done simultaneously. The situation for concurrent row broadcasting is different. A column bus contension will happen if the sources (or destinations) of some row broadcastings are in the same column. The situation is called row broadcasting conflict. For example, in figure 5 (a) row broadcasting conflict occurs, because to send data from PE(0,0) to PE(0,2) through global communication path, PE(0,0) has to write to M(0,0) which will conflict with PE(2,0)'s writing to M(0,0). In general, these broadcastings should be done sequentially. However, there are two ways to get around it. The first way is to skew the source (in case of source conflict) one step to the right (or left) through local link if possible, then the row broadcastings can be done concurrently (see figure 5 (b)). However, if the conflict involves too many sources, then this method is not efficient. The second way is to map the problem tasks in a transposed manner, then every row broadcasting changes to column broadcasting, and no conflicts will occur (see figure 5 (c)). This method is particularly suitable to algorithms in which only row broadcasting conflict exists. We will show the usefulness of this technique later.

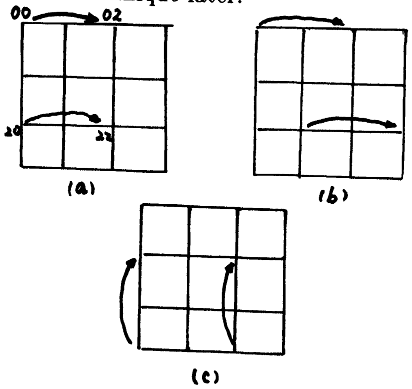

**Figure 5:** Row broadcasting conflict.

## 4. Performance analysis

The performance of $m^2$-mesh is studied by comparing it to other mesh related networks.

### 4.1. $m^2$-mesh vs. mesh

For problems requiring extensive information transfers, $m^2$-mesh is not necessary better than mesh. For example, $\Omega(N^{1/2})$ time is required to solve sorting problems on MCC, no matter with or without broadcasting [20, 8]. However, in general for ordinary algorithms $m^2$-mesh performs much better than mesh, as can be seen below.

1.Communication between any two processors: This requires $2(N^{1/2}-1)$ steps on mesh, but 2 steps on $m^2$-mesh.

2.Broadcasting: On mesh, this requires $O(N^{1/2})$, but on $m^2$-mesh, 2 steps are sufficient.

3.Permutation: $m^2$-mesh can perform permutation easier and faster. The lower bound for any permutation on mesh is $3(N^{1/2}-1)$ steps. On $m^2$-mesh, any permutation can be done in $2N^{1/2}$ steps. Moreover, the system overhead is different. For mesh, performing different permutations may require different routing algorithms. Besides, in each routing step, a masking function has to be computed, because some processors may need transfer data, some may not. Therefore the overhead is very large. In the case of $m^2$-mesh, our routing algorithm proposed in the last section is universal, i.e., independent of permutations. Also, system overhead is reduced significantly; because during routing, processors are activated row by row regularly.

### 4.2. $m^2$-mesh vs. mesh with single broadcasting

The mesh with single broadcasting interconnection is proposed in [20]. It's easy to see that $m^2$-mesh can simulate mesh with single broadcasting. So we have the following lemma.

**Lemma 1**: Any algorithm taking $\theta(n)$ time on mesh with single broadcasting can be executed on $m^2$-mesh in O(n) time.

For some algorithms, $m^2$-mesh performs better. This can be seen in the next section.

### 4.3. $m^2$-mesh vs. mesh with multiple broadcasting

The comparison between the two architectures is done in two aspects.

1.Permutation: Mesh with broadcasting structure doesn't perform better than mesh in terms of permutations. So, in general $3(N^{1/2}-1)$ steps are required to perform permutation on mesh with multiple broadcasting. Also, the control overhead is large and the routing algorithms are complex. For $m^2$-mesh, $2N^{1/2}$ steps are required. Also, the overhead is low.

2.Broadcasting: For row broadcasting, column broadcasting, or one to all broadcasting, both networks perform equally well. When row broadcasting conflict happens, $m^2$-mesh is worse. In the worst case, if row broadcasting conflict involves $N^{1/2}$ rows, then $m^2$-mesh could be $N^{1/2}$ steps slower. However, by using the technique mentioned in section 3, this can be prevented in some cases.

### 4.4. $m^2$-mesh vs. tree

We can use row broadcasting or column broadcasting to simulate tree operations. Therefore, using the same argument as in [8], we have the following lemma:

**Lemma 2**: If n data items are distributed in n different rows with one in each row, then any non-trivial semi-group computation of n data items can be performed in O(logn) steps.

## 5. Applications

The $m^2$-mesh is an architecture with a varity of data routing capabilities. So its potential is promising. For algorithms requiring lots of information flow (such as sorting), $m^2$-mesh can perform at least as well as mesh. So any parallel algorithms designed for mesh can be adopted by $m^2$-mesh. However, if global communications are required, $m^2$-mesh is much better architecture. In the following, we will discuss some application examples. Other applications can be probed by using the technique described here.

### 5.1. Semi-group computations

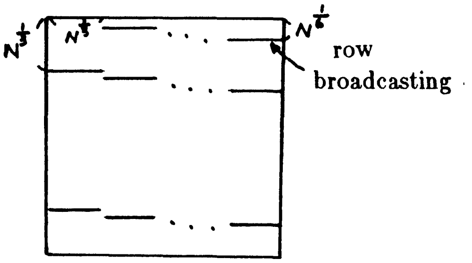
This type of computations include finding maximum, minimum, sum of N data items, etc.. We have the following theorem for these problems.

**Theorem 1**: A semi-group operation of N data items can be performed in $O(N^{1/6})$ time in a $m^2$-mesh.

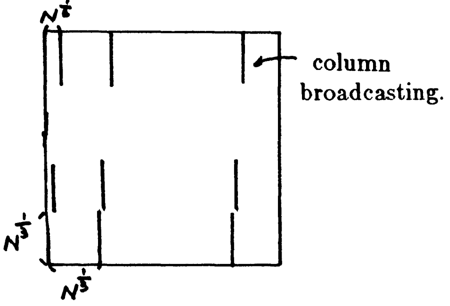
*Proof*: An algorithm for semi-group operations taking $O(N^{1/6})$ in 2-MCC with multiple broadcasting was porposed in [8]. Our proof exploits the same algorithm, except that we have to prove that every step of that algorithm can be simulated here. We will not list the original algorithm here. Based on that algorithm, the following two arguments are sufficient to prove this theorem.

(1) The operation of finding the Max of a block of data within $N^{1/6}$ x $N^{1/6}$ PE's using local communication can be executed on $m^2$-mesh in exactly the same way as in a mesh with multiple broadcasting architecture.

(2) The algorithm exploits concurrent row broadcasting operations, but no concurrent column broadcasting. Therefore we can transpose the original problem tasks so that no row broadcasting conflict will occur. For example, the following communications are required in that algorithm:



By transposing the assignment of problem tasks, the communications are as follows:



This way the row broadcasting conflict can be prevented. So from that algorithm, $O(N^{1/6})$ time is sufficient.

### 5.2. Algorithms with nested loops

Algorithms with nested loops cover a broad range of algorithms in signal processing, linear algebra, graph theory, and others. Examples of this type of algorithms include Finite Impulse Response (FIR) filtering algorithm, matrix multiplication, LU decomposition, transitive closure algorithm, etc.. The mapping of this type of algorithms to systolic array and array processor has drawn a lot of attention recently [7, 14, 13, 5]. One of the most effective way to map this type of algorithms is via algorithm transformation [14, 13]. In [10], the algorithm transformation technique is applied to mapping algorithms to array processors with mesh interconnection. One important conclusion there is that if a given array processor has broadcasting capability, then sometimes algorithms can be mapped to architecture with shorter execution time. For example, consider an algorithm with dependence matrix D. The way to map algorithm to mesh architecture is by finding a transformation T such that the transformed algorithm has a shorter execution time. The transformation T transforms D to $D'$ (=TD). One of the constraints in solving T is that every element in the first row of $D'$ should be greater than zero. However, if the system has broadcasting capability, this constraint can be released. (For details of reason for this argument, please see [10].) Besides, the criteria for considering tradeoff among computation time, communication time and local memory size of each processor will be different if broadcasting capability is provided by the architecture. Therefore, $m^2$-mesh can be used to solved algorithms with nested loops more efficiently than by using mesh architecture.

*Example 1*: Convolution computation. Given two sequences h(k) and x(k), k = 1, 2, ...., n, the convolution of h and x is defined as

$$y(j) = \sum_{k=1}^{n} h(k)x(j\text{-}k) \quad j = 1, ..., n.$$

This algorithm can be implemented by the following Fortran-like program:

```
  DO 10 j = 1,n
  DO 10 k = 1,n
    y(j) = h(k) * x(j-k) + y(j)
10 CONTINUE
```

The dependence matrix for this algorithm is

$$D = \begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \end{bmatrix}$$

Without using broadcasting, we found that the transformation

$$T_1 = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

is optimal, and the transformed matrix $D_1'$ is

$$D_1' = \begin{bmatrix} 1 & 1 & 2 \\ 1 & 0 & 1 \end{bmatrix}$$

The number of computation steps $M_1$ and the number of data routing steps $R_1$ using this transformation are

$$M_1 = 2n$$

$$R_1 = 2n\text{-}1$$

respectively.

Now, consider another transformation

$$T_2 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

Using this transformation, the transformed dependence matrix is

$$D_2' = \begin{array}{c} \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} \\ \begin{array}{ccc} y & h & x \end{array} \end{array}$$

The number of computation steps and data routing steps are

$$M_2 = n$$

$$R_2 = n\text{-}1$$

respectively.

Therefore, this transformation results in a faster algorithm. However, from $D_2'$, it can be seen that the value of h vector must be broadcasted during computation. Therefore, this is not a valid transformation for mesh without broadcasting capability, but is a good one for the $m^2$-mesh.

### 5.3. Parallel linear algebra algorithms

From the analysis in previous sections, there are mainly two things that $m^2$-mesh performs better than mesh architecture:

1. The communication between any two processors on $m^2$-mesh requires only two steps. However, it could be as worse as $2(N^{1/2}\text{-}1)$ steps on mesh.

2. $m^2$-mesh has broadcasting capability.

In the following, we will show that these two characteristics match directly with the requirements of many parallel linear algebra algorithms.

*Example 2*: Gauss-Jordan algorithm for computing a solution X of AX = B. Assume A is N by N, and B is N by M, this algorithm can be described as follows:

```
for j = 1 step 1 until N do
    row i <-- row i - $(a_{ij}/a_{jj})$row j, $(1 \le i \le N, i \ne j)$;
  $x_{ij}$ <-- $a_{ij}/a_{ii}$, $(1 \le i \le N, N+1 \le j \le N+M)$.
```

In the jth step of the algorithm, row j is broadcasted to all other rows. This can be done in $M^2$-mesh in two routing steps only. Then all rows can perform computations simultaneously. Therefore this algorithm can be solved on $m^2$-mesh efficiently.

*Example 3*: C-K algorithm for triangular system problem [4]. This algorithm, proposed by Chen and Kuck, can be described as follows:

```
row i = (row i)/$a_{ii}$   $1 \le i \le N$
for j = 1 step 1 until N-1 do

    row i = row i - $\sum_{k=j}^{2j-1} a_{i,i-k} rowi-k$
                    $j+1 \le i \le N$

$x_i = a_{i,N+1}$        $1 \le i \le N$
```

Assume the elements in one row of the matrix are mapped to one row of processors. When $j = j_1$, the processors at the ith row need information from processors at row $i\text{-}j_1$, row $i\text{-}j_1\text{-}1$, up to row $i\text{-}2j_1\text{-}1$. Hence, the communication cost is $2j_1\text{-}1$. However, on $m^2$-mesh, this can be achieved in 2 steps by using broadcasting. Overall, the communication cost of this algorithm on mesh is

$$J_1 = 1+2+ \ldots.+ N\text{-}1 = O(N^2)$$

While on $m^2$-mesh, only O(N) steps are required.

## 6. Conclusion

In this paper we proposed a multiplexed-multiple-bus mesh parallel computer system. The system not only retains most of the useful characteristics of mesh connected computers, but also augment them with efficient broadcasting and permutation capabilities. This architecture doesn't increase too much the hardware of each processor. The only significant cost is that N shared memory modules are required. However, with today's VLSI technology memories are rather inexpensive. We have shown that $m^2$-mesh has a much more powerful routing capability than mesh. We also showed that a wide range of applications are possible. More applications can be explored by using the architecture characteristics of $m^2$-mesh and the idea of mapping technique discussed in this paper.

# ON THE UNIVERSALITY OF MULTISTAGE INTERCONNECTION NETWORKS *

*T.H. Szymanski*

Department of Electrical Engineering
University of Toronto

Abstract – We present a simple analytic model for the blocking probability of circuit switched multistage interconnection networks (MINs) when the set of requests submitted during each cycle is a randomly selected permutation. This model provides a quantitative measure of a network's permutation capability. We present an analytic model for the number of conflict free permutations realizable in a multipath network, and we present an analytic model for the expected number of cycles required to realize an arbitrary permutation in a network (i.e., the universality of a network). These models and techniques solve many interesting theoretical problems in the realm of interconnection network modelling.

However, these models also have practical aspects; they give a quantitative measure of the connectivity of a network, and they give an approximate figure of merit of a network's ability to supply data vectors to array processors in SIMD array processor architectures.

## 1. Introduction

The *permutation capability* of an multistage interconnection network (MIN) can be loosely defined as the blocking probability of the network when the requests submitted during each cycle form a randomly selected permutation. The *rearrangeability* of a MIN can be defined as the ability to realize an arbitrary permutation in one cycle [4]. The *universality* of a MIN can be loosely defined as its ability to realize an arbitrary permutation in multiple network passes (where each pass requires one cycle) [21].

Non-blocking (rearrageable) switching networks have been the subject of extensive theoretical research. Of the known rearrageable networks, large crossbars are far too expensive, and the various MINs that meet this criteria ([4][14][29]) require precomputed global routing for each individual permutation. The necessity for precomputed global routing makes these networks impractical, especially if the permutations are not known at compile time.

Many suboptimal (nonrearrangeable) MINs with simple distributed routing algorithms, such as banyan networks [8] and the Augmented Data Manipulator (ADM) [1], have been analyzed for aspects of their permutation capabilities or universalities. However, to date "there does not exist any satisfactory technique which compares and quantifies permutability of ADM, Banyan and other MINs" [2].

An analytic model that yields the blocking probability of a banyan network when the request pattern submitted during each cycle is a randomly selected permutation (and when the usual decentralized routing algorithm for banyan networks is used) has been presented in [27]. We use the techniques presented in [27] to develop an alternate analytic model, which will be used throughout this paper. The development of this alternate analytic model illustrates the generality of the technique described in [27].

Using this analytic model, we derive an accurate approximation for the number of conflict-free permutations realizable by a multipath MIN (i.e., the number of permutations realizable in one pass). Previously, no general techniques have been proposed for estimating the number of conflict free permutations in multipath MINs. Lower and upper bounds on the number of conflict free permutations in the AMD have been presented in [1], and a complex analysis for the exact number of conflict free permutations in the ADM has been presented in [15][16]. Our technique is simple and general, and can be used to obtain models for arbitrary networks such as the ADM and the many variations of banyan networks, using various decentralized routing algorithms.

We present an accurate analytic model for the expected number of network passes required to realize an arbitrary permutation, i.e., the universality of a MIN, when simple distributed routing algorithms are used. Upper bounds for the expected number of network cycles required to realize an arbitrary permutation in certain banyan networks (when precomputed global routing is used) have been presented [2][28]. It has been shown that by using precomputed global routing, the omega network [12] can realize an arbitrary permutation in 3 passes [21][25]. However, the fastest known algorithm for the routing requires $O(\log^4{}_2 N)$ time on an array processor [25]. A simpler routing algorithm that results in a universality of $6\log_2 N-1$ passes for a variation of the omega network has been presented in [25]. Our analysis is fundamentally different from these in that we assume a simple distributed routing algorithm is used; in the first pass, all requests in the permutation are submitted to the network. Requests that are not established in one pass must be resubmitted in the next pass, etc. The modelling technique we use is very general, and can be used to create models for the universality of other MINs using various decentralized routing algorithms.

While these models and techniques solve many interesting theoretical problems, they also have practical aspects. The number of simultaneous, conflict free connections possible in a network (when the requests form a permutation) is a quantitative measure of the *connectivity* of a network. "The connectivity of a MIN is critical with respect to the overall performance of a large parallel system" [2].

The universality of a network has often been used as an approximate figure of merit for the suitability of the network in *Single Instruction Multiple Data* (SIMD) array processor architectures. These machines operate in synchronization on numeric applications that can be "vectorized". When the processor array accesses a vector in unison, the resulting request distribution is (usually) a permutation. "One of the most significant factors in determining the performance of an array processor is the system's capability for providing data vectors at a rate matched to the processor rate" [12]. The system's capability for providing data vectors is closely related to its universality (or indirectly to its permutation capability), and hence "the permutation capability of a network is extremely important for the efficient operation of a supersystem" [2].

Section 2 includes the necessary definitions. Section 3 presents a simple analytic model for the blocking probability of MINs when the set of requests submitted during each cycle are a randomly selected permutation. Section 4 presents an analytic approximation for the expected number of conflict-free permutations realizable by a multipath MIN (in one cycle). Section 5 presents an analytic approximation for the expected number of network cycles required to realize an arbitrary permutation, i.e., the universality of a MIN. Section 6 summarizes the paper and

contains some concluding remarks.

## 2. Definitions

In a multiprocessor system, an ***interconnection network*** is used to connect $N$ processors to $M$ memories, as shown in fig. 1a. The crossbar network is non-blocking for all permutations, and hence is a candidate for array processor systems, but it is far too expensive for large $N$. Unique path multistage interconnection networks (***unipath MINs*** or ***banyan*** networks [8]) provide a reasonable alternative to large crossbars. A square $k^n \times k^n$ banyan network of size $N$ consists of $\log_k N$ stages, where each stage consists of $N/k$ crossbar switches of size $k \times k$, as shown in fig. 1b. ***Banyan*** networks have a number of desirable features; their cost grows only moderately as the network size increases and they use very simple, distributed routing algorithms [8].

Two fundamental criteria in the selection of an interconnection network are fault tolerance and performance. Banyan networks can be extended in many ways to significantly improve their fault tolerance, and such improvements may result in performance improvements. Since any practical multiprocessor system will almost certainly require a fault tolerant interconnection network, it is important to have analytic models that are general, and that can be used on these extended networks, as well as on the unipath networks.

### 2.1. Fault Tolerance

Banyan networks can be extended in many ways to significantly improve their fault tolerance. Assuming link failures are the predominant failure mechanism [19], each link in a network can be replaced by 2 links, as shown in fig. 2a. When each link is replaced by $d$ links, we call the resulting network a $d$-dilated network [10]. If total switch failures are a predominant failure mechanism, then the $d$ links in a dilated network that replace one link in the unipath network can actually be distributed among a number of the switches in the next stage [23]. In a 2-augmented network, one link leads to the same switch as it would in a unipath network, and the other link leads to a functionally equivalent switch. These networks are called ***augmented*** networks [23]. A 2-augmented delta network is shown in fig. 2b. The solid lines represent links leading to the same successor as they normally would, and the dotted lines represent links leading to equivalent successors. (The regular distributed routing algorithm is slightly modified; see [23]). Throughout this paper, we do not distinguish between dilated and augmented networks (their performances are similar [23,26]); denote either of these multipath networks as $p$-path MINs, where $p$ is the path multiplicity.

Banyan networks can also be replicated to improve their fault tolerance. We consider only dilated (or augmented) networks in this paper; see [26] for an analysis of replicated networks.

### 2.2. Performance Under Random Distributions

We now define the operating environment of MINs considered in this paper. We assume that the network is synchronously circuit switched; a system clock defines a ***cycle*** in the network; during the beginning of any cycle, a processor issues a request with probability $u$ (0). Assume (for now) that requests are randomly and evenly distributed over the memories, and are independent from cycle to cycle. For each request, the network tries to establish a circuit switched connection from the processor to the desired memory. The routing algorithm is very simple; in every stage, a switch that receives a request examines a particular bit in the destination, selects an appropriate output link, and forwards the request out on that link [8]. If the network has multiple paths (i.e., $p > 1$), then assume the switch randomly selects a free link from the $p$ appropriate links, and forwards the request on that link. One reason for the popularity of these networks is their simple distributed routing algorithms.

A connection may not be established because $p+1$ or more requests compete for $p$ output links at a particular switch; we say that ***link contention*** has occurred; $p$ requests are selected randomly and forwarded, and the others are ***blocked***, and must be resubmitted during the next cycle. Hence, during one cycle only a fraction of the submitted requests will have their connections established. Let $pb$ be the ***blocking probability*** of a network; if $N$ requests are submitted in one cycle, then $N \cdot pb$ requests are expected to be blocked during that cycle. Under these operating assumptions, (i.e., circuit switched MINs with random request distributions) numerous models exist for the blocking probability of a network [10] [22].

### 2.3. The Universality of an Interconnection Network

A very important practical operating assumption is to suppose $N$ requests are submitted during each cycle, where these $N$ requests form a permutation of the memory module indices (i.e., the requests are ***uniquely*** distributed). This situation occurs in ***Single Instruction Multiple Data*** (SIMD) array processors executing numeric algorithms. ***Data skewing*** algorithms are used to map the data (i.e., vectors or matrices) into the memories in such a way so that when the set of $N$ processors issues a request for a vector, the resulting request pattern is a permutation (of the memory module indices). One approximate figure of merit for a network's ability

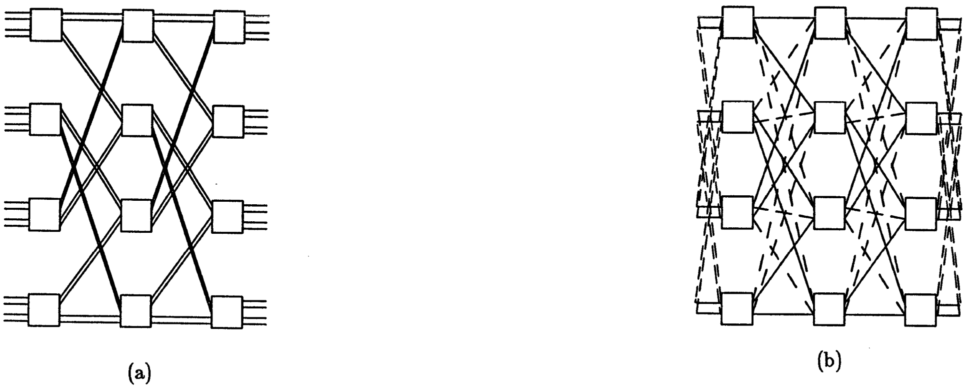

**Fig. 2:** a) a 2-dilated $2^3 \times 2^3$ delta network. b) a 2-augmented $2^3 \times 2^3$ delta network. (Delta networks [22] are a subclass of banyan networks [8]).

to supply data vectors is its universality. However, most permutations generated by an array processor are highly structured (i.e., they are not randomly selected permutations) [12] and a better figure of merit would be a model that yields the universality of a MIN when certain permutation classes are used. Lawrie has shown that the omega network can realize many permutation classes frequently arising in array processors [12]. Other architectures where the permutation patterns are not necessarily highly structured apparently include MIMD parallel reduction machines and logic machines [9].

In this paper, we present a simple analytic approximation for the blocking probability of a network when the requests submitted during each cycle form a randomly selected permutation. We present an analytic approximation for the number of conflict free permutations realizable by a network (i.e., the number of permutations that can be realized in one cycle), and we present an analytic approximation for the expected number of cycles required to realize an arbitrary permutation, i.e., the universality of a MIN.

## 3. The Permutation Capability of Multistage Interconnection Networks

We present a conceptually simple analytic model for the performance of generalized $p$-path $k^n \times k^n$ banyan networks, under either random or unique memory request distributions, in this section. It is first necessary to derive an analytic model for the blocking probability of generalized $p$-path $k^n \times k^n$ MINs under the assumption of random, uniform request distributions. This model is then modified (in the next sub-section) to yield the blocking probability under the assumption of unique memory request distributions (or simply *under unique distributions*).

### 3.1. Analysis of Multistage Interconnection Networks Under Random Distributions

In this section, an analytic model for the blocking probability of generalized $p$-path $k^n \times k^n$ MINs under random distributions is presented.

The assumptions for the analysis are as follows: 1) during the beginning of each cycle every processor issues a request with probability $u(0)$; 2) requests are randomly and uniformly distributed among the memories; and 3) unsatisfied requests in any cycle are ignored, and a new set of requests is issued during the next cycle subject to 1) and 2).

We assume that any physical link between stages $i$ and $i+1$ carries one request with probability $u(i)$, the aggregate link utilization. Hence, the probability that a switch in a particular stage receives $i$ requests can be modelled as a simple binomial distribution. Since each $p$-path $k \times k$ switch has $pk$ physical inputs, the probability that $i$ requests arrive at the switch in stage $m+1$ is given by

$$\binom{pk}{i} u(m)^i (1-u(m))^{pk-i}$$

The probability that $j$ of these requests select a particular logical output port is given by

$$\binom{i}{j}\left(\frac{1}{k}\right)^j \left(1-\frac{1}{k}\right)^{i-j}$$

In general, due to path multiplicity the first $f$ stages will not block, where $f$ is given by

$$f = \left\lfloor \log_k p \right\rfloor$$

The aggregate link utilization $u(f)$ after stage $f$ is simply $u(0)/p$.

In general, after any stage $m+1$ we are interested in $p(i)$, the probability that $p$ logically equivalent links carry $i$ requests. $p(i)$, for $0 \leq i \leq p$, can be calculated as follows

For $j < p$:

$$p(j) = \sum_{i=j}^{pk} \binom{pk}{i} u(m)^i (1-u(m))^{pk-i} \binom{i}{j}\left(\frac{1}{k}\right)^j \left(1-\frac{1}{k}\right)^{i-j} \quad (1.1)$$

For $j = p$:

$$p(j) = \sum_{i=p}^{pk} \binom{pk}{i} u(m)^i (1-u(m))^{pk-i} \sum_{t=p}^{i} \binom{i}{t}\left(\frac{1}{k}\right)^t \left(1-\frac{1}{k}\right)^{i-t} \quad (1.2)$$

After each stage $m+1$, we need to calculate the aggregate link utilization $u(m+1)$, as follows

$$u(m+1) = \sum_{i=0}^{p} \frac{p(i) \cdot i}{p} \quad (1.3)$$

The blocking probability of a network of size $N \geq 2^{f+1}$ (assuming each memory services at most 1 request in each cycle) is then

$$pb = 1 - \frac{p(0)}{u(f)} \quad (1.4)$$

The comparison of this model with simulations of various augmented and dilated networks can be found in [26]. The model is exact for unipath networks, but is only an approximation for multipath networks. Simple refinements of this model can also be found in [26].

### 3.2. Analysis of Multistage Interconnection Networks Under Unique Distributions

We can now adapt this model to yield the blocking probability of the network under the assumption of unique memory request distributions, using the technique presented in [27]. The blocking probability under unique distributions is the probability that an issued request will block, when the requests form a randomly selected permutation.

The assumptions for the analysis are as follows: 1) during the beginning of each cycle every processor issues a request with probability $u(0)$; 2) requests are uniquely and uniformly distributed among the memories; and 3) unsatisfied requests in any cycle are ignored, and a new set of requests is issued during the next cycle subject to 1) and 2).

Consider the $2^3 \times 2^3$ banyan network shown in fig. 1b. An output link from the first stage can reach 4 different memories, and a switch in the first stage can reach 8 different memories. The first request arriving at a switch in the first stage selects an output link with probability 4/8. A second request arriving at the same switch selects the same output link with probability 3/7, and selects the other output link with probability 4/7.

The preceding technique can be generalized; consider the probabilities of requests selecting outputs at a particular $p$-path $k \times k$ crossbar switch in stage $m$ of the banyan network. Each output link leads to $k^{n-m}$ memory modules. The first request selects a particular output link with probability $k^{n-m}/k^{n-m+1}$. Given that the first request selects a particular output link, then the second request selects that same output link with probability $(k^{n-m}-1)/(k^{n-m+1}-1)$.

As a notational convenience, define function $p\_s(s,r,m)$ as the probability that a request at a switch in stage $m$ will select a particular output link given that $s$ requests have already selected that link, and that $r$ requests have already selected other links.

$$p\_s(s,r,m) = \begin{cases} \dfrac{k^{n-m}-s}{k^{n-m+1}-s-r}, \text{ for } s < k^{n-m},\ r+s < k^{n-m-1} \\ 0, \textit{ otherwise} \end{cases}$$

In a similar manner, define function $p\_ns(s,r,m)$ as the probability that a request at a switch in stage $m$ will not select a particular output link given that $s$ requests have already selected that link, and that $r$ requests have already selected other links.

$$p\_ns(s,r,m) = \begin{cases} \dfrac{(k-1)k^{n-m}-r}{k^{n-m+1}-s-r}, \text{ for } r < (k-1)k^{n-m},\ s+r < k^{n-m+1} \\ 0, \textit{ otherwise} \end{cases}$$

Assuming that the events occurring at the inputs of each switch in stage $m+1$ of the banyan network are independent, (which will result in a slightly pessimistic blocking probability), then the probability that $i$ requests arrive on $k$ input links of a switch in stage $m+1$ is given by

$$\binom{k}{i} u(m)^i (1-u(m))^{k-i}$$

Given that $i$ requests arrive at a switch in stage $m+1$, the probability that $j$ of these requests select a particular output and that $i-j$ of these requests do not select that same output is given by

$$\binom{i}{j} \prod_{s=0}^{j-1} p\_s(s,0,m) \prod_{r=0}^{i-j-1} p\_ns(j,r,m)$$

Hence, eq. (1) can easily be modified to yield the blocking probability of $p$-path $k^n \times k^n$ banyans under unique distributions. Due to path multiplicity, the first $f$ stages will not block, where $f$ is given by

$$f = \lfloor \log_k p \rfloor$$

Under unique distributions, the last $l$ stages will not block, where $l$ is given by

$$l = \lfloor \log_k p \rfloor + 1$$

We need a value for $u(f)$, the aggregate utilization on links leaving stage $f$; since the first $f$ stages did not block, let $u(f) = u(0)/p$. In general, after any stage $m+1$ we are interested in $p(i)$, the probability that $p$ logically equivalent links carry $i$ requests. $p(i)$, for $0 \le i \le p$, can be calculated as follows

For $j < p$:

$$p(j) = \sum_{i=j}^{pk} \binom{pk}{i} u(m)^i (1-u(m))^{pk-i} \cdot \qquad (2.1)$$

$$\binom{i}{j} \prod_{x=0}^{j-1} p\_s(x,0,m) \prod_{x=0}^{i-j-1} p\_ns(i,x,m)$$

For $j = p$:

$$p(j) = \sum_{i=p}^{pk} \binom{pk}{i} u(m)^i (1-u(m))^{pk-i} \cdot \qquad (2.2)$$

$$\sum_{t=p}^{i} \binom{i}{t} \prod_{x=0}^{j-1} p\_s(x,0,m) \prod_{x=0}^{i-t-1} p\_ns(i,x,m)$$

After each stage $m+1$, we need to calculate the aggregate link utilization $u(m+1)$, as follows

$$u(m) = \sum_{i=0}^{p} \frac{p(i) \cdot i}{p} \qquad (2.3)$$

The blocking probability of the network is then

$$pb = 1 - \frac{u(n-l)}{u(f)} \qquad (2.4)$$

This model is compared with simulations in the next subsection.

#### 3.2.1. Comparison of Model with Simulations

We now compare this simple analytic model with a number of simulations, for various unipath and multipath MINs.

Fig. 3 illustrates the blocking probabilities for various augmentations of $k^n \times k^n$ banyans of size $N$ under unique distributions. (The $pb$ of dilated and augmented networks, with the same path multiplicity, differ by only a few percent [26]; these simulations happen to be for augmented networks, although the model is more accurate for dilated networks). These figures indicate that the model is reasonably accurate.

There are two major sources of error in this model. First, the analytic model for the $pb$ under the assumption of random, independent requests is only an approximation itself, and has an error of a few percent. Secondly, when the model is adapted for unique distributions, the assumption that requests arriving at the inputs of a switch are statistically independent introduces some inaccuracies. However, more refined analyses can take these considerations into account (see [26]).

Hence, eq. (2) can be used as a quantitative measure of a $p$-path $k^n \times k^n$ banyan network's permutation capability. The techniques presented here are general, and hence models for other MINs are easily created.

### 4. On the Expected Number of Conflict-Free Permutations in Multipath MINs

A simple technique for determining the exact number of conflict free permutations in unipath $2^n \times 2^n$ MINs has been presented in [1]. The extension to unipath $k^n \times k^n$ MINs is simple and is presented here.

In a unipath MIN with $N$ processors and $N$ memories, there are exactly $N$ links between each stage. If a permutation (of $N$ requests) is conflict-free, every link must carry one request. Hence,

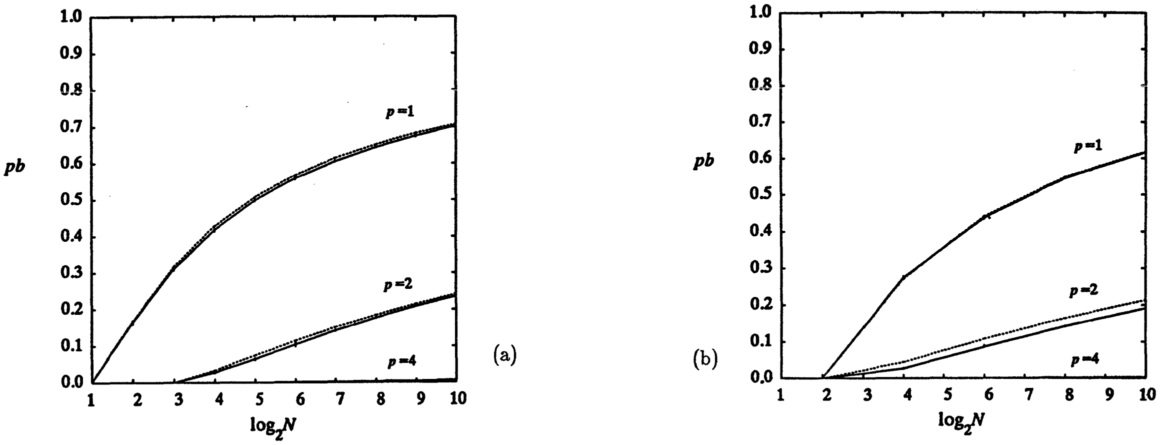

Fig. 3: (a) *pb* for various augmentations of $2^n \times 2^n$ networks with $N$ sources under unique distributions. (b) *pb* for various augmentations of $4^n \times 4^n$ networks with $N$ sources under unique distributions. (solid curves are simulations with 95% confidence intervals shown; dashed curves are analytic.)

each $k \times k$ switch will have $k$ requests arriving at its inputs, and must have $k$ requests leaving on its outputs (so that no requests block). Each switch can therefore perform $k!$ mappings of its inputs to its outputs, i.e., there are $k!$ distinct settings for each switch. Since there are $N/k$ switches per stage, and $\log_k N$ stages, then the exact number of conflict free permutations in a unipath network is simply

$$(k!) \exp \left(\frac{N}{k} \cdot \log_k N\right) \tag{3}$$

In a multipath network, the analysis is much more difficult. Since there are more than $N$ links between each stage, each link does not necessarily carry a request, and each switch does not necessarily have $k$ requests arriving at its inputs. The previous model can be adapted to estimate the number of distinct switch settings in a multipath MIN (see [20]), however this estimate "does not come close to estimating the number of permutations realizable by the [gamma] network. Estimating the actual number of permutations seems to be much harder, and is left as a challenging open problem" [20]. In this section, we present an analytic model for the expected number of conflict free permutations in multipath MINs.

Let $X_i$ be the event that $i$ requests block in one cycle, given that $N$ requests which form a permutation are submitted initially. In this section, we wish to find an analytic model for the probability distribution function *pdf* [6] of $X_i$, for $0 \leq i \leq N$. Let $P(X_i)$ represent the *pdf* of $X_i$.

The simplest approach for the *pdf* is to assume that all events are independent, and that $P(X_i)$ is simply binomially distributed;

$$P(X_i) = \binom{N}{i} pb^{\,i} (1-pb)^{N-i} \tag{4}$$

Fig. 4 illustrates the observed $P(X_i)$ versus the computed values for various networks. (Note that we used the *pb* obtained from simulations when computing these *pdf* 's.)

From fig. 4, we observe that the independence assumption is very accurate for the multipath banyans, and reasonably close for the unipath banyans. We can actually test the quality of the *pdf* by using the $\chi^2$ ***goodness of fit*** test [6]. At a 5% level of significance, the hypothesis is rejected for most unipath networks, and accepted for all multipath networks that we tried.

Given that the *pdf* is reasonable for multipath networks, we can accurately estimate the number of conflict-free permutations in these networks $N_p$ as follows;

$$N_p = N! \cdot (1-pb)^N \tag{5}$$

For unipath networks the *pdf* is less accurate, primarily because the independence assumption is not valid. A slightly more complicated multinomial distribution that explicitly models the effects of the statistical dependence is required for the *pdf* of unipath networks (see [26]).

In general, we are not interested in simulating a network to obtain a measurement for the *pb* used in eq. (5). Eq. (2.4) gives a reasonably accurate estimate of *pb* , which can be used in eq. (5).

### 5. The Expected Number of Network Cycles Required to Realize an Arbitrary Permutation

In this section, we develop an analytic model for the expected number of network cycles required to realize an arbitrary permutation, i.e., the universality of a network. The universality of various networks has been examined by numerous researchers. When global (i.e., precomputed) routing algorithms are used, the universalities of some networks have been established, and upper or lower bounds for others have been established. When distributed routing algorithms are used, the only results to date are simulations for the universality [15][31].

A proof for an upper bound for the number of cycles required to realize any arbitrary permutation in unipath $2^n \times 2^n$ banyans has been presented in [2]. The basic idea was to count the number of requests that must use a specific link in the network in the worst-case, i.e., if the worst case permutation would require $m$ requests to use a specific link, then the upper bound for the number of cycles is $m$ . The upper bound on the number of cycles in a $2^n \times 2^n$ banyan was shown to be $2^{\lfloor n/2 \rfloor}$. An identical bound (but using a slightly different technique) has been derived in [28].

However, the implied assumption in this bound is that the critical link will be utilized by a request in each cycle, and that the request that used it will indeed be established. To ensure this assumption would require precomputed routing for each individual permutation to optimally schedual requests over the critical link.

If the usual simple, distributed banyan routing algorithm is used, this upper bound does not apply (it will be exceeded occasionally). This situation occurs when a request uses the critical link during a cycle and is blocked at a later stage in the same cycle, hence requiring the use of the critical link again. Numerous examples of this situation can be found for networks of size $N \geq 8$. The correct upper bound (assuming a distributed routing algorithm) must also consider the conflicts that may occur at the

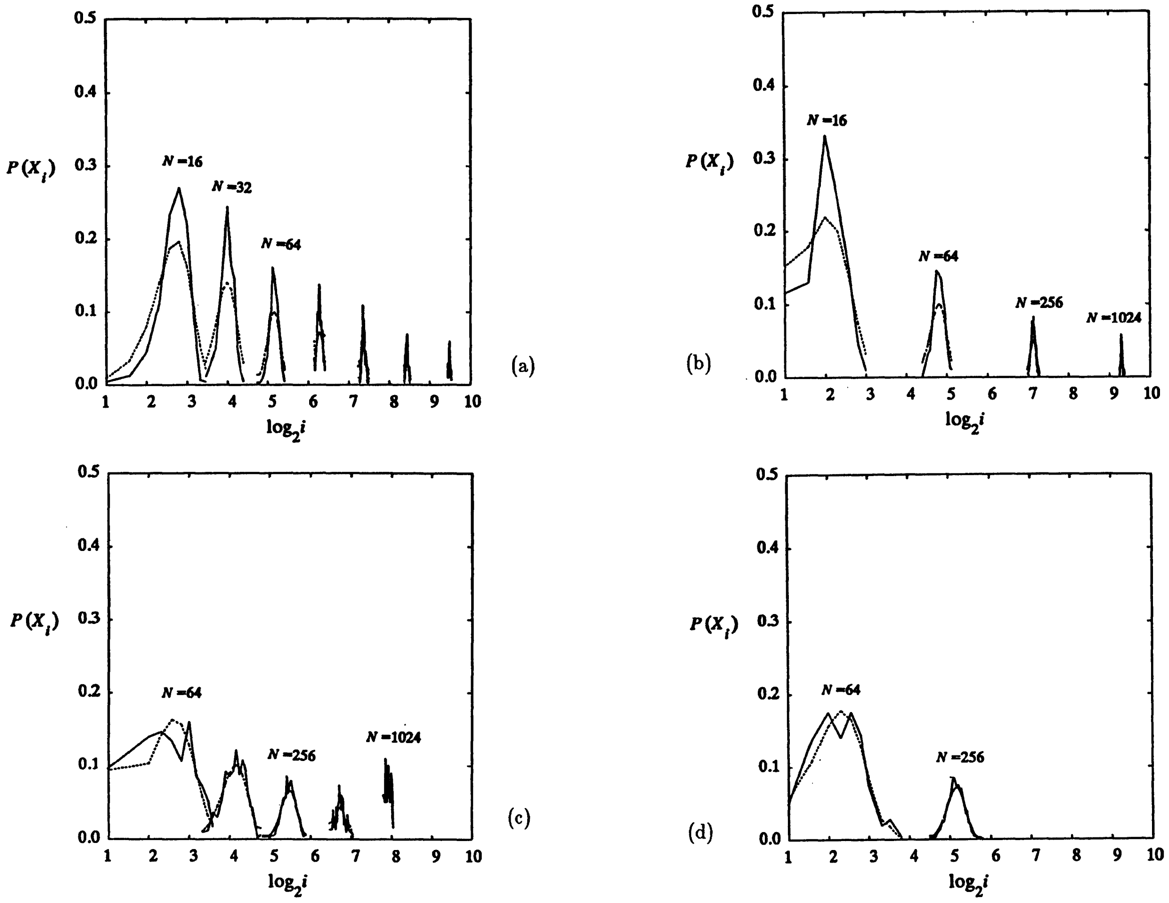

Fig. 4: a) $P(X_i)$ for unipath $2^n \times 2^n$ banyans. b) $P(X_i)$ for unipath $4^n \times 4^n$ banyans. c) $P(X_i)$ for 2-augmented $2^n \times 2^n$ banyans. d) $P(X_i)$ for 2-augmented $4^n \times 4^n$ banyans. (solid curves are simulations; dashed curves are analytic.)

switch after the critical link, and is simply $2 \cdot 2^{\lfloor n/2 \rfloor}$ [26].

In this section, we present an analytic model for the expected number of (synchronous, circuit switched) network cycles required to realize an arbitrary permutation. The accuracy of this model depends on the accuracy of the *pdf* for $X_i$. As we will show, the model is very accurate for multipath networks, and optimistic for unipath networks.

The analytic model is very simple; we use a time-varying *markov* model with $N+1$ states, denoted $S_i$, for $0 \leq i \leq N$, as shown in fig. 5. We also maintain a counter $c$, which represents how may network cycles have been executed; initially, $c = 0$. Each state $S_i$ represents the probability that $i$ requests are still unsatisfied after $c$ cycles and must be resubmitted in the next network cycle. This model has one source state, $S_N$, and one sink state, $S_0$. Initially, all $N$ requests in a permutation are unsatisfied, so $S_N = 1$, and all other states are 0. A variable $E_c$ represents the expected number of cycles required to realize any permutation, and $E_c = 0$ initially.

For each network cycle, we update every state, as follows. Consider updating state $S_i$; this state is the probability that $i$ requests remain unsatisfied, and this state can be reached from any state $S_j$, where $j > i$ and where $S_j > 0$. The physical events that correspond to this state transition are simple; the processor array submits $j$ requests in one cycle, $i$ of them are blocked, and the rest are accepted. The blocking probability of the network, when $j$ requests are submitted, can be computed from eq. (2.4). The probability that $i$ of these requests are blocked can be computed from eq. (4). Hence, the state transition rates for the entire markov model can easily be computed during each network cycle.

During each cycle $c$ ( $c = 1,2,3....$), some number of requests $j$ are satisfied (by reaching $S_0$); these contribute the value $c \cdot j / N$ to the expected number of cycles $E_c$. After a number of cycles (iterations), the model will converge to a stable state (in absence of numeric errors, the steady state will have $S_0 = 1$, and all other states equalling 0). The process can be terminated when $E_c$ remains relatively constant, and the resulting $E_c$ is the expected number of network cycles required to complete an arbitrary permutation.

Fig. 6 illustrates the analytic results and simulations for various networks.

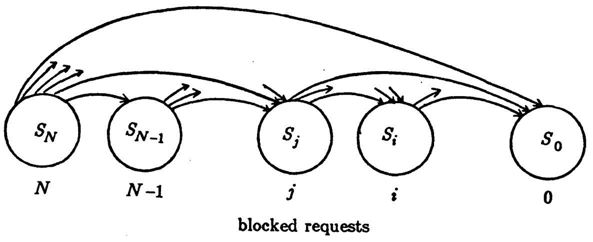

Fig. 5: markov model for an $N \times N$ MIN.

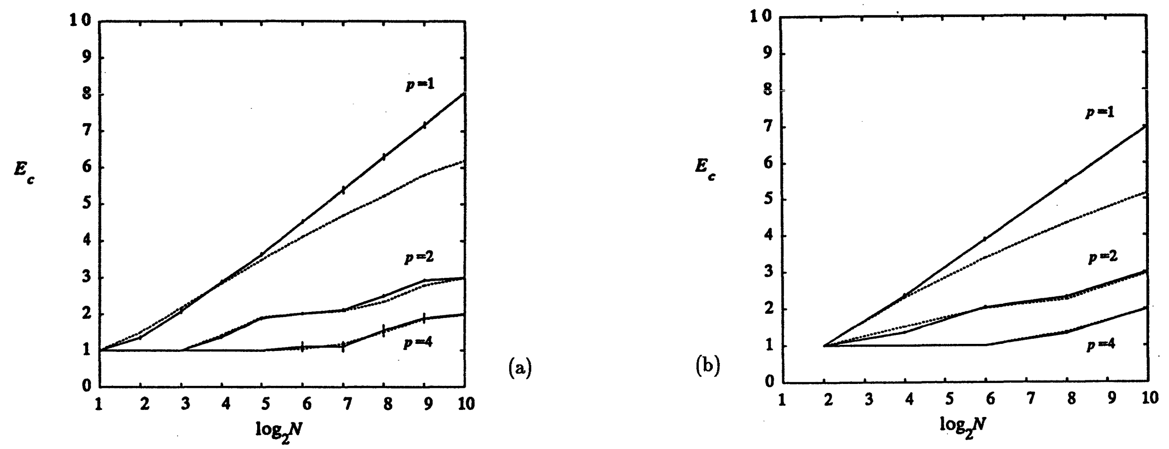

Fig. 6: a) $E_c$ for various $p$-path $2^n \times 2^n$ banyans. b) $E_c$ for various $p$-path $4^n \times 4^n$ banyans. (solid curves are simulations with 95% confidence intervals shown; dashed curves are analytic.)

Fig. 6 indicates that the model is very accurate for multipath networks, and optimistic for large unipath networks. However, most practical networks will almost certainly have some path multiplicity, hence these models can be used.

A more accurate analytic model for the probability distribution function of unipath networks can be found in [26] (this model accounts for the effects of the statistical dependence of requests arriving at one switch). This more refined $pdf$ model can be used in this markov model to create a more accurate approximation for the unipath case [26].

Perhaps the most suprising observation is the performance of the 4-path networks. The 4-path $2^n \times 2^n$ network has a blocking probability of about .007 at $N=1024$; with such a low blocking probability, we would expect that the average number of passes required to realize a permutation would be about 1. However, fig. 6 indicates that two passes (on average) are required at $N=1024$. Similarly, the 4-path $4^n \times 4^n$ banyan has a blocking probability of about .004 at $N=1024$, and yet still 2 passes (on average) are required to realize an arbitrary permutation.

The true performances of $p$-path networks must reflect on the bandwidth of the links used in the network. We assume that each link in a $p$-path $k^n \times k^n$ network has $1/p$ times the bandwidth compared to a link in the unipath $k^n \times k^n$. (The number of pins available on an integrated circuit is limited: by doubling the number of logical input/output links, each link will have half as many pins, and hence will have approximately half the bandwidth.) Hence, assume that each pass in a $p$-path network takes $p$ times as long as a pass in the unipath network (when the switch degree remains the same).

From fig. 6 it is clear that a 2-path network actually outperforms a unipath network by about 25% (for switches of fixed degree 2 or 4). Consider a network of size $N=1024$ made with 2×2 switches. The unipath network will require about 8 cycles to realize an arbitrary permutation, and the 2-path network will require about 3 cycles (each about twice as slow) to realize an arbitrary permutation. However, this estimate can be pessimistic: The unipath network will require about 8 memory access times whereas the 2-path network will require only about 3 memory access times. If the path establishment and data transfer delays are insignificant components of the network cycle time (i.e., the network cycle time is dominated by the memory access time), then the performance improvement could be much higher. Hence, the true performance improvement should also consider the memory access times, plus time spent on path establishment and error checking, etc.

In addition to offering significant performance improvements (when the realization of arbitrary permutations is the performance criterion), the 2-path network is also significantly more fault-tolerant [23].

## 6. Conclusions

We have presented a simple analytic model for the blocking probability of circuit switched MINs when the set of requests submitted during each cycle is a randomly selected permutation. In general, such models are created by adapting an analytic model of a network's blocking probability when the requests are assumed to be random and independent. The techniques are general, and hence analytic models for the performance of arbitrary MINs, under the assumption of unique distributions, are relatively easy to create.

We have presented a general technique to determine an analytic approximation for the expected number of conflict free permutations in multipath MINs (when simple distributed routing algorithms are used). This technique can be used for multipath networks such as the Gamma network [20] and the ADM [1]. No such general technique has been presented in the literature previously, although lower and upper bounds (and in one cases an exact number) on the number of conflict free permutations realizable in certain MINs have been presented. The number of conflict-free permutations realizable by a MIN when distributed routing algorithms are used is a quantitative measure of the connectivity of the network.

We have presented a general technique to determine an accurate analytic approximation for the expected number of passes required to realize an arbitrary permutation in a network, i.e., the universality of a network, when simple distributed routing algorithms are used.

An interesting result concerning network performance was observed. A 2-path network (of degree 2 or 4) will require 3 or fewer passes on average to realize an arbitrary permutation for reasonably sized networks (i.e., network size ≤ 1024). A 2-path network will outperform the corresponding unipath network significantly, and offer significant fault-tolerance improvements aswell. In addition, the performance of a 2-path MIN compares very well with the best known universality of 3 passes through a unipath omega network using global, precomputed routing [21][25][30] (where both networks have switches of degree 2).

These models solve many interesting theoretical problems in the realm of interconnection network modelling. However, these models also have a very practical aspect. They give a quantitative measure of the connectivity of a MIN. Previously, when comparing interconnection networks for their suitablility in SIMD array processors, numerous techniques have been used. One such technique was to estimate the number of cycles one network requires to simulate another [24]. Using the models presented in this paper, one can evaluate the average performance of a particular network analytically (when realization of arbitrary permutations is the performance criterion). However, it must be pointed out that real SIMD machines typically use a small number of permutation classes where the permutations tend to be highly structured, and a better figure of merit would be the network's ability to realize those frequently occurring permutations.

# Synthesis of a Family of Cellular Permutation Arrays

By
A. Yavuz Oruc
Electrical, Computer and Systems Engineering Department
Rensselaer Polytechnic Institute, Troy, NY 12180

## Abstract

Group theory provides a convenient means for formulating and solving some nontrivial problems in permutation network theory. This paper uses group theoretic techniques to provide a unified approach for cellular permutation array design. More specifically, the networks of Kautz et al and Bandyopadhyay et al are shown to be geometric reperesentations of iterative coset decompositions of symmetric groups. This result was used by Oruc and Oruc to develop a linear-time set up algorithm for cellular permutation arrays. This paper examines another application, namely, the design of a family of cellular permutation arrays.

## 1. Introduction

Permutation networks have been extensively investigated in the parallel processing literature. By now, the researchers in the field know how to design such networks with aysmptotically optimal cell counts[1], and extensive research results have also appeared about how these networks are incorporated into parallel processing[2]. The objective of the present paper is to exhibit some interesting relations between a family of permutation networks known as cellular permutation arrays, and coset decompositions of symmetric groups. Cellular permutation arrays were investigated primarily by Kautz et al[3] and Bandyopadhyay et al[4]. Unlike optimal permutation networks, cellular permutation arrays use redundant cells, and thus they are not optimal in terms of cell counts. Nevertheless, they have certain attractive features. One such feature is that the links or wires connecting the programmable cells in these networks are local and require no crossing. More significantly, it was recently shown[5] that an n-input cellular permutation array can be set up in O(n) time, whereas the best known set up time for an n-input Benes network is $O(n\log_2 n)$.

These properties of cellular permutation arrays call for a careful investigation of such networks. As an effort in this direction, we show that cellular permutation arrays proposed in the papers [3,4] can all be characterized as iterative decompositions of symmetric groups into cosets. A direct consequence of this fact is a parametrized design technique for cellular permutation arrays, that is, a design technique by which it is possible to specify the cell sizes and permutations based on the design constraints in question. In the remainder of the paper we shall formalize these ideas and elaborate on them in detail.

## 2. Network Characterization

We first establish the relation between the coset decompositions of symmetric groups and cellular permutation arrays. Let $\Sigma_i$ denote the symmetric group over the set of symbols $(1,2,\ldots,i)$; $1\le i\le n$. It can be shown that[6]:

$$\Sigma_i = \Sigma_{i-1}e+\Sigma_{i-1}(1\ i)+\Sigma_{i-1}(2\ i)\ldots+\Sigma_{i-1}(i-1\ i) \quad (1)$$

for all i; $3\le i\le n$ where $\Sigma_2 = (e,\ (1\ 2))$, and e denotes the identity permutation. Similarly,

$$\Sigma_i = e\Sigma_{i-1}+(1\ i)\Sigma_{i-1}+(2\ i)\Sigma_{i-1}\ldots+(i-1\ i)\Sigma_{i-1} \quad (2)$$

(1) and (2) are, respectively, the iterative right and left coset decompositions of $\Sigma_n$ into $\Sigma_{n-1}$, $\Sigma_{n-2}$, ..., $\Sigma_2$. In both cases, the map e and transpositions $(i\ j)$; $1\le i\le j-1$ are the right (or left) coset leaders of $\Sigma_{j-1}$ in $\Sigma_j$; $3\le j\le n$. Moreover, these two decompositions are the group-theoretic representations of what are known as regular and reverse KLW permutation arrays[3,6]. Fig. 1 depicts the two networks for n=4. If each cell in the either network can perform the only two permutation maps possible over its inputs as indicated, then one easily verifies the firm equivalence between regular and reverse KLW permutation arrays and the iterative decompositions given in (1) and (2).

One can also decompose $\Sigma_n$ into $\Sigma_i$; $2\le i\le n-1$ by using cycle maps as coset leaders instead of transpositions. That is, it can be shown that[6]:

$$\Sigma_i= \Sigma_{i-1}e+\Sigma_{i-1}(i\ i-1)+\Sigma_{i-1}(i\ i-2\ i-1)\ldots+ \Sigma_{i-1}(i\ \ 1\ 2\ldots i-1) \quad (3)$$

and,

$$\Sigma_i= e\Sigma_{i-1}+(i\ i-1)\Sigma_{i-1}+(i\ i-1\ i-2)\Sigma_{i-1}\ldots+ (i\ i-1\ldots 2\ 1)\Sigma_{i-1} \quad (4)$$

Equations (3) and (4) are the group-theoretic representations of what are known, respectively, as regular and reverse BBC networks[4,6]. As an example, we depict these two networks for n=5 in Fig. 2. The cycle maps shown inside the cells with three or more inputs are coset leaders while the cell with two inputs in each network corresponds to $\Sigma_2 =(e,\ (1\ 2))$.

A direct implication of the four decompositions stated above is that the corresponding networks are symmetric, i.e., they can realize all of $\Sigma_n$, and that the networks can be set up for an arbitrary permutation in linear time. The reader may refer to [5] for a detailed description of the set up procedures. Another consequence of these characterizations of cellular permutation arrays is a parametrized design technique which we shall consider in the following section.

## 3. Network Design

It should be noted that the KLW and BBC networks described above are two extreme examples of realizing symmetric groups by iterative coset decompositions. They are extreme in the sense that while the KLW networks use $n(n-1)/2 = O(n^2)$ cells, BBC networks need n-1 or O(n) cells to construct. Of course, the complexity of the cells in the two cases are quite different. In any event, however, we may be subject to certain physical constraints in realizing $\Sigma_n$ by a cellular permutation array. For example, it may be cost ineffective to place each cell of a KLW network in a separate chip, and yet it may be infeasible to contain all of the permutations of a large cell of a BBC network within a single chip. Thus, what is needed is a design technique to realize symmetric groups by cellular permutation arrays subject to the specifications of the coset leaders, and the size and the number of cells to be used by the network in question.

We can formalize the above problem as follows. Given positive integers n and m; $2 \leq m \leq n$; design an n-input cellular permutation array consisting of N(n,m) k-input cells where $2 \leq k \leq m$ and $n-1 \leq N(n,m) \leq n(n-1)/2$. We shall describe two constructions both with pseudo triangular geometries.

In the first construction[7], we shall permit cells with 2, 3, 4,..., up to k inputs. The pseudo triangular permutation network is then directly obtained by grouping together the permutations of 2-input cells of a KLW network columnwise into 2, 3, ..., up to k-input cells. As an example, such a network for n=11 is constructed as shown in Fig. 3. It is easily verified that the column of cells with the jth vertical input in the network can perform all of the transpositions (i j); $1 \leq i \leq j-1$, and hence the symmetricity of the network immediately follows. It can also be shown that the number of cells in an n-input pseudo triangular permutation array which is so constructed is

$$N(n,m) = (f+1)(n-1-(m-1)f/2) \qquad (5)$$

where $f = L\ n-1/m-1$ . Finally, we note that, instead of transpositions, one can easily map the cycles of BBC networks into the columns of this type of cellular permutation array after some algebraic manipulations. Whether one uses transpositions or cycles is an implementation problem which can be investigated independently from the considerations discussed here.

In the second construction we shall assume that all cells have the same number of inputs. This assumption leads to a pseudo triangular cellular permutation array which is depicted in Fig. 4 for n=11. In this case, we must let the leftmost cell generate $\Sigma_m$ over its inputs. The cells in subsequent columns will then need only to realize the required coset leaders. The reader can again verify that the column with the jth vertical input can be made to realize all of the transpositions (i j); $1 \leq i \leq j-1$. Thus, the symmetricity of the network is guaranteed. The construction is easily generalized to n inputs, and furthermore it can be shown that such a network consists of N(n,m) cells where:

$$N(n,m) = (f+1)(n-m+1-(m-1)f/2) + g \qquad (6)$$

where $f = L\ m-m+1/m-1$ and g=1 if $n-m+1 \bmod m-1 \neq 0$ and g=0 otherwise.

The above network constructions underscore the degrees of freedom in cellular permutation array design. We shall not describe the detailed implications of these constructions here. It should be obvious how one can manipulate the formulas in (5) and (6) to explore various design alternatives subject to constraints on n, m and N(n,m).

## 4. Summary and Conclusions

The paper has established the structural equivalence between cellular permutation arrays and coset decompositions of symmetric groups. Based on this equivalence, we have constructed two new families of cellular permutation arrays, and shown that BBC and KLW networks are special cases of these networks. We have also outlined a parametrized design technique which can be used to synthesize cellular permutation arrays when there are certain constraints on the cell sizes and permutations. We note that the networks described here all have triangular geometries, a fact that follows from the linear iterative nature of the symmetric group decompositions considered in the paper. It will be worthwhile to determine whether there exist other decompositions of symmètric groups which may lead to new families of cellular permutation arrays.

## ABSTRACT

Fault-tolerant network architectures for multiprocessor systems are emerging as an important area of study. Theoretical studies of algorithms, simulation of the NYU Ultracomputer architecture and construction of a small prototype machine led to a joint proposal by NYU and IBM (Yorktown Heights) to implement the architecture in a system with up to 512 processors, including an implementation of the "Fetch-and-Add" shuffle network that is key to the success of this architecture. Techniques proposed so far to achieve fault-tolerance in interconnection networks cannot support the "Fetch-and-Add" primitive satisfactorily. In this paper, we present a multistage interconnection network based on the Omega network that supports the "Fetch-and-Add" instruction and also provides fault-tolerance. Basically, the approach uses 4×4 switches as switching elements in a multistage network, and uses an extra stage of such switches to enable four independent paths to be set up between any source and any destination. Conventional approaches to fault tolerance in interconnection networks involve using only one of the paths at a particular time for propagation of a message, with the redundant paths being used only if failure is detected in the first path. In our scheme, we propose transmisson of four copies of a message through the network simultaneously, with voting being performed on the copies at the memory network interface. The design of the switching elements constituting the network is described. Properties of the Omega network and a rigorous scheduling discipline enforced in the implementation of the switches in the proposed network make it possible to send four copies of every message synchronously through the network. This allows concurrent correction and detection of message transmission errors.

## 1. INTRODUCTION

The current interest in large scale parallel processors has motivated a large amount of research on multistage interconnection networks for parallel processing. Buffered interconnection networks are an integral component of several machines currently under development, including the Cedar machine at the University of Illinois [1], the NYU Ultracomputer [2] at the New York University and the RP3 at IBM [3].

With the advent of VLSI technology, it has become cost-effective to include a large number of processors and memory modules in a multiprocessing system. The hardware system organization is determined primarily by the interconnection structure used between the memory modules and the processors. Many multistage interconnection networks have been proposed such as the baseline [4], delta [5], Generalized Cube [6], Omega [7], STARAN flip [8], etc. for parallel/distributed systems. The Generalized Cube is representative of these networks in that they are topologically equivalent to it.

An important criterion for estimating the performance of a multiprocessor system is its reliability. To a large extent the reliability of the system depends on that of the interconnection network. A fault-tolerant interconnection network can tolerate faults to some degree and still provide reliable communication between any input-output pair. Some amount of redundancy has to be present to achieve fault-tolerance. In what is known as information redundancy, error detecting/correcting codes are used [9]. Such schemes require minimal additional hardware but fault-tolerance is limited to the data being transferred. Faults in the control portion of the network may not be tolerated. Another approach is hardware redundancy in which multiple paths are created between the inputs and outputs of the network. Multiple paths can be created by the addition of an extra stage to the multistage network as in [10], [11], [12], or by providing redundant links as in [13], and [14]. The INDRA network [15] uses a redundant stage as well as redundant links.

The schemes proposed so far consider the design of the interconnection network at a very high level or on a totally theoretical basis. Also, the designs proposed so far are not aimed at any specific multiprocessor system. In this paper we propose an interconnection network suited for the Research Parallel Processor Prototype (RP3) project [3] initiated in the IBM Research Division in cooperation with the Ultracomputer Project of NYU [2].

The proposed network supports the Fetch-and-Add primitive of the NYU Ultracomputer. The Fetch-and-Add instruction is an interprocessor synchronization operation. It permits highly concurrent execution of operating system primitives and application programs. The advantage of Fetch-and-Add over Test-and-Set and Compare-and-Swap to serialize locking and reservation operations in database applications has been discussed in [16]. The format of this instruction is F&A(X,a), where $X$ is an integer variable and $a$ is an integer expression. This is an indivisible operation and it is defined to return the old value of $X$ and to replace $X$ by the sum of $X+a$. The Fetch-and-Add operation follows the serialization principle: If $X$ is a shared variable and many Fetch-and-Add operations simultaneously address $X$, the effect of these operations is as though they occurred in some (unspecified) serial order.

In Section 3, we present in detail the design of the switching elements constituting the proposed interconnection network. In Section 4 we prove certain properties of the network which makes it possible to achieve fault-tolerance.

## 2. OVERVIEW OF PROPOSED NETWORK

The proposed interconnection network is based on the Omega network [7]. An Omega network with N inputs and N outputs consists of $n = \log_B N$ stages of $B \times B$ switching elements. A $B^n \times B^n$ Omega network is constructed using $B \times B$ switching elements and $B{*}B^{n-1}$ shuffles interconnecting the stages. A $P{*}Q$ shuffle is the permutation of $PQ$ elements defined as

$$\pi(i) = \left\lfloor Pi + \left\lfloor \frac{i}{Q} \right\rfloor \right\rfloor_{mod\ PQ} \qquad 0 \leqslant i \leqslant PQ-1$$

In the proposed network, 4x4 switching elements are used (B=4). By adding an extra stage to the Omega network obtained as defined above, redundant paths between the processors and memory modules are created. 4x4 switches are used instead of 2x2 switches so that four redundant paths can be obtained. Hence, it consists of ($\log_4$N + 1) stages. It has been proven in [17] that the four paths created are unique i.e. they use independent links and independent switching elements at every stage of the network except at stage 0 and stage $n$ ($n$ = $\log_4$N) of the network. To make the first and last stages also fault-tolerant, the 4x4 switch can be modified as explained in Sections 3.2 and 3.3. In our fault model, a fault constitutes:

(1) Complete failure of one switching element.

(2) Failure of one link between any two stages of the network.

Conventional approaches to fault-tolerance in interconnection networks [10, 13, 14, 17] involve the use of disjoint redundant paths between any source/destination pair. Once a failure of a switch/link in the path of a message is detected, an alternate path is selected. The mechanism of detection of a failure can be performed either off-line through diagnosis [4] or on-line by using error correcting codes [9]. Off-line diagnosis is not applicable in case of transient or intermittent failures which have been shown to occur more frequently than permanent failures [18, 19]. An on-line fault detection/location mechanism may use coding techniques. Simple algebraic codes such as Hamming codes or cyclic codes [20] can be used for detecting errors in the address portion $X$ of a message $(X, a)$ but not for the data portion $a$ because the Fetch-and-Add primitive requires arithmetic operation to be performed on the data portion of the message. For the data portion, arithmetic codes such as the residue codes and the AN codes would have to be used [20]. However, these codes may be used for detecting errors but not for correcting them. Even if the codes are used only for error detection, implementation of the encoding/decoding circuitry is very complex. Besides, such circuits would have to be designed to be totally self-checking. Considering that such circuits would have to be provided in each switching element of the network, it is not cost-efficient to adopt this scheme. A less costly technique would be to place the encoding circuitry at the PNI and the decoding circuitry at the MNI. However, in this technique, once an error is detected, the message has to be sent through an alternate path and it may be impossible to recover from the deleterious effects produced by the erroneous message. Consider what happens if message $(X, a)$ changes to $(Y, c)$. This could have several effects:

(1) A wrong value would be returned to the processor from which $(X, a)$ originated.

(2) Memory location $X$ will not be updated.

(3) Memory location $Y$ will be written into when it should not have been written into.

(4) If there is a message $(Y, b)$ also propagating through the network, combining of $(X, a)$ (changed to $(Y, c)$) and $(Y, b)$ may take place when no combining should have taken place. As a result, a wrong value would be returned to the processor from which $(Y, b)$ originated and a wrong value would be written into memory location $Y$.

(5) In case there are several messages propagating through the network with destination $Y$, the effect of combining the erroneous message $(X, a)$ (changed to $(Y, c)$) with all these messages may be disastrous [*]. Recovery from the effects of combining in that case may be extremely difficult or even impossible since combining of the erroneous message $(X, a)$ with non-erroneous messages may have taken place at various stages of the network.

Thus, due to a single fault, several errors may be generated. In the proposed scheme, all four paths are used to send four copies of a message simultaneously through the network. Voting is carried out on the four copies in the Memory Network Interface. This enables correction of message transmission errors due to any number of faults along a single path, or, detection of message transmission errors due to any number of faults along two paths, as messages propagate through the network.

## 3. DETAILED NETWORK DESIGN

This section describes in detail the design of the switching elements constituting the network. First, message transfers within and between stages is described for stages 1 through $(n-1)$ and then for stages 0 and $n$.

### 3.1. Stages 1 through $(n-1)$

Each switch has four input and four output ports. One queue is associated with each input-output port pair. Hence, there are four IN queues associated with each output port (Fig.1). These are labeled as IN0, IN1, IN2, and IN3. IN0 is connected to input port 0, IN1 to port 1 and so on. When a message arrives at an input port it is first determined which output port the message is bound for by decoding the relevant two bits in the destination address of the message. Then the message is placed in the appropriate IN queue of the particular output port. Messages are sent to the next stage of the network depending upon their priority. The priority is established by following a round-robin discipline, starting with the queue having the smallest label. This round-robin scheduling scheme is illustrated by the following example.

EXAMPLE 1: Messages $a, b, c, d, e, f, g, h, i, j$ arrive at various input ports of a switch over a period of five cycles and are routed to output port p as shown in Fig.2. For the purpose of this example assume that none of these messages can be combined. Messages $a$, $b$ and $c$ arrive in the same cycle at input ports 0, 2 and 3 respectively. Suppose this is cycle C. Messages $d$ and $e$ arrive in cycle C+1 at ports 1 and 3 respectively. In cycle C+2 messages $f$, $g$, $h$, and $i$ arrive at input ports 0, 1, 2, and 3 respectively and are routed to output port p. In cycle C+3 message $j$, arriving at input port 3, is routed to output port p. These messages are sent to the next stage in ten cycles in the order $a, b, c, d, e, f, g, h, i$, and $j$. Note that after message $c$ is sent to the next stage, message $d$ is sent to the next stage and not message $f$. Any blank slots in the IN queues are skipped while following the round-robin scheduling of messages. □

[*] The possibility of there being several requests to the same memory location simultaneously has been discussed in [21].

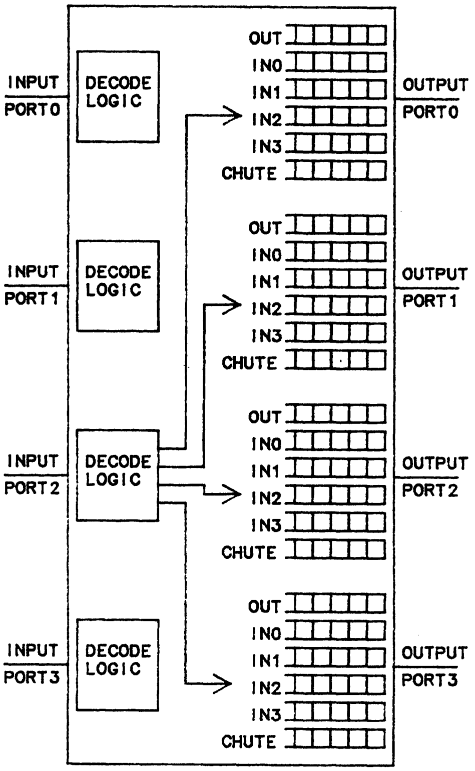

Fig. 1. *A 4x4 Switch in an Intermediate Stage of the Network*

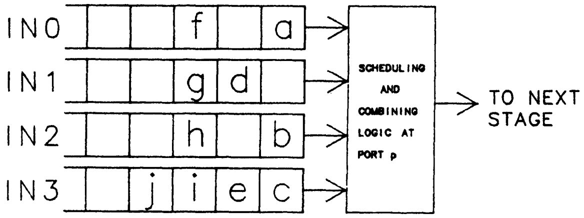

Fig. 2. *Round-Robin Scheduling Discipline at Output Port of a Switch in the Network*

Implementation of the correct ordering of the messages and possible combining of messages is based on the scheme proposed in [22]. For the benefit of the reader, the scheme proposed in [22] is now described briefly. The scheme has been used for a network consisting of 2x2 switching elements called Ultraswitches. Three columns of shift registers called the IN column, the OUT column and the CHUTE column are associated with each output port of a switch. These columns of shift registers are connected as shown in Fig.3. Messages arrive at the IN column and shift up one position at each cycle. Similarly, messages shift down one position in the OUT column at each cycle. If a message in the IN column is adjacent to a slot on the OUT column that is empty, then it shifts to that slot. In addition, this scheme detects a message in the IN queue going to the same address as another message already in the OUT queue. The message in the IN queue is then placed in the CHUTE column. The two messages move synchronously and arrive at the combine logic simultaneously. The combine logic detects the possibility of combining and combines the two messages so that only one message is sent to the next stage of the network.

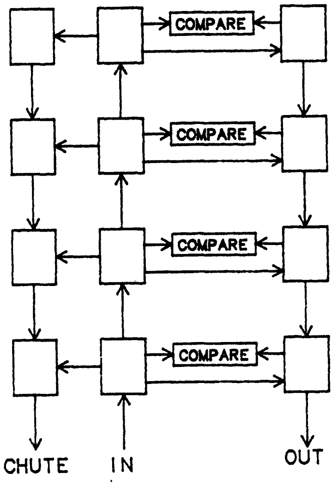

Fig. 3. *Design of the Output Port of the Ultraswitch*

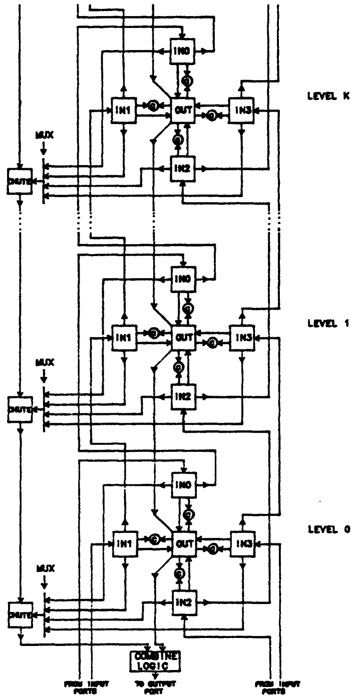

Fig. 4. *Design of the Output Port of a Switching Element in the Proposed Scheme*

In the proposed scheme, at each output port there are four IN queues labeled 0, 1, 2, and 3 as described earlier. In addition, at each output port there is one OUT queue and one CHUTE queue. These queues are connected as shown in Fig.4. Possible movements of messages is indicated by the arrows. Control signals have been omitted from the figure for the sake of clarity. A message arriving at an input port is placed in the appropriate IN queue of an output port at level 0. Messages in the IN queues then move to the OUT queue, to the CHUTE (if combining is possible), or one level up in the IN queue. The movements of messages in one cycle can be described by dividing the cycle into three phases:

**Phase One:** The messages at level 0 of the OUT queue and the CHUTE are sent to the combine logic. The function of the combine logic is the same as in the scheme proposed in [22]. Messages arriving at the four input ports are placed at level 0 of the appropriate IN queues. Messages already in the IN queues move to the OUT queue, the CHUTE or the next level up in the IN queue. The movement of messages is decided according to the following conditions:

(1) If the OUT queue slot is empty at any level, the message at that level in the IN queue wih the smallest label moves into the OUT queue at that level. The other messages at that level move up one level.

(2) At every level, if the OUT queue slot is full and the CHUTE slot is empty, then the messages in the IN queues are compared with the message in the OUT queue at that level to find out if any of the messages in the IN queues can be combined with the message in the OUT queue. From the result of the comparison if it is found that none of the messages in the IN queues can be combined with the message in the OUT queue at a level, then all messages in the IN queue at that level move up one level. If one of the messages can be combined, that message is moved to the CHUTE at that level. The rest of the messages at that level move up one level. If more than one message can combine with the message in the OUT queue, then among these messages the message in the IN queue with the smallest label is moved to the CHUTE at that level. The rest of the messages at that level move up one level.

(3) If OUT queue slot is full at a level and the CHUTE slot is also full at that level then all messages at that level move up one level.

**Phase Two:** Messages in the OUT queue and the CHUTE do not move. Messages in the IN queues move to the OUT queue, the CHUTE or the next level up in the IN queue. Movement of the messages in the IN queues is decided according to the conditions described for phase one.

**Phase Three:** Messages in the OUT queue and the CHUTE do not move. Messages in the IN queue may move only within the level they are in; they cannot move to a higher level. If any message in an IN queue can be combined or moved to the OUT queue it is moved to the CHUTE or the OUT queue at its own level.

EXAMPLE 2: The movement of messages in the three phases is illustrated in Figs.5a and 5b. During four clock cycles, messages *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, *i* and *j* reach an output port p. Assume that none of these messages can be combined. It is easy to extend the example when combining is possible. Hence, only IN queues and the OUT queue at output port p are shown. Messages *a*, *b*, *c*, *d* arrive at the same time at the four input ports of the switch and are all bound for output port p. They are placed in the four IN queues associated with output port p at level 0, in phase one of cycle one. In phase two of cycle one, message *a* moves to the out queue, and messages *b*, *c*, *d* move up one level. In phase three of cycle one, message *b* moves to the OUT queue. Messages *c* and *d* do not move. This is the end of the first cycle. In phase one of the second cycle, message *a* is sent to the next stage; message *b* moves one level down in the OUT queue; message *c* moves to the OUT queue; message *d* moves up one level; messages *e* and

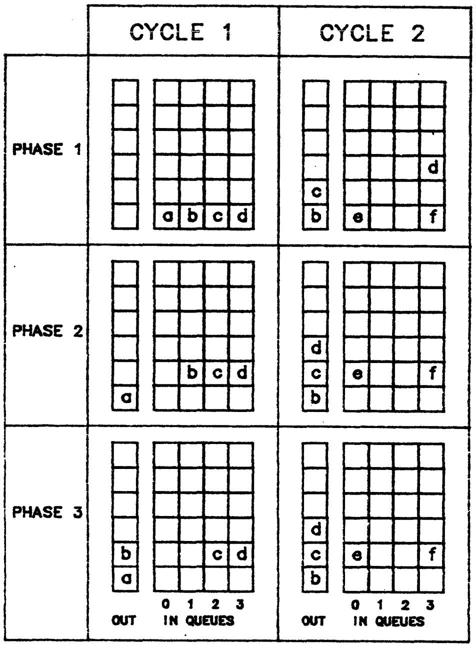

Fig. 5a. *Movement of Messages in the Three Phases of a Cycle.*

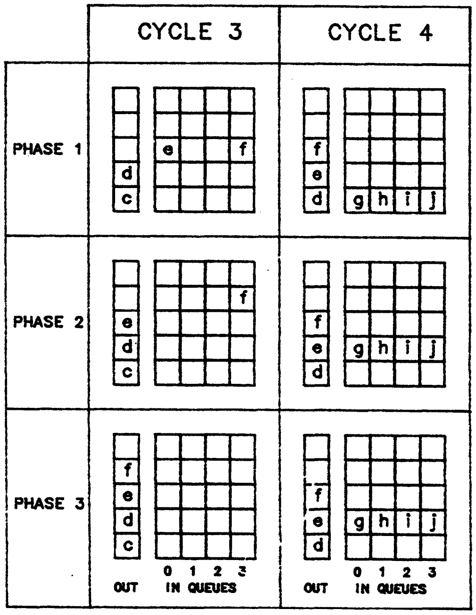

Fig. 5b. *Movement of Messages in the Three Phases of a Cycle.*

$f$ at input ports 0 and 3 of the switch are placed in IN queues 0 and 3 at level 0. Further movements of messages are also depicted in Fig.5. □

Synchronization of the the movement of messages in the three phases can be achieved by using a suitable clock. When different switches receive clock signals by different paths, they should receive clocking events at the same time. Synchronization errors due to clock skews can be avoided by lowering clock rates and/or adding delay to the circuits. Another way is to take advantage of the propagation delay down a long wire by having several clock cycles in progress along its length. This behaviour can be simulated by replacing long wires with strings of buffers. This will restore signal levels and prevent backward noise propagation [23].

### 3.2. Stage 0

Stage zero is the extra stage of the network. Logically, stage zero switches have four inputs and four outputs. A message arriving at any input port in this stage is broadcast to all four output ports of the switch. Thus a message arriving at input port 2 of a switch in stage zero is put into IN queue 2 of each output port of the switch. It is then sent to stage one as described above.

Physically, the replication of messages can be done by the Processor Network Interface (PNI) logic. Thus stage zero receives 4N inputs and it consists of N 4x1 switches i.e. one switch for each output of stage zero. The four IN queues associated with each output port are in one switch. Thus, each switch has four IN queues, one OUT queue and one CHUTE queue as shown in Fig.6. The four copies of a message enter stage zero at different 4x1 switches and are placed in the appropriate IN queues. Movement of messages and any possible combining can go on as in stages 1 through $n-1$. Essentially, the 4x4 switch has been broken up into four 4x1 switches so that each is on a separate chip. Failure of any one of these chips can be tolerated.

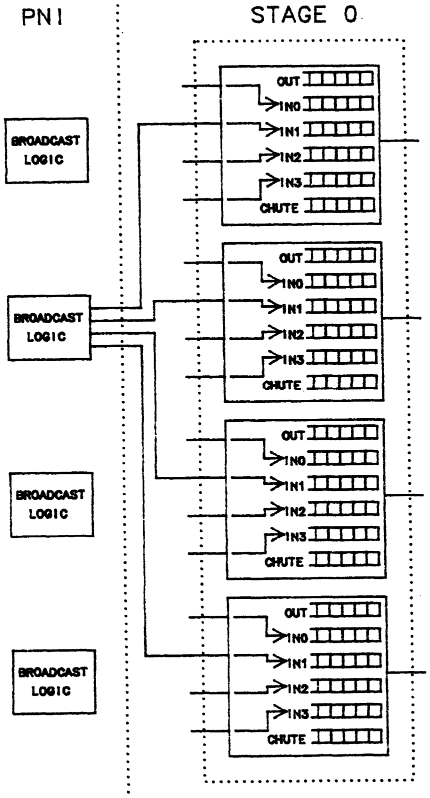

Fig. 6. *Physical Implementation of a 4x4 Switch in Stage 0 of the Network.*

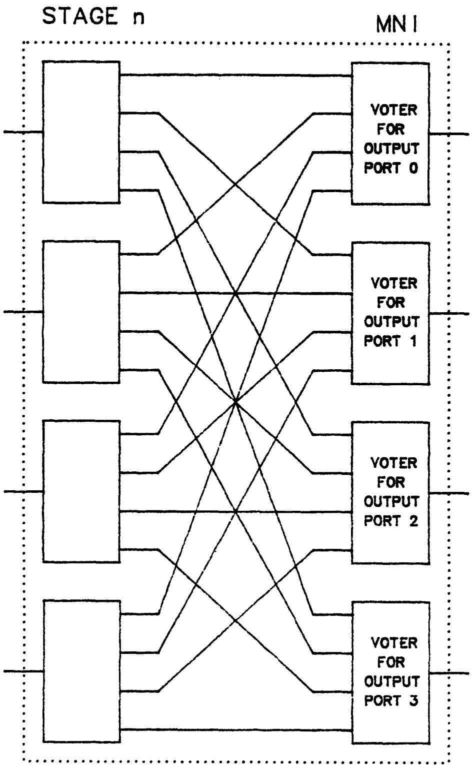

Fig. 7. *Physical Implementation of a 4x4 Switch in Stage n of the Network.*

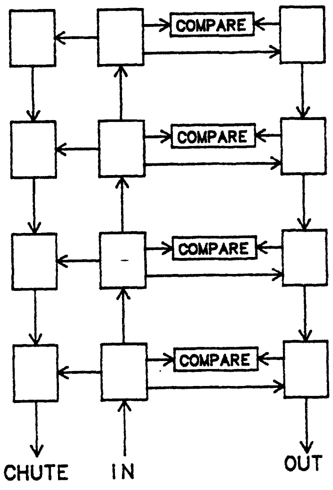

Fig. 8. *Output Port of a Switch in Stage n of the Network.*

### 3.3. Stage n

Logically, each switch in the last stage of the network (stage $n$) receives the four copies of a message, one copy arriving at each input port. The topology of the network and the scheduling of the movement of messages guarantees that the four copies arrive simultaneously at the last stage. Voting is carried out on the four copies. If at most one copy is erroneous, the correct message is routed to the appropriate output port. If two copies are erroneous, the error is detected.

In the physical design of the network, voting can be carried out by the Memory Network Interface (MNI). Each switch in the last stage has one input and four outputs. The physical implementation of a logical 4x4 switch in the last stage is depicted in Fig.7. There are N such 1x4 switches. In each switch, there are four OUT queues, one for each output port. Each output port of a switch has one OUT queue, one IN queue and one CHUTE queue. These queues are connected as shown in Fig.8. The four copies of a message arrive at four 1x4 switches. A message arriving at the input port of a switch is placed in one of the IN queues depending upon the address of its destination. Two messages in the same queue may combine if their destination address within a module are same. Each output of the N 1x4 switches is hardwired to a voting unit in the MNI. There are N such voting units, each being hardwired to four outputs of stage $n$ on the network side and to one memory module on the other side. The MNI receives the four copies, carries out the voting, and routes the message to the appropriate memory module.

## 4. NETWORK PROPERTIES

In this section we will show that the four copies of every message move synchronously through the network. This will be proved by making use of the topology of the network and the scheduling discipline described in Section 3. For the purpose of this section, the switches in stages 0 and $(n-1)$ will be considered to be 4x4 switches.

NOTATION : To distinguish between the four copies of a message, we introduce the notation $(X,a)^0$, $(X,a)^1$, $(X,a)^2$, $(X,a)^3$, to denote the four copies of a message $(X,a)$.

NOTATION : A switch $i$ in stage $s$ of the network will be denoted by $(s,i)$.

LEMMA 1: All copies of a message enter different switches in stages 1 through $(n-1)$ at the same input port of the switches.

PROOF: The inputs and outputs of all the stages are labeled from 0 to N-1 in binary as $m$-bit addresses ($m$ = $\log_2$N). Suppose a message originates at processor

$$a_0\, a_1\, a_2 \dots\, a_{m-2}\, a_{m-1}$$

and the address of its destination is

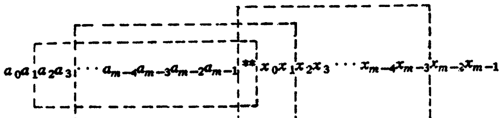
$$x_0\, x_1\, x_2 \dots\, x_{m-2}\, x_{m-1}.$$

The path of the message through the network is traced in Table 1. It can be seen from Table 1 that for every stage between 1 through $(n-1)$ of the network, the least two significant bits of the address in the input port address column are same for all the copies. Since these two bits specify the input port within a switch, the four copies of a message do enter at the same input port of different switches in the same stage. □

LEMMA 2: In an intermediate stage, if the four copies of a message $(X,a)$ enter a stage at switches $(s,i)$,$(s,j)$,$(s,k)$, and $(s,l)$ at port p and one copy of a message $(Y,b)$ enters switch $(s,i)$ at port q, then the other copies of $(Y,b)$ must enter at switches $(s,j)$,$(s,k)$, and $(s,l)$ at port q.

Table 1

| Stage No. | Address of Input Port | Address of Output Port |
|---|---|---|
| Stage 0 | $a_2a_3a_4a_5 \cdots a_{m-2}a_{m-1}a_0a_1$ | $a_2a_3a_4a_5 \cdots a_{m-2}a_{m-1}00$<br>$a_2a_3a_4a_5 \cdots a_{m-2}a_{m-1}01$<br>$a_2a_3a_4a_5 \cdots a_{m-2}a_{m-1}10$<br>$a_2a_3a_4a_5 \cdots a_{m-2}a_{m-1}11$ |
| Stage 1 | $a_4a_5a_6 \cdots a_{m-2}a_{m-1}00a_2a_3$<br>$a_4a_5a_6 \cdots a_{m-2}a_{m-1}01a_2a_3$<br>$a_4a_5a_6 \cdots a_{m-2}a_{m-1}10a_2a_3$<br>$a_4a_5a_6 \cdots a_{m-2}a_{m-1}11a_2a_3$ | $a_4a_5 \cdots a_{m-2}a_{m-1}00x_0x_1$<br>$a_4a_5 \cdots a_{m-2}a_{m-1}01x_0x_1$<br>$a_4a_5 \cdots a_{m-2}a_{m-1}10x_0x_1$<br>$a_4a_5 \cdots a_{m-2}a_{m-1}11x_0x_1$ |
| ... | ... | ... |
| Stage n-1 | $00x_0x_1x_2x_3 \cdots x_{m-6}x_{m-5}a_{m-2}a_{m-1}$<br>$01x_0x_1x_2x_3 \cdots x_{m-6}x_{m-5}a_{m-2}a_{m-1}$<br>$01x_0x_1x_2x_3 \cdots x_{m-6}x_{m-5}a_{m-2}a_{m-1}$<br>$11x_0x_1x_2x_3 \cdots x_{m-6}x_{m-5}a_{m-2}a_{m-1}$ | $00x_0x_1 \cdots x_{m-4}x_{m-3}$<br>$01x_0x_1 \cdots x_{m-4}x_{m-3}$<br>$10x_0x_1 \cdots x_{m-4}x_{m-3}$<br>$11x_0x_1 \cdots x_{m-4}x_{m-3}$ |
| Stage n | $x_0x_1 \cdots x_{m-6}x_{m-5}x_{m-4}x_{m-3}00$<br>$x_0x_1 \cdots x_{m-6}x_{m-5}x_{m-4}x_{m-3}01$<br>$x_0x_1 \cdots x_{m-6}x_{m-5}x_{m-4}x_{m-3}10$<br>$x_0x_1 \cdots x_{m-6}x_{m-5}x_{m-4}x_{m-3}11$ | $x_0x_1 \cdots x_{m-3}x_{m-2}x_{m-1}$ |



$a_0a_1a_2a_3 \cdots a_{m-4}a_{m-3}a_{m-2}a_{m-1}$ ** $x_0x_1x_2x_3 \cdots x_{m-4}x_{m-3}x_{m-2}x_{m-1}$

Fig. 9. *Tracing the Path of a Message from the Address of its Source and Destination.*

PROOF: This can be proved by first determining the condition under which two messages originating from different processors will meet at a switch in a stage $s$. Consider a standard Omega network (no extra stage). Suppose a message originates at processor

$$a_0\, a_1\, a_2 \dots\, a_{m-2}\, a_{m-1}$$

and the address of its destination is

$$x_0\, x_1\, x_2 \dots\, x_{m-2}\, x_{m-1}.$$

The path of the message can be traced by selecting an $m$-bit window at each stage from the concatenated source and destination address bits (Fig.9). At succesive stages, the window is shifted right by two bits. For two messages to meet at a stage the most significant $m-2$ bits in the windows of the two messages for that stage must match. These bits specify the switch at which the two messages meet in the stage. From Fig.9 and Table 1 ("Address of Output Port" column) it can be seen that when an extra stage is added to the network, the $m$-bit window is chosen from

$$a_0\, a_1 \dots\, a_{m-1} ** \,x_0\, x_1 \dots\, x_{m-1}$$

in any intermediate stage, where ** is 00, 01, 10 and 11. The four windows corresponding to the four values of ** identify the particular copy of a message. Thus, if one copy of two messages meet at a switch, the other copies must also meet. □

LEMMA 3: The four copies of every message exit stage 0 of the network simultaneously.

PROOF: From the design of stage 0 switches discussed in Section 3.2 we know that for a message $(X,a)$ arriving at an input port p of switch $(0,i)$, its copies $(X,a)^0$, $(X,a)^1$, $(X,a)^2$, and $(X,a)^3$ will be placed in IN queue p at each output port of switch $(0,i)$ at the same time. The round-robin scheduling discipline ensures that all the copies have the same priority in being sent to the OUT queue or to the CHUTE of the respective output ports. Hence, they will exit stage zero and enter stage one simultaneously. □

LEMMA 4: If there is a message at level $l$ of the OUT queue at an output port, then there will be messages at all levels less than $l$ in the OUT queue.

PROOF: This is proved by considering the movement of messages in the IN queues during the three phases of a cycle as described in Section 3.1. The following points are noted about the messages in the IN queues:

(1) In all phases of a cycle, messages can move to the OUT queue or to the CHUTE.

(2) In phases 1 and 2, messages may move move to a higher level in the IN queue. However, movement of a message to the OUT queue or to the CHUTE is given priority over moving to a higher level. Thus, if a message can move to the OUT queue, it is sent to the OUT queue instead of one level higher in the IN queue.

(3) During phase 3, messages may not move to a higher level. As a result, when messages in the OUT queue and the CHUTE move in phase 1 of the next cycle, an empty slot between two messages in an OUT queue will never be created.

Hence, if $l$ is the highest level in the OUT queue in which there is a message, then there are messages in all levels from 0 through $(l-1)$ of the OUT queue. □

THEOREM 1: All copies of a message enter/exit any stage between 1 and $(n-1)$ of the network simultaneously.

PROOF: We prove the result by induction on the stage number at which copy 0 of a message enters. Consider a message $(X,a)$ entering stage 1 at switches $(1,i)$,$(1,j)$,$(1,k)$ and $(1,l)$. From Lemma 3 we know that the four copies of $(X,a)$ enter stage 1 of the network simultaneously. Suppose $(X,a)^0$ enters stage 1 at switch $(1,i)$ at port p at time $t$. From Lemma 1 we know that the other copies of $(X,a)$ will enter switches $(1,j)$,$(1,k)$ and $(1,l)$ at port p. Since the destination of all the copies is the same, all copies will be routed to the same output port, say, $q$. $(X,a)^0$, $(X,a)^1$, $(X,a)^2$ and $(X,a)^3$ will be placed in the IN queues $p$ at output ports $q$ of switches $(1,i)$,$(1,j)$,$(1,k)$ and $(1,l)$ simultaneously. Since all copies are in IN queues with the same label, they have equal priority in being sent to the OUT queue or to the CHUTE.

From Lemma 4 we know that there are no empty slots between messages in an OUT queue. Hence, one message can be sent to the next stage in every cycle if there is any message at an output port. Suppose at the time when $(X,a)^0$ arrives at $(1,i)$ there are $d$ messages waiting in the IN queues and the OUT queue at output port $q$. Suppose none of these $d$ messages can be combined with each other. (The case when combining is possible is considered separately in Theorem 2). If $(X,a)^0$ does not combine with any of the d messages, then $(X,a)^0$ will experience a delay of $d$ cycles beore it is sent to the next stage. From Lemma 1 and Lemma 2 we know that if there are $d$ messages in the IN queues and the OUT queue at output port $q$ of switch $(1,i)$, then there must be $d$ messages at output port $q$ of switches $(1,j)$,$(1,k)$ and $(1,l)$. Hence, all copies of $(X,a)$ will experience a delay of $d$ cycles before being sent to the next stage.

Thus, in all stages, all copies move synchronously i.e. delays for all copies of a message in any stage will be the same. □

THEOREM 2: If one copy of a message combines with another message then all the other copies of the two messages are guaranteed to combine.

PROOF: It has been proved in Theorem 1 that all copies of a message are placed at level 0 of the IN queues with the same label. It has also been proved that the four copies are placed in the IN queues simultaneously. Initially, when all queues are empty, if one copy of a message in the IN queue moves to the OUT queue, the other copies would also move to the OUT queue. When there are messages waiting in the OUT queue, if one copy of a message moves up one level in the IN queue, the other copies would also move up one level. Hence, all copies are always at the same level of the IN queue or the OUT queue. All copies of a message in the IN queue will be compared to copies of the same message in the OUT queue. Hence, if one copy of a message moves to the CHUTE, all the copies must also move to the CHUTE at the same time. So if one copy of a message combines, then all other copies of the message must combine. □

## 5. CONCLUSION

Clearly, by sending four copies of a message instead of one, we have increased the network traffic. It may seem that this would greatly degrade the performance of the network. However, it should be noted that in the IBM RP3 computer the Fetch-and-Add instructions are routed to the combining network and all others to the non-combining network. Of all the requests generated by a processor, it has been experimentally determined that the percentage of Fetch-and-Add instructions is less than 25% [24]. Hence the network traffic is not very high when a single copy of every message is sent through the network and increasing the traffic by a factor of four is justified.

The design of a fault-tolerant multistage interconnection network based on the Omega network has been presented in this paper. The design of the switching elements constituting the network was described in detail. It supports the Fetch-and-Add instruction of the NYU Ultracomputer and the IBM RP3 computer. It also provides concurrent correction and detection of message transmission errors. The only additional hardware needed is an extra stage. Compared to the Omega network, this amounts to N/4 extra switching elements if there are N processors. Some properties of the proposed network were proven that are also applicable to the Omega network. The proposed design considers message transmission from the processors to the memory modules. It is assumed that a similar network exists for the return path.

Abstract -- With the aim of designing a highly available distributed computer system, a kind of interconnection network with mixed static and dynamic topologies has been proposed and developed. This paper gives a quantitative analysis of the fault-tolerance performance of the network,including the processor connectivity and the worst-case diameter. The method used in the analysis is constructive in nature so that the result not only shows a higher fault-tolerance capability of the proposed interconnection network than that of other existing schemes, but also may serve as the basis of a distributed fault-tolerant routing algorithm with low space and time overheads.

## INTRODUCTION

A distributed computer system may be judged by many different criteria. Reliability and availability are among those important attributes of the system which should be given the most emphasized consideration. With the aim of designing a highly available distributed computer system, a kind of interconnection network with mixed static and dynamic topologies has been proposed and implemented [1] - [2]. This network connects a great number of geographically dispersed processors relying on the principle of static topology, which is characterized by point-to-point links between processor-nodes [3]. So any two processors which are not directly connected by a link need to have their messages relayed by intervening processors. However,in distinction with the ordinary interconnection network with static topology, the proposed network does not use fixed, passive, and dedicated links between processors, but rather establishes these links through a set of explicit switching elements.Therefore, the system can be dynamically reconfigured by properly setting these switching elements to make the communication links active, changable,and sharable among a number of processor pairs. Introduction of dynamic topology into the static interconnection network significantly enhances its performance, especially the fault-tolerance capability.

As summarized in [4], fault-tolerance is an inherent characteristic of the interconnection network. Fault-tolerance can be achieved only if the network can facilitate multiple-path,multiple-pass, and fault-tolerant switching elements. Redundant communication paths are allowed in most static interconnection topologies. Some static interconnection networks can tolerate multiple node/link failures or failures of subnetworks into which the network is partitionable. More attention has been paid to the improvement of fault-tolerance performance of dynamic interconnection topology. Extra-stage, multiple routing-pass, redundant link,error-correcting code, and fault-tolerant switching elements are various schemes which have been proposed. To take advantages of both static and dynamic topologies, it is,therefore, reasonable to combine them in developing a new kind of fault-tolerant interconnection network.

Compared with similar fault-tolerant networks most recently published in the literature[5] - [6], the network analized in this paper differs in many special features, such as low connection-complexity, high fault-tolerance, short diameter, ease of routing, as well as suitability for distributed computer architecture. All these are the general requirements which should be satisfied by a fault-tolerant interconnection network.

In this paper, after a brief description of the proposed interconnection network in the next section, a qualitative analysis of its fault tolerance will be given in the third section. This analysis contains a few typical examples which may help in deriving a quantitative evaluation of the network in the fourth section. The way of analysis adopted is constructive in nature so that the proof of the theorem will automatically imply, as its direct consequence, the basic idea of routing strategy based on which a distributed fault-tolerant routing algorithm with dynamic reconfiguration of the system could be developed. Finally, as an evaluation of the proposed network, a comparison of its fault-tolerance capability with respect to other existing networks will be given.

## DESCRIPTION OF THE MIXED GROUP-SHUFFLE INTERCONNECTION NETWORK

Interconnection network with mixed static and dynamic topologies combines the idea of interconnecting geographically dispersed processors through point-to-point links and the idea of sharing these links among processors through dynamically reconfigurable switching elements. Such a kind of interconnection network may be constructed on the basis of any existing multi-stage dynamic interconnection network by distributing the switching elements to the processors. In this way, the resulted mixed interconnection network becomes more adaptable to matching the distributed computer system architecture. The dynamic interconnection network which has been chosen as the basis of implementation in our work of developing a highly available distributed computer system is the multi-stage shuffle-exchange network [4].

The resultant network developed in this way is called the mixed group-shuffle interconnection network due to the following structural principle. It consists of m stages, each containing $r^m$ processors, where r is an integer denoting the number of processors in each group. Each processor can be labeled by the combination of two numbers C.P , where C is the stage number for $0 \leq C \leq m-1$ with

0190-3918/86/0000/0335 $01.00 © 1986 IEEE

C = 0 corresponding to the leftmost stage, and P is the processor number within the stage for $0 \leq P \leq r^m - 1$ with P = 0 corresponding to the top row. The integer r is also the radix in which the processor number P can be represented as

$$P_{m-1}P_{m-2}\ldots\ldots P_1P_0, \quad 0 \leq P_i \leq r-1,\ 0 \leq i \leq m-1.$$

The network takes r processors with the labels

$$C.P_{m-1}P_{m-2}\ldots P_1X \qquad X = 0, 1, \ldots, r-1$$

in the same stage as a group and establishes connections between the groups in the successive stages according to the group-shuffle interconnection function defined as follows:

$$\text{group-shuffle}(P_{m-1}P_{m-2}\ldots P_1X) = P_{m-2}\ldots P_1XP_{m-1}.$$

That means: the group of r processors labeled $C.P_{m-1}P_{m-2}\ldots P_1X$ in each stage can be conceptually viewed as to be connected to the group of r processors labeled $(C+1).P_{m-2}\ldots P_1XP_{m-1}$ in the succeeding stage, and all the groups of processors in the last stage are connected to the corresponding groups in the first stage. All the connections may be thought of as to be performed by the r$\times$r switches. Thus the whole network forms a closed loop of m stages,each containing $r^{m-1}$ groups with r processors in each group. Therefore the total number of r$\times$r switching elements for interconnecting $mr^m$ processors is $mr^{m-1}$.

Despite the fact that the radix r can be chosen arbitrarily, we have chosen in our design r=4 for simplicity of implementation based on the 2$\times$2 switching elements only. The interconnection of four 2$\times$2 switching elements for performing 4-to-4 crossbar interconnection is shown in Fig.1. Here, using four 2$\times$2 switching elements to replace one 4$\times$4 switching element, we can take the following additional advantages:

·The in-degree (number of incident arcs) and the out-degree (number of outgoing arcs) of each processor are both equal to 2 instead of 4, but every processor can still send messages directly to any one of the four processors in the succeeding stage, and every processor can still receive messages from any one of the four processors in the preceeding stage.

·Each processor can use two switching elements to communicate with the corresponding processors in the neighboring stage. This guarantees a certain degree of redundancy of switching elements for a higher fault tolerance.

The overall structure of a mixed group-shuffled interconnection network with r = 4 is shown in Fig.2. For simplicity, the details of implementation of switching elements have been neglected.

Another property of the proposed interconnection network which is noteworthy is its short diameter, defined as the maximum of the minimum distances between all pairs of processors measured in the number of links. In normal operation, when no failed links, switches or processors exist in the network, the diameter of an m-stage network with $mr^m$ processors is equal to $2m - 1 = O(\log_r N)$, where N is the total number of processors in the network. This can be derived by the following reasoning: every processor can take m steps to send messages to any processor in the same stage, and if any destination processor in the intermediate stage on the way can not be reached within the first m steps, then it must be reached within additional m - 1 steps from the source stage.

## QUALITATIVE ANALYSIS OF FAULT-TOLERANCE

A great number of redundant paths existing between any pair of processors makes the mixed group-shuffle interconnection network highly fault-tolerant. For the evaluation of this performance, we will take the following criteria in our analysis:

·Processor connectivity -- maximum number of faulty processors (with any worst-case distribution) which can be removed without danger of isolating any working processor from the rest of the network.

·Worst-case diameter -- diameter of the network survived after removing the maximum number of tolerable faulty processors as determined above.

·Simplicity of the routing algorithm adaptable to the requirement of fault-tolerance.

By a qualitative analysis, it is easy to determine the upper bound of the processor connectivity from the following straight argument:

At first, no any stage can be tolerant of more than r - 1 faulty processors, because these r or more faulty processors may contain all the successors of a processor in the preceeding stage and thus completely isolate their parent from the network.

Secondly, the processor connectivity can not be better than r - 1 faulty processors in every stage. In other words, if any r - 1 faulty processors are removed from each stage, part of the working processors would be isolated from the survived network, and no communication paths can be guaranteed between any arbitrary pair of processors. A special case suffices to prove this conclusion. Suppose we have the following worst-case distribution of faulty processors. All the r - 1 faulty processors in the second stage are successors of the source node in the first stage, so only one good processor can be reached in the second stage from the source processor. This good processor may, in turn, have all its successors, except one, becoming malfunctioning, thus only one good processor in the third stage can be reached from it. This situation may exist and propagate from stage to stage until, at last, the single reachable good processor in the last stage may have its single good successor just coincident with the source processor. In consequence, all these good processors, one from each stage, may just form a closed loop which is isolated from the remaining processors of the network. This is obviously a situation contradictory to the requirement of the definition of processor connectivity.

The network, however, can survive this worst situation if there is just one less faulty processor in any one stage than the above mentioned case. This gives, therefore, the upper bound of processor connectivity which equals to r - 2 faulty processors in any one stage and r - 1 faulty processors in every other stage. This constitutes the condition of the theorem which will be proved in the next section for a quantitative analysis of the network.

It was stated above that the diameter of the network under normal conditions without node/link failures is equal to 2m - 1, i.e. any destination processor can be reached from any source processor within two passes. This is true even when there exists some limited number of faulty nodes in the network. To find the corresponding fault-tolerant condition we will follow the routing strategy indicated in Table 1. By this routing strategy, a shortest path is established between any two processors $0.P_{m-1}\ldots P_1P_0$ in stage 0 and $k.Q_{m-1}\ldots Q_1Q_0$ in stage k. When the message is traversing along the selected path from stage to stage, the processor number as a base-r code is cyclically shifted left digit by digit, and during each shift the least significant digit of the current code is replaced by a new digit. Thus the whole process of routing can be turned into a procedure of generating a replacing vector R formed by these new digits as denoted by $R_0, R_1, \ldots R_{k-1}, Q_0, Q_{m-1}, \ldots Q_2, Q_1$ in Table 1. For guaranteeing maximum flexibility and fault-tolerance, we leave the selection of the communication path free at the first k steps of traversal and only at the last m steps let it be fixed by the digits $Q_0, Q_{m-1}, \ldots, Q_1$. Thus we are allowed to have some freedom in selecting the digits $R_0, R_1, \ldots R_{k-1}$. The more we have selectable digits $R_i$, $0 \leq i \leq k-1$, the higher fault-tolerance could be realized. Therefore it is the value of k which determines the fault-tolerant condition.

From the architectural point of view, the network analyzed in this paper can be conceptually thought of as a closed multiple-rooted r-nary tree, in which every node may be viewed as a root and, at the same time, may serve as the leaf of other nodes. So the stages 1 and k-1 are the bottlenecks of the equivalent tree structure, and they can tolerate smallest number of faulty nodes. Therefore, the problem can be stated as follows: A path is to be selected from stage 0 to stage k with two passes through an m-stage network. If in stage 1 there exist r-1 faulty nodes, but no one can be the child of the starting node; in stage k-1 there exist r-2 faulty nodes; and in each of the remaining stages (including stages 0 and k) there exist r-1 faulty nodes; then what is the minimum value of k which makes the fault-tolerance realizable? This question will be answered by the Lemma 2 whose proof will be given in the next section.

Here we just give two examples as shown in Figs.3 and 4. The first example in Fig.3 shows a successful case with r = 4, m = 4, k = 3. Among the total $r^k = 64$ codings of $R_0, R_1, R_2$ digits, only 50 codings are needed to mask all the possible faulty nodes (with worst-case distribution), so that there still remain 64 - 50 = 14 codings which can be used to select the free paths containing only good processors. For the second example with r = 4, m = 8, k = 3, as shown in Fig.4, since k is so small that its $r^k = 64$ possible codings are just enough to mask all the possible faulty processor numbers, no one coding remains to allow any valid path to be selected. Therefore the minimum value of k for r=4 and m=8 for two-pass fault-tolerant routing under the specified conditions is equal to 4.

It should be noted that the two-pass fault-tolerant conditions specified here do not hold for any arbitrary pair of source and destination nodes. We will investigate this general case in the next section.

Table 1 Routing Strategy From Node $0.P_{m-1}\ldots P_1P_0$ to Node $k.Q_{m-1}\ldots Q_1Q_0$ With Distance m+k

| Stage | Processor Number | Replacing digit | No.of free proc. | No.of equiv. codes |
|---|---|---|---|---|
| 0 | $P_{m-1}P_{m-2}\cdots P_1P_0$ | -- | -- | -- |
| 1 | $P_{m-2}P_{m-3}\cdots P_1R_0P_{m-1}$ | $R_0$ | $r$ | $r^{k-1}$ |
| 2 | $P_{m-3}P_{m-4}\cdots P_1R_0R_1P_{m-2}$ | $R_1$ | $r^2$ | $r^{k-2}$ |
|  | ......... | ... | ... | ... |
| i | $P_{m-(i+1)}\cdots P_1R_0\cdots R_{i-1}P_{m-i}$ | $R_{i-1}$ | $r^i$ | $r^{k-i}$ |
|  | ......... | ... | ... | ... |
| k-1 | $P_{m-k}\cdots P_1R_0\cdots R_{k-2}P_{m-k+1}$ | $R_{k-2}$ | $r^{k-1}$ | $r$ |
| k | $P_{m-(k+1)}\cdots P_1R_0\cdots R_{k-1}P_{m-k}$ | $R_{k-1}$ | $r^k$ | 1 |
| k+1 | $P_{m-k-2}\cdot\cdot P_1R_0\cdot\cdot R_{k-1}Q_0P_{m-k-1}$ | $Q_0$ | $r^k$ | 1 |
|  | ......... | ... | ... | ... |
| m-1 | $R_0R_1\cdots R_{k-1}Q_0Q_{m-1}\cdots Q_{k+2}P_1$ | $Q_{k+2}$ | $r^k$ | 1 |
| 0 | $R_1R_2\cdots R_{k-1}Q_0Q_{m-1}\cdots Q_{k+1}R_0$ | $Q_{k+1}$ | $r^k$ | 1 |
| 1 | $R_2R_3\cdots R_{k-1}Q_0Q_{m-1}\cdots Q_kR_1$ | $Q_k$ | $r^{k-1}$ | $r$ |
|  | ......... | ... | ... | ... |
| i | $R_{i+1}\cdot\cdot R_{k-1}Q_0Q_{m-1}\cdot\cdot Q_{k-i+1}R_i$ | $Q_{k-i+1}$ | $r^{k-i}$ | $r^i$ |
|  | ......... | ... | ... | ... |
| k-1 | $Q_0Q_{m-1}\cdots Q_2R_{k-1}$ | $Q_2$ | $r$ | $r^{k-1}$ |
| k | $Q_{m-1}Q_{m-2}\cdots Q_1Q_0$ | $Q_1$ | -- | -- |

## QUANTITATIVE ANALYSIS OF FAULT-TOLERANCE

The final purpose of the quantitative analysis is to prove the following theorem. As a preliminary step, three lemmas will be proved first.

Theorem In a m-stage (m = 2) mixed r-nary group-shuffle interconnection network, if there exist no more than r - 2 faulty processors in at least one stage, and no more than r - 1 faulty processors in every other stage, communication can be performed between any pair of the remaining good processors; and the diameter of the survived network is equal to

$$D = \begin{cases} 3m, & m = 2\ ; \\ 4m - 1, & 3 \leq m \leq 5\ ; \\ 3m + \lceil 2\log_r m \rceil + 2\ , & m > 5\ . \end{cases}$$

Lemma 1 Under the condition specified by the Theorem, if some node has r - 2 faulty children, then no more than 2 steps must be made in order to reach a node whose all children are good nodes.

Proof. Starting from a node in the first stage with r - 2 faulty children, the message can be sent through one step to one of the two good nodes in the second stage, and then, from either of these two nodes with at most r - 1 faulty children, the message can be sent further to one of

$$2r - (r - 1) = r + 1$$

nodes in the third stage. Since the fourth stage has at most r - 1 faulty nodes which could be the children of these r + 1 predecessors, at least two of these predecessors can not be followed by any faulty nodes.

For the case of m = 2, the children of the r + 1 good nodes in the third stage (i.e.the first stage) may coincide with each other, thus resulting in fewer effective good nodes in the first stage. But the Lemma 1 still holds since all the r - 2 faulty nodes in the fourth stage (i.e. the second stage) are children of the same source node.

Lemma 2 Under the condition specified by the Theorem, if there are at most r - 2 faulty nodes in stage k - 1, then starting from any node in stage 0 with no faulty children, the message can be sent to any destination node in stage k through m + k steps, where

$$k = \begin{cases} 0 , & m = 2 ; \\ m - 1 , & 3 \leq m \leq 5 ; \\ \lceil 2\log_r m \rceil + 2 , & m > 5 . \end{cases}$$

Proof.

Case 1 m = 2

Starting from any node in stage 0 with no faulty children, in the first step the message can be sent to all r groups in stage 1, so that in the second step all good nodes in stage 2 (i.e. stage 0) can be reached. Therefore, k = 0.

Case 2 m = 3

The routing paths followed for sending a message from the node $0.P_{m-1}P_{m-2}\ldots P_1P_0$ to the node $k.Q_{m-1}Q_{m-2}\ldots Q_1Q_0$ through m + k steps are listed in Table 1. The replacing digits $R_0,R_1,\ldots,R_{k-1}$ of the replacing vector R must be selected in such a manner that all the processors to be passed through are distinguishable from the faulty nodes. This requirement can be expressed in the form of a set of inequalities for all stages 0 through m - 1 and for both passes. From stage i in Table 1 we have

$$P_{m-i-1}..P_1R_0..R_{i-1}P_{m-i} \neq F \quad \text{for the first pass}$$

$$R_{i+1}..R_{k-1}Q_0Q_{m-1}..Q_{k-i+1}R_i \neq F \quad \text{for the second pass}$$

where F denotes the set of all faulty node numbers in stage i. According to the condition specified by the Lemma 2, this set should contain no more than r - 2 elements for i = k - 1 and no more than r - 1 elements for all other i, $0 \leq i \leq m-1$ except i = k-1.

Great flexibility of selecting routing paths is provided by the R vector, but it has only k digits $R_0,R_1,\ldots,R_{k-1}$ which can be used to serve this purpose. The total $r^k$ different codings of these k digits are used in either of the following two ways:

- Part of the codings of the R vector must be avoided or excluded in order to mask all faulty nodes in the network;
- The remaining part of the codings can be used to choose the good nodes to establish the valid communication paths.

The goal of the proof of this Lemma is to determine the minimum value of k with respect to values of m and r such that after subtracting the first part of the codings from $r^k$ the difference still remains positive, i.e. there remains at least one coding of the R vector for setting up a good connection between any source node and any destination node.

From Table 1 it can be seen that since processor numbers in different stages contain different numbers of R digits, the numbers of equivalent R-codings for masking one faulty node in different stages are also different, as indicated in the last column of Table 1.

From the condition of the Lemma, in each of the stages 0 and 1 a maximum of r - 1 faulty nodes may exist and must be excluded from the R-codings only for the second pass. Therefore,with the worst distribution of faulty nodes, r - 1 different codings of $R_0R_1\ldots R_{k-1}$ must be avoided for stage 0; and r - 1 different codings of $XR_1\ldots R_{k-1}$ must be avioded for stage 1, where X = 0,1,...,r-1. This means an equivalent number of r(r-1) codings of $R_0R_1\ldots R_{k-1}$ must be excluded from $r^k$ for stage 1.

For stages 2 through k - 2, faulty nodes may exist in both passes. Since no digits of the R vector appear at the same digit positions for any stage in the two passes, the worst-case distribution is as follows:

- r - 1 faulty nodes exist in each stage i, $2 \leq i \leq \lfloor k/2 \rfloor$, for the first pass, which is equivalent to $(r-1)r^{k-i}$ different codings of the R vector;
- r - 1 faulty nodes exist in each stage i, $\lfloor k/2 \rfloor + 1 = i = k-2$, for the second pass, which is equivalent to $(r-1)r^i$ different codings of the R vector.

Since the digit positions of the R vector in each stage i, $2 \leq i \leq \lfloor k/2 \rfloor$, for the first pass overlap with the corresponding digit positions of the code of the destination node in the same stage for the second pass, the worst-case distribution may be that one of the r - 1 faulty codings for the first pass just coincides with the faulty coding for the second pass (See the example in Fig.4, where coding 20321310 coincides between the two passes in stage 2). This is equivalent to a number of $r^i$ additional codings of the R vector which must be excluded from $r^k$ for each stage i, $2 \leq i . \leq \lfloor k/2 \rfloor$.

Similarly, a number of $r^{k-1}$ additional codings of the R vector must be excluded from $r^k$ for each stage i, $\lfloor k/2 \rfloor + 1 = i = k-2$, in the first pass, because its source code digits may coincide with the corresponding R digits of one of the r - 1 faulty nodes for the second pass.

However, between the first pass and the second pass for each stage i, $2 \leq i \leq k-2$, r - 1 excluded codings of the R vector are duplicated. They should be added back to the $r^k$ total codings.

Similar argument holds for the stage k - 1 with the only difference that $(r-2)r^{k-1}$ equivalent faulty codings of the R vector may exist in the second pass, r additional equivalent faulty codings of the R vector may exist in the first pass, and between them r - 2 codings are duplicated.

For all the remaining stages from stage k through stage m - 1, r - 1 codings of the R vector must be excluded from each first-pass expression.

After all the different faulty codings stated above are subtracted from the total $r^k$ possible codings of the R vector, the difference obtained should still be positive, indicating that there remains some coding available for selecting good nodes along the communication path. This leads to the inequality given on the next page.

In fact, the inequality (1) involves two inequalities, one for k being odd, and the other for k being even. Transformation of the expression (1) yields the two inequalities (2) and (3) which give the implicit functions of k with respect to the values of radix r and the number of stages m of the network.

$$r^k - \sum_{i=2}^{\lfloor k/2 \rfloor} (r - 1)r^{k-i} - \sum_{i=\lfloor k/2 \rfloor+1}^{k-2} (r - 1)r^i - \sum_{i=2}^{\lfloor k/2 \rfloor} r^i$$

$$- \sum_{i=\lfloor k/2 \rfloor+1}^{k-2} r^{k-i} - (r - 2)r^{k-i} - r - (r - 1)$$

$$- (r - 1)r - (r - 1)(m - k) + (r - 1)(k - 3)$$

$$+ (r - 2) > 0 \qquad (1)$$

$$2r^{\lceil k/2 \rceil} \cdot \frac{r - 2}{r - 1} + \frac{2r^2}{r - 1} - (r - 1)(m - 2k + r + 4)$$

$$- 2 > 0 \qquad \text{for } k = \text{odd} ; \qquad (2)$$

$$r^{k/2} \cdot \frac{(r + 1)(r - 2)}{r - 1} + \frac{2r^2}{r - 1}$$

$$- (r-1)(m - 2k + r + 4) - 2 > 0$$

$$\text{for } k = \text{even}. \qquad (3)$$

Numerical solutions to the last two inequalities (2) and (3) are listed in Table 2, which indicates that for practical values of m and r, the value k equals to 3.

Table 2 Values of k as a function of r and m

| k | | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| m | r=4 | 3 | 4--7 | 8--20 | 21--33 | 34--77 |
| | r=8 | 3 | 4--11 | 12--68 | 69--111 | 112-- |
| | r=16 | 3 | 4--19 | 20--90 | 91--225 | 226-- |

For a rough estimation by the order of magnitude, it can be proved that the above inequalities hold true when we take either of the two values of k:

$$k = \lceil 2\log_r m \rceil + 2 \quad \text{or} \quad k = m - 1.$$

Therefore we have the following solution

$$k = \min\{\lceil 2\log_r m \rceil + 2, \; m - 1\}$$

or

$$k = \begin{cases} m - 1 & 3 \leq m \leq 5 \\ \lceil 2\log_r m \rceil + 2 & m > 5 \end{cases} \qquad (4)$$

From the solution we conclude that when k is larger than or equal to the values listed in Table 2 or calculated from (4) there must exist at least one coding of the reconfigurating vector R necessary for establishing a communication path between any source node $0.P_{m-1}...P_1P_0$ and any destination node $k.Q_{m-1}...Q_1Q_0$ through m+k steps.

The proof of the above Lemma also shows that the condition can be relaxed to permit more than r - 2 faulty nodes in stage k - 1, so long as these faulty nodes have their codes with ≤ r - 2 different values at LSD position. This can be seen from Table 1 when we look at the processor number in stage k - 1 for the second pass, which contains the digit $R_{k-1}$ at the least significant digit (LSD) position so that the excluded codings of the R vector can be expressed as $R_0R_1...R_{k-1} = XX...R_{k-1}$, where X stands for any digit from 0 through r - 1.

Lemma 3 Under the condition specified by the Theorem, starting from any node in stage 0 with no faulty children, i steps are enough to send a message to another node in stage i with no faulty children, where $1 \leq i \leq m - 1$.

Proof. Since the source node in stage 0 has no faulty children, the first step will lead to r good nodes in stage 1. Among these r good nodes, at most r - 1 nodes can have faulty children, therefore at least one node is free of faulty children. The same argument can be extended to the following stages.

Now, having proved the above three Lemmas, we are ready to prove the Theorem stated at the beginning of this section. For simplicity of description, we will label the source stage as stage 0. Of course, this stage 0 may be different from the stage 0 which we labeled in the proof of Lemma 2.

Proof of the Theorem.

Case 1. All the children of $0.P_{m-1}...P_1P_0$ are good nodes.

a) The faulty nodes in stage k - 1 have r-1 different values at LSD position.

The condition of the Theorem tells us that there must be at least one stage with no more than r - 2 faulty nodes. Assume this occurs in the stage (k - 1 + i)modm, where $1 \leq i \leq m-1$. According to Lemma 3, a traversal of i steps will lead to a node in stage i with no faulty children, then according to Lemma 2, taking additional m + k steps will lead further to any node in stage (k + i)modm. Thus the maximum traversing distance will be equal to

$$(m - 1) + (m + k) + (m - 1) = 3m + k - 2.$$

b) The faulty nodes in stage k - 1 have ≤ r - 2 different values at LSD position.

According to Lemma 2, traversing through the first m + k steps can lead directly to any node in stage k, so that the maximum distance will be

$$(m + k) + (m - 1) = 2m + k - 1 .$$

Case 2. The node $0.P_{m-1}...P_1P_0$ has faulty children.

a) The number of faulty children of the node $0.P_{m-1}...P_1P_0 \leq r - 2$ .

According to Lemma 1, traversing through the first two steps can lead to a node with no faulty children, then the routing can follow the path as in case 1, so that the maximum distance is

$$(3m + k - 2) + 2 = 3m + k .$$

b) The number of faulty children of the node $0.P_{m-1}...P_1P_0 = r - 1$ .

Under the condition of the Theorem, there must be at least one stage with a node whose faulty children ≤ r - 2. Assume it is the stage i, $1 \leq i \leq m - 1$, to say the nearest stage from stage 0. At first, the route starts from the node $0.P_{m-1}..P_1P_0$ and arrives this stage i through i steps, then, according to Lemma 1, it can reach a node with no faulty children through 2 additional steps.

It should be noticed, however, that if any node in some stage has r - 1 faulty children, then the faulty nodes of the next stage which must be masked will have their codes of the form $F_{m-1}..XF_0$, where X = 0, 1,...,m-1. The LSD can have only one value $F_0$, determined by the MSD of the parent node in the preceeding stage. Similarly, from stage 1 to stage i, each stage will have faulty nodes with only one value at the LSD position.

After the node in stage i + 2 with no faulty children has been reached via the first i + 2 steps from the source node $0.P_{m-1}\ldots P_1P_0$, the route will be continued under the condition of case 1(b). If $k + i < m$, then additional $m - (k + i)$ steps are needed to reach the stage $(m - k + 2)$ so that $[(m - k + 2) + (k - 1)]\text{mod}m = 1$. If $k + i \geq m$,then $[(i + 2) + (k - 1)]\text{mod}m \geq 1$. Both cases will have the (k - 1)th stage whose faulty nodes take no more than r - 2 values at LSD as required by the condition of case 1(b). Therefore, the maximum distance is equal to

$$(m - 1) + 2 + (2m + k - 1) = 3m + k .$$

In summary, communication between any pair of good nodes can be performed under the fault conditions specified by the Theorem, and the diameter of the network may be increased to 3m + k, where k is determined by Lemma 2. After substitution for k, the diameter is

$$D = \begin{cases} 3m , & m = 2 ; \\ 4m - 1 , & 3 \leq m \leq 5 ; \\ 3m + \lceil 2\log_r m \rceil + 2 & m > 5 . \end{cases}$$

## EVALUATION OF THE FAULT-TOLERANCE PERFORMANCE

For a comparative evaluation of the fault-tolerance capabilities of the proposed interconnection network, we take as the reference two similar networks recently published in the literature [5] -- [6]. The result of comparison is listed in Table 3.

Table 3 Comparative Evaluation of The Fault-Tolerance Performance

| Network | Kumar-Reddy(84) | Pradhan(85) | Mixed group-shuffle |
|---|---|---|---|
| Number of processors | $r^m + r^{m-1}$ | $r^m$ | $mr^m$ |
| Degree | 2r | r or r+1 | r(logical) |
| Fault-tolerant Capability | 2r - 1 | r-1 or r | m(r-1)-1 |
| Normal-case Diameter | m | 2m - 1 | 2m - 1 |
| Worst-case Diameter | 3m + 6 | 6m - 3 | $3m+\lceil 2\log_r m\rceil+2$<br>or 3m + 3 |

The number of faulty processors which the three networks can be tolerant of in each stage is roughly the same, but if we refer the processor connectivity to the total number of processors and the processor-degree, then the mixed group-shuffle interconnection network appears to be more advantageous. It can accomodate m times more processors and connects them with smaller physical degree.

The normal-case diameter of the three networks relative to the degree of topology is roughly the same, but if again we refer it to the total number of processors, then the effective diameter of the mixed group-shuffle interconnection network is the shortest.

The worst-case diameter of the mixed group-shuffle interconnection network is also the shortest, especially when its relative value with respect to the normal-case diameter is taken. Its maximum distance of communication under faulty conditions is only 1.5 times longer than that under normal conditions, whilst for the other two networks the faulty condition would increase the diameter in 3 times.

The mixed group-shuffle interconnection network is simple in implementation. The basic idea of the fault-tolerant routing algorithm can be derived on the basis of the Theorem just proved.From Table 1 it can be seen that under normal operation a reconfigurating or replacing vector R should be found and used to replace the code of the source processor digit by digit on the way forward from stage 0 to stage k, and then the remaining digits of the code of the source node as well as the digits of the R vector are gradually replaced by the code of the destination node digit by digit on the way through stages k+1,...,m-1,0,1,... until the destination node in stage k is reached. Thus the combination of the $R_i$ , $0 = i = k-1$,digits and the destination code digits in the form of

$$R_0R_1R_2\ldots R_{k-1}Q_0Q_{m-1}\ldots Q_2Q_1$$

can be used as the routing vector for the purpose of routing control. Since the reconfigurating vector is independent of the destination and transparent to the intermediate processors, it needs to be calculated only once and reserved in the source processor for later use. Under faulty operation, the only work which the source processor should do is to calculate a modified reconfigurating vector and attach it to the destination code digits. In order to accomplish this, each processor must reserve a complete list of faulty nodes of the system. Each time when this list is updated to add or delete any faulty node(s), the reconfigurating vector should be updated. Since the length of each modified reconfigurating vector $< 3m$, the memory space overhead is small. Since the recalculation of the reconfigurating vector needs to be done only when the faulty conditions change, the time overhead is small too.

## CONCLUSION

The basic principle of constructing a multistage interconnection network with mixed static and dynamic topologies is given, and the group-shuffle interconnection function is defined to develop its typical structure. The resulted m-stage ($m \geq 2$) r-nary mixed group-shuffle interconnection network serves the object of analysis of this paper, where r is the number of processors per group.

Three criteria of fault-tolerance performance of the interconnection network are observed. The processor connectivity allows no more than r - 2 faulty processors in at least one stage and no more than r - 1 faulty processors in every other stage. In total, the maximum number of allowable faulty processors with any worst-case distribution is m(r - 1) - 1. The worst-case diameter under the above faulty condition is shown to be

$$3m + \min\left\{m-1,\ \lceil 2\log_r m\rceil + 2\right\}$$

or practically

$$3m + 3 ,$$

which is approximately 1.5 times longer than the diameter of the network under normal conditions.

The proofs of the Lemmas and the Theorem for the processor connectivity and the worst-case diameter gives the basic idea of the fault-tolerant routing control, which helps deriving a simple distributed fault-tolerant routing algorithm for the proposed interconnection network.

Comparative evaluation of the fault-tolerance performance among three similar interconnection networks reveals the advantageous cahracteristics owned by the proposed network.

The proposed mixed interconnection network has been implemented in an experimental distributed computer system THUDS, developed in Tsinghua university, Beijing, China. Though analysis has shown some potential of achieving high system performance, only experience in its application will prove finally its appropriateness and suitability for a variety of distributed processing needs.

# Massively Fault-tolerant Cellular Array

Myoung Sung Lee and Gideon Frieder

Department of Electrical Engineering and Computer Science
University of Michigan
Ann Arbor, MI 48109

**Abstract** — *Massively fault-tolerant cellular array* is an array of identical cells with connections only to immediate neighbors, where the cells and the connections may be defective with high probabilities. The cell can function as a processing element, as a memory, or as a switching element that connect to other cells. On the defective array, a large cluster of interconnected working cells is formed and the cells without an adequate number of working neighbors are pruned out from the cluster. The working cells in the cluster are configured into a graph that determines the function of the array. The algorithms for forming the cluster, pruning the cluster, and configuring the cells into a linear array, a two-dimensional array, and a binary tree are described, and simulation results are presented.

## Introduction

With the progress in VLSI technology, we will be able to manufacture huge number of devices on a chip, but we may be unable to avoid many defects. Under current integrated circuit architecture, we can tolerate few defects on a chip. With huge number of devices on a chip, we could afford the redundancy necessary to provide fault-tolerant operations. With enough redundancy, we should be able to devise a fault-tolerant architecture which allows efficient computation in spite of many defects.

Fault-tolerant multiprocessors and configuration of cells on the defective array in the context of wafer-scale integration has been studied by many researchers [6,12,1,14,9,17,7,4,11,15,13]. In fault-tolerant multiprocessor systems, introduction of spare parts and reconfiguration has been used in a limited scale. On the VLSI architecture, where huge numbers of devices are available and connections between them are difficult and defects cannot be eliminated, several different approaches has been tried.

In technology-oriented approaches, discretionary wiring and laser personalization have been used for fault-tolerance on VLSI. In these methods, separate nonreversible processing steps are employed for each chip to reconfigure circuits on the defective integrated circuit. In other approach, programmable switches are provided between cells [17,7], and the switches are used to configure working cells in the defective circuit. Here electrical configuration and reconfiguration is possible, but the switches should be fault-free, and some means to program the switches should be provided. In cellular array approach, cells can be used as switches as well as processing elements [12,1,9,4]. This allows distributed self-configuration, and maintains the general advantages of cellular array which derives from its homogeneous and regular structure.

To take full advantage of reconfigurable defective cellular, we need distributed self-configuration where the global defect pattern of cellular array is not needed. However they were not efficient when many cells were defective. With adequate computing power in each cell, however, distributed self-configuration can be done efficiently. In this paper we describe a cellular array that can be efficiently configured despite many defects. The cellular array, called *massively fault-tolerant cellular array,* is an array of identical cells with connections only to immediate neighbors, where each cell can function as a processing element, as a memory, or as a switching element that connects to other cells. Input and output terminals are connected only at the boundaries of the array. This cellular array anticipates the occurrence of massive defects in the cells and in the interconnections. The cellular array is designed in such a way that there exist a set of working cells that maintains a desired processing capability despite many defective cells and defective interconnections.

To maintain processing capability despite many defective cells and interconnections, cells in the massively fault-tolerant cellular array need to have some mechanism to identify the defective cells and interconnections, and configure themselves around the defective cells. By employing built-in self-testing techniques, we should be able to devise a testing mechanism by introducing additional testing hardware. In this work, we assumed that by some mechanism, each cell knows if its neighbor and the connection to the neighbor is working or defective.

After the defective cells are identified, we form a big cluster of interconnected working cells from a subset of all working cells in the array. The cells without an adequate number of working neighbors are pruned out from the cluster. We then configure the cells in the cluster into a graph that specifies the function of the array.

In the following sections, we describe the architecture of the massively fault-tolerant cellular array, and the algorithms for the formation of the cluster, the pruning of the cluster, and the configuration of the cells into a linear array, a two-dimensional mesh, and a complete binary tree. Simulation of the massively fault-tolerant array and simulation results of the formation of the cluster, pruning, and configuration of cells into a linear array, a two-dimension mesh, and a complete binary tree are shown on arrays of size 40 by 40, 80 by 80, and 120 by 120.

## Massively Fault-tolerant Cellular Array

The three regular interconnection patterns studied in this paper are shown in Figure 1. They are selected to study the effect of the number of the neighbors on the behaviour of the cellular array. The three arrays with the three interconnection patterns of Figure 1 are called *square array, hexagonal array,* and *octal array* respectively. Figure 2 shows a square array with defective cells and defective interconnections. Note that although the initial array is regular, the ensuing array is not (see Figure 2), as the faults cause breakdown in the regularity of the array.

Though there are many defects, there are still many working cells in the array so that useful computation can be per-

formed. The computations that the array is intended to perform will determine how the working cells are configured. The logical interconnection of cells for any particular computation can be represented by a graph, called the *computation graph* in this paper. The configuration of cells into a computation graph is the process of embedding the computation graph in the defective array. The embedding of the computation graph in the defective array is represented by a graph, called the *connection graph*. For example, the tree in Figure 3(a) is a computation graph; Figure 3(b) shows an embedding of the tree on the defective square array; Figure 3(c) is the connection graph of the embedding of Figure 3(b).

In Figure 3(b), some cells are mapped to the nodes of the computation graph, while other cells are used to connect the cells that are mapped into the nodes of the graph. The cells mapped into the nodes of the graph are called the *computation cells,* and the cells used to connect the computation cells are called the *connection cells.* The connection cells are represented by dots on the connection graph.

A cell in the massively fault-tolerant cellular array is configured into a computation graph by identifying the logical connections of the cell. For example, a cell is configured into a binary tree by saving in special registers the directions of the neighbors as a father, a left child, and a right child of the cell. The configuration can be changed by changing the contents of the registers. The configuration is performed in a distributed fashion: each cell makes a decision only with the information that is available at the cell.

## Architecture of a Cell

Each cell has a processor, local memory, Communication Registers, an ID Register, Neighbor Status Registers, a Status Register, a Pattern Register, and Connection Registers. Figure 4 shows the architecture of a cell in the square array. The registers are explained below:

**ID Register:** Stores the row and column indices of the cell in the array.

**Neighbor Status Register, NS[0..N-1]:** Stores the status of the neighbors. The neighbor can be defective, working, or pruned out. Here N is the number of immediate neighbors.

**Status Register, SR:** Stores the current status of the cell. The states of a cell are "idle", "live", "pruned", "comp", "conn", and "mem". The status of all working cells are initially "idle". The clustering procedure changes the status of the cells belonging to a big interconnected cluster to "live", and the pruning procedure changes the status of the working cells without an adequate number of cells to "prune", so that they are not used in the configuration procedure. The configuration procedure changes the status of the "live" cells to "comp" or "conn", depending upon whether the cell is used as a computation cell or a connection cell. Finally, the status of a cell is "mem" when the cell is used as a memory.

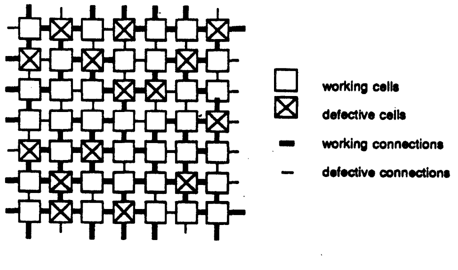

**Figure 2.** A defective square cellular array

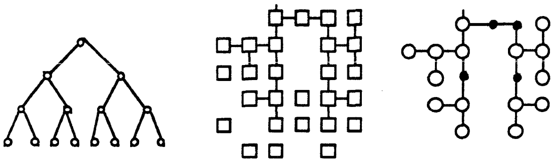

(a) computation graph (b) embedding of a tree on a defective array (c) connection graph

**Figure 3.** A computation graph, its embedding and a connection graph

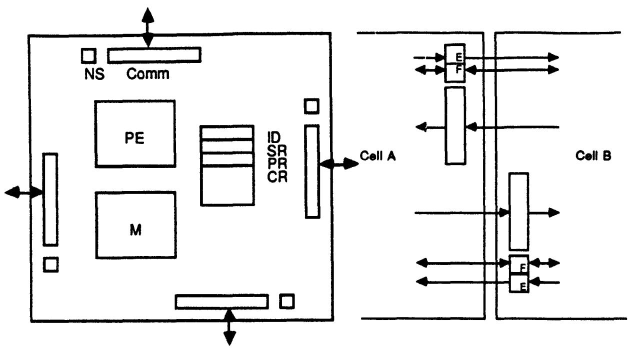

**Figure 4.** Architecture of a cell and communication register of the cellular array

**Pattern Register, PR:** Stores the current configuration pattern. The configuration patterns that are recognized are linear array, two-dimensional mesh, complete binary tree, and spanning tree.

**Connection Register, CR[0..N-1]:** Stores the directions of neighbors in the logical configuration specified by the Pattern Register, PR. The meanings of the CR[0..N-1] are different for each configuration. When PR specifies that the configuration is a linear array, CR[0] is the direction of the predecessor, and CR[1] is the direction of the successor. When PR specifies a binary tree, CR[0..2] are the directions of the father, the left child, the right child, and CR[3] is the level of the cell. When PR specifies a two-dimensional mesh, CR[0..3] are the directions of the up, right, down, left neighbors of the cell, and CR[4..5] are the row and column indices of the cell in the two-dimensional mesh. When PR specifies a graph, CR[0..3] are the directions of the two sources and two destinations. Finally when PR specifies a spanning tree, CR[0] is the direction of the father, and CR[1..N-1] are the directions of the sons.

**Communication Registers, Comm[0..N-1]:** These are used for communication between the cells. Cells communicate with other cells by sending and receiving messages through Communication Registers. Each Communication Register provides a one-way communication between two cells. Between a boundary of two cells, two Communication Registers provide two-way communication. Figure 4 shows a pair of Communication Registers. The arrows on the Figure 4 shows the directions of the information. The fields of the Communication Register are as follows.

| | |
|---|---|
| **Full Bit, FB:** | Shows if the Communication Register is full or empty. |
| **Enable Bit, EB:** | Shows if the other cell is willing to receive the message. If EB is 0, the other cell may not read the Communication Register. EB is used to prevent deadlock. |
| **Messages, Mesg:** | Contains the messages. |

The FB is used to synchronize the communication between two cells. A cell can read a Communication Register when the Communication Register is full, and after the cell reads the Communication Register, FB is reset to 0. If a cell wants to read a message from an empty Communication Register, the cell waits until FB is set again. A cell can write to an empty Communication Register, and if a cell initiates write to a full Communication Register, the cell has to wait until EB is set. This provides the synchronization between two cells.

**Processor:** The processor is an instruction set processor with small instruction set. The instructions includes usual arithmetic, logical, data transfer, program control operations, and send and receive for input and output. "Send (dir, message)" writes the "message" on the Communication Register in "dir" direction: return from "Send" acknowledges that the message is written to the Communication Register. "Recv (dir)" reads a message either from the Communication Register in "dir" direction, or from any full Communication Register if "dir" is "any": return from "Recv" acknowledges that a message is available at the Communication Register in "dir" direction.

**Controller:** In the massively fault-tolerant cellular array, an external machine is attached to the boundary cells to control the operation of the array. The external machine initiates the operations of the array, and provides the data to the array by sending messages to the array. The external machine will be called a *Controller*.

When the massively fault-tolerant cellular array is powered on, Neighbor Status Registers, NS[0..N-1], of each cell are set to indicate the status of the neighbors of each cell (working or defective) by some testing mechanism. The hardware and algorithms for the testing have not been devised yet. We assumed that the testing can be done by some mechanism.

After the testing is finished, the controller initiates the clustering procedure which identifies the largest cluster of interconnected working cells in the array. After all the cells in the cluster are given identification numbers, the controller initiates the pruning procedure which prunes out the cells in the cluster without an adequate number of working neighbors. The controller then initiates the configuration procedure to configure the cells in the cluster into a desired computation graph. When the Controller sends a message to a cell at the boundary of the array, the cell relays the message to its neighbor cell, and the message will propagate through the working cells. The cells will be configured into a graph specified by the operation field of the message. The configuration of the cells is finished when all the cells set their Configuration Registers correctly, and the boundary cell connected to the controller returns an appropriate message to the controller.

## Formation of the Cluster of Cells

Since the cells in the cellular array connect only to the immediate neighbors, when a cell wants to communicate with another cell which is not directly connected to it, the message should be relayed by intervening working cells to the target cell. Therefore, a small cluster of working cells surrounded by defective cells cannot be used. The array can be useful only when a large cluster of of interconnected working cells is formed in the array.

We can use *percolation theory* [16,3] to predict if a large cluster appears on the array, and if the cluster appears, to predict the size of the cluster. According to the percolation theory there exist a *critical probability* such that when the probability that a cell is working is more than the critical probability, there appears an infinite cluster of interconnected working cells in the defective infinite array of cells.

## Percolation Theory and the Cellular Array

Consider a lattice $L$ defined as a graph of $N$ sites (or vertices) and $M$ bonds (or lines). In most cases of practical interest, $L$ will be a regular two or three dimensional lattice of finite or infinite extent. In the *bond problem*, each bond of $L$ is *occupied* (or *open*, or *working*, etc.) with probability $p$ or *vacant* ( or *blocked*, or *defective*, etc.) with probability $1-p$. Occupied bonds are *connected* if they meet at a common site, and a connected set of $s$ bonds form a *bond cluster* of size $s$. In the *site problem*, each site is occupied with probability $p$ and vacant with probability $1-p$. Occupied sites are connected to form *site clusters* if they are adjacent through the bonds of $L$.

For an infinite lattice $L$ there is a critical probability $p_c = p_c(b, L)$ or $p_c(s, L)$ for the bond or site problems such that for $p < p_c$ all clusters will be finite while for $p > p_c$ there will, with positive probability, be an infinite cluster in $L$. The infinite cluster is called a *percolation cluster*. We can define the *percolation probability*, $P(p)$, as the probability that a site, chosen at random, belongs to an infinite cluster. One defines the *critical probability*, $p_c$, as

$$p_c = \sup\{p|P(p) = 0\}.$$

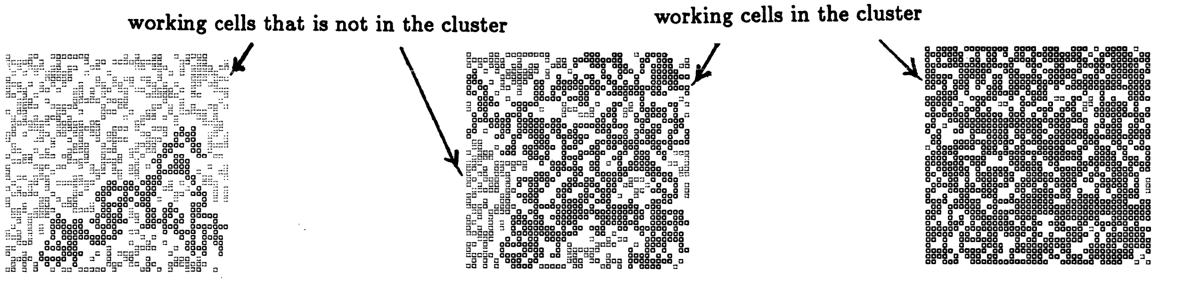
The sites in the percolation model corresponds to the cells of the massively fault-tolerant cellular array, and the bonds in the percolation model corresponds to the connections between cells. In the site percolation problem, all the bonds are assumed to be occupied and only the sites can be vacant; this corresponds to the assumption that all connections are working and only cells can be defective. In the bond percolation problem, all the sites are assumed to be occupied and only the bonds can be vacant; this corresponds to the assumption that all cells are working and only connections can be defective.

Since the area of a cell is much bigger than the area of a connection in the cellular array, and the defect probability of an integrated circuit is at least proportional to the area of the integrated circuit, the defect probability of a cell is much greater than that of a connection. Therefore, as a first approximation, the array can be modeled by the site percolation model. On the site percolation model of the defective array, we can take into account that connections can be defective by associating connections with neighboring cells. When a connection is defective, the cells associated with the defective connection are considered defective. When we need to use the working cells connected to the defective connections, the defective array should be modeled by the combination of site and bond percolation problem [8].

In percolation theory the *percolation cluster* is an infinite cluster that appears on the infinite lattice. On the cellular array of finite size, we define the *percolation cluster* as the largest cluster that is connected to all four borders of the array when the array is rectangular. Using the percolation theory, we can predict that the percolation cluster will appear in the defective cellular array when the probability that a cell is working, $p$, is more than the critical probability, $p_c$ of percolation theory.

Figure 5 shows the formation of the clusters in a square array, where the critical probability is 0.59. Here cells in solid boxes belong to the largest cluster. When $p$ is 0.5, the percolation cluster does not appear (Figure 5(a)); when $p$ is 0.61, a thin percolation cluster appears (Figure 5(b)); when $p$ is 0.75, a thick percolation cluster appears (Figure 5(c)).

However, as we can see in Figure 5(b), even though the percolation cluster appears in the array, when $p$ is not high enough, the percolation cluster is "thin", contains many branches, and does not include many boundary cells. The cells on the thin



working cells that is not in the cluster
working cells in the cluster

(a) p = 0.5; a percolation cluster does not appear.

(b) p = 0.61; a thin percolation cluster appears.

(c) p = 0.75; a thick percolation cluster appears.

**Figure 5.** The formation of clusters on the square array

percolation cluster may not be used effectively because communication between two cells in the thin cluster is difficult, and configuration of cells into a computation graph is not efficient. Furthermore, input and output on the thin percolation cluster is difficult due to the lack of the boundary cells. Therefore the thin percolation cluster in Figure 5(b) may not be useful. When $p$ is high enough, the percolation cluster that appears in the array is "thick", and has many boundary cells. The cells in the thick cluster may be used effectively for configuration and computation. The cluster in this case is shown in Figure 5(c).

The usefulness of the percolation cluster depends on the computation graph that will be embedded on the percolation cluster. For example, a percolation cluster may be considered adequate enough to embed a linear array but the same percolation cluster may not be adequate to embed a two-dimensional array.

## Formation of the Cluster

When $p$ is more than $p_c$, we can form a percolation cluster of working cells in the defective array. The cluster is formed by connecting the working cells into a spanning tree which spans all the working cells connected to a certain boundary cell. The controller sends a message to a working cell at the boundary, where the message specifies that a spanning tree of working cells be formed. The cell that received the message from the controller becomes the root of the spanning tree.

After a spanning tree is formed with the cell that received a message from the controller as the root of the spanning tree, the cell returns the number of cells connected into a spanning tree to the controller. If the number is large enough, the cells in the spanning tree are taken as the percolation cluster. If the number is not large enough, another message is sent to some other working cell on the boundary, and a new spanning tree is formed with the new cell as the root of the spanning tree. This process continues until a percolation cluster is found, or the controller gives up finding a percolation cluster in the defective array.

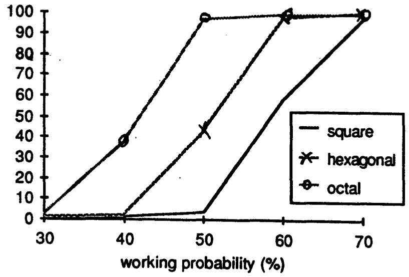


**Figure 6.** Percentage of working cells that are in the largest cluster

When a cell receives a message from a neighbor, the cell changes its state by setting the Status Register, SR to "live", and it saves the direction of the neighbor on CR[0] as the father of the cell. The cell then sends the message to its working neighbors. If a neighbor returns the message that the neighbor is a part of the spanning tree, the direction of the neighbor is saved on CR[1..N-1] as a son. The spanning tree grows in depth first order. The enabling and disabling of communication registers is necessary to prevent deadlock.

Figure 6 show the percentage of working cells that are in the largest cluster in the 120 by 120 square, hexagonal, and octal array, respectively. The experimental results are generally in agreement with percolation theory. From Figure 6 we can see that more than 90% of working cells belong to the percolation cluster when $p$ is more than 0.7 on the square array, when $p$ is more than 0.6 on the hexagonal array, and when $p$ is more than 0.5 on the octal array.

## Assignment of Id

After the working cells are connected into a spanning tree, the cells on the spanning tree are assigned identification numbers. The identification number of a cell is the row and column indices of the cell in the array. The identification number is saved in the ID register.

The controller sends a message to the root cell of the spanning tree, where the first field of the message specifies the operation, and next fields are the row and column indices of the root cell. When a cell receives the message, the cell saves the row and column indices on the Id register, and computes the Id of the son. Then the cell sends the message with the computed Id to the son. When the cell receives the message from the son, it iterates the same operations on the next son.

## Pruning

After a percolation cluster of working cells is formed in the defective array, the cells in the percolation cluster can be configured into a computation graph. However, some cells in the percolation cluster form a single-width dead-end branch, and they may not be configured effectively. Furthermore, they may slow down communications between cells. To facilitate the configuration of working cells and the communication between cells, we may prune out the dead-end branch of cells from the percolation cluster. Figure 7 shows an example of such a pruning.

Pruning of the dead-end branches from the cluster can be generalized to ***pruning-to-k***. The Pruning-to-k operation prunes out the cells which are connected to less than or equal to k working neighbors. Here $k$ is called the ***level*** of the pruning. Pruning of the dead-end branch corresponds to pruning-to-1:

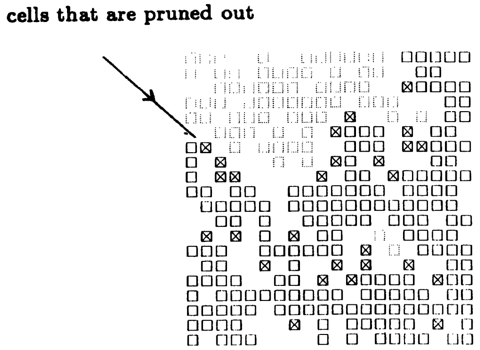

**Figure 7.** Pruning of dead-end branches from a cluster

the cells connected to only one working neighbor are pruned out from the cluster. Pruning is applied repetitively until no more cells are pruned.

By pruning the cells from the cluster, we can have a cluster of tightly connected cells. After the pruning-to-k operation, all the cells in the cluster are connected to at least k+1 working neighbors. This can facilitate the configuration of cells into a graph and the communication among the cells in the cluster.

The Controller initiates the pruning operation by sending a message to a cell in the percolation cluster. The message consists of a field specifying the pruning operation and the level of the pruning, $k$. When a cell receives the message from a neighbor, the cell counts the number of working neighbors, and compares the number of working neighbors with the pruning level $k$ specified on the message. If the number of the neighbor is not greater than the pruning level, the cell prunes itself from the cluster by changing its Status Register, SR, to "pruned" from 'live'. Then the cell sends messages to its working neighbors that it has been pruned out. The neighbors set their Neighbor Status Register accordingly. The cell which received the message from the Controller returns the message containing the number of pruned cells to the Controller. The controller sends the pruning message again until no more cells are pruned out from the cluster.

Figure 8 shows the pruning of cells from the percolation cluster on the square, hexagonal, and octal array of size 40 by 40, 80 by 80, and 120 by 120. The pruning level $k$ was restricted to less than half the number of neighbors. When the pruning level is more than half the number of neighbors on the network, most of the cells are pruned out leaving only a small isolated cluster of cells.

From the experiments, we can see that when the working probability is high enough, most of the cells in the percolation cluster are connected to several working neighbors. When the working probability is 80%, on the square array, more than 95% of the cells have two or more working neighbors, on the hexagonal array, more than 95% of the cells in the cluster have three or more working neighbors, and on the octal array, more than 95% of the cells in the cluster have four or more working neighbors.

## Configuration of Cells

The cells have to be configured into a general computation graph which specifies the function of the array. Before the configuration of the cells into a general computation graph, we studied the configurations into three particular graphs: linear array, complete binary tree, and two-dimensional array (mesh). Many computations can be done efficiently on these graphs.

The configuration of cells into a computation graph is the process of embedding the computation graph on the defective array. Since the cells that does not belong to the percolation cluster cannot be used, computation graph is embedded on the percolation cluster. Note that when the percolation cluster appears on the defective array, most of the working cells belong to the percolation cluster.

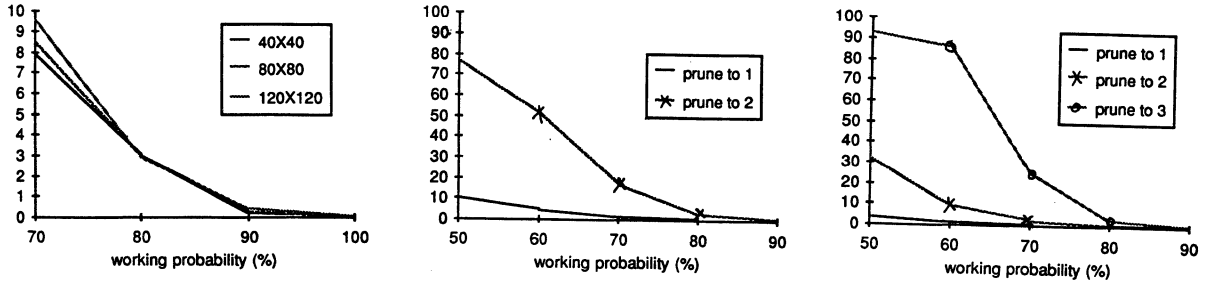
The efficiency of the configuration into a graph $G$, $e_G$, is defined as

$$e_G = \frac{\text{number of cells used as computation cells}}{\text{number of working cells in the cluster}} \times 100$$

The delay $d_G(C_1, C_2)$ between the two cells, $C_1$ and $C_2$, in a configuration into a graph $G$ is defined as one plus the number of connection cells between the two cells $C_1$, and $C_2$. Therefore, the delay between two directly connected cells is 1, and the delay is 2 when there is one connection cell between two cells. The *maximum delay* of the configuration is the maximum delay among all two adjacent computation cells, and the *average delay* of the configuration is the average of all delays among two adjacent computation cells.

We define the *degree* of a graph $G$, $d_G$, as the average degree of the vertices of the graph. To configure the cells in the defective array into a computation graph of degree $d_G$ efficiently, the number of neighbors on the array, or the degree of the array, $d_A$, needs to be greater than $d_G$. When $d_A$ is less than $d_G$, the efficiency of the configuration becomes low. We can expect that cells can be configured into a linear array ($d_G$ = 2), and a tree ($d_G$ = 3) efficiently on the square array ($d_A$ = 4), the hexagonal array ($d_A$ = 6), and octal array ($d_A$ = 8). But the configuration of cells into a mesh ($d_G$ = 4) on the defective square array may not be as efficient as the configuration on the hexagonal array or on the octal array.

On the following sections overview of configuration procedures into a linear array, a tree, and a mesh are described. The detailed algorithms can be found in [10].



(a) square array

(b) hexagonal array

(c) octal array

**Figure 8.** Percentage of cells in the largest cluster that are pruned out

## Linear Array

In the linear array, every cell has two neighbors: the predecessor, and the successor. The configuration of cells into a linear array is the process of identifying predecessors and successors and saving the directions of the predecessors and successors in the Connection Registers, CR[0], and CR[1].

The configuration procedure consists of three parts: Linear, Extend, and Join. Procedure Linear grows the linear array into the defective array of cells. When the linear array is grown in the defective array by the Procedure Linear, Procedure Extend finds the cells which are not in the linear array, but which can be connected into the linear array. Then Procedure Join connect the cells identified by Procedure Extend into the linear array. By combining the three procedures, Linear, Extend, and Join, most of the cells in the cluster are connected into the linear array.

The controller initiates the configuration by sending a messages to a cell at the boundary of the array. The message consists of the fields specifying the operation, the number of cells to be connected into the linear array, the direction of the successor neighbor. When a cell $B$ receives a message from a neighboring cell $A$, the cell $B$ sets the Pattern Register PR to "linear array", saves the direction of the cell $A$ on CR[0] as a predecessor. Then the cell $B$ tries to grow the array by adding a neighbor as its successor. First, if the neighbor $C$ specified as the successor on the message is working, the message is sent to $C$. If $C$ is connected to the linear array, the linear array grows from $C$ again. The cell $C$ returns the message to $B$ with the number of cells on the linear array after $C$. Then cell $B$ saves the direction of the cell $C$ on CR[1] as a successor, and increases the number of cells by one, and returns the message to the predecessor, $A$. If $C$ fails to be connected into the linear array, then the neighbor on the direction of the growth of the linear array as specified on the message is tried. If this fails too, then any working neighbor is tried. If all fail, the linear array retracts to the cell $B$, and growth of linear array is tried at cell $B$ again. Since the cells do not know the global state of the network, the linear array can be grown into the dead-end, and the cells may have to backtrack often.

When Procedure Linear is finished, the cell at the boundary which received the message from the Controller returns the number of cells connected into the linear array to the controller. If the number of cells is less than the number the Controller wants, the controller sends a new message to the cell. The new message consists of the fields specifying Procedure Extend, and the number of cells to be joined to the linear array. The cells which were not part of the linear array but adjacent to the linear array are identified and joined into the linear array.

With the three configuration procedures, Linear, Extend, and Join, most of the cells are configured into a linear array when the working probability of a cell is adequate. Figure 9 shows the cells connected into a linear array on the square array. Figure 10 shows the efficiency of the configuration of linear array on the square array, on the hexagonal array, and on the octal array of size 120 by 120.

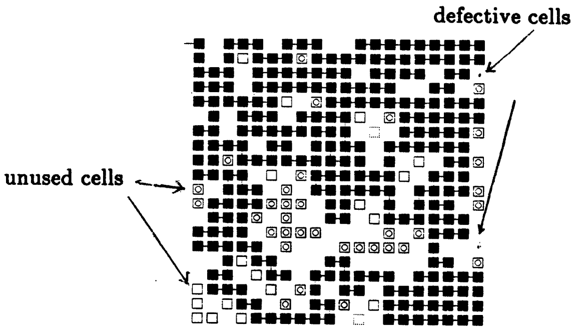


Figure 9. Configuration of cells into a linear array in the defective square array, p = 0.8

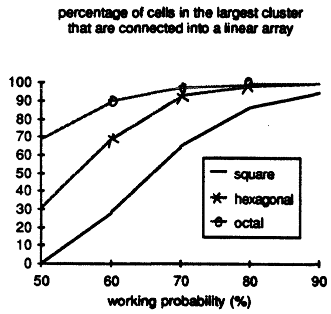

Figure 10. Efficiency of linear array configuration

From the Figure 10, we can see that most working cells are connected into a linear array. Since degree of the linear array is two, the configuration of cells into a linear array should be efficient on all arrays even when working probability of a cell is not high. As the coordination number of the array increases, efficiency of the configuration increases rapidly. On the square array, when the working probability is 80%, more than 85% of the working cells are connected into the linear array. On the octal array, with the working probability 60%, about 90% of the working cells are connected into the linear array.

Since all computation cells are connected directly to the other computation cells without intervening connection cells, no delay has been introduced, and the average delay is 1.

## Tree

In the complete binary tree, every cells have three neighbors: a father, a left child, and a right child. The working cells of the defective array are configured into a complete binary tree by setting their Connection Registers CR[0..2] to the directions of a father, a left child and a right child of each cell respectively, and saving the level of the cell in the tree on CR[3]. (The level of the leaf node is defined as one, and the level of a father is one more than that of its child.) Some working cells are used as the nodes of the tree, which are *computation cells,* and some are used as *connection cells,* which are used to connect computation cells.

Since the topology of the binary tree and that of the array of cells does not match, we need to use many working cells as connection cells even when there is no defects in the network. Koren [9] studied embedding of a tree in a defective square array, but his procedure allows few defects, and its efficiency is very low when there are many defects. The algorithm sets all working cells in the row and the column of the defective cell as connection cells, thereby making a reduced array without defect of one less row and one less column for each defects. Note that when there are many defects, none of the rows and columns will be without defective cells.

The algorithm we devised allows efficient configuration even when many cells are defective. The algorithm has two parts: Tree, and Retract. Procedure Tree connects the cell into a tree, and Procedure Retract retracts the subtree when it can not increase the level of a subtree

The Controller initiates the configuration into a tree by sending a message to a cell at the boundary of the array. The message consists of a field specifying the operation, and the level of the tree desired. If the cells are successfully configured

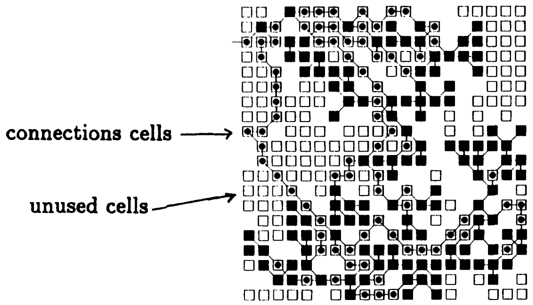

**Figure 11.** Configuration of cells into a tree in the defective octal array, p = 0.7

into a tree of the level specified on the message, the cell returns the level of the tree. The Controller then increases the level of the tree by one, and sends the message again to the cell until the desired level is achieved.

When a cell receives the message from the father cell, the cell tries to increase the level of the left subtree by one. If it is successful, the cell tries to increase the level of the right subtree by one. If it is successful, the level of the tree has been increased by one, and the cell returns the message to its father. But if it fails, the cell is changed into a connection cell, the right subtree is retracted, and the tree expansion is tried at the left subtree again. If the level of the left subtree cannot be increased, the left subtree is retracted, and the cell is changed to the connection cell, and the tree expansion is tried at the right subtree again. The tree is expanded in breadth-first order. Figure 11 shows the trees embedded in an octal array.

Since the average degree of the tree graph is three, configuration of cells into the tree in the square, hexagonal, and octal array could be efficient even when working probability of a cell is not high. Table 1 shows the maximum level of the tree into which cells are configured. Note that to increase the level of a tree by one, the number of computation cells in the tree should be multiplied by two. Table 2 shows the efficiency of the configuration, and Table 3 shows the average delay of the configuration. As the number of neighbors in the array increases, and as the working probability increases, efficiency of the configuration increases, and average delay decreases.

We compared the efficiency of our configuration algorithm with the embedding of H-tree in a defectless square lattice. H-tree is a complete binary tree embedded in a recursive pattern that looks like the letter 'H' [2]. H-tree is known to be the most efficient way of embedding a complete binary tree in a square lattice. The maximum level of H-tree that can embedded in a defectless square lattice is 9 in a 40 by 40 lattice, and 11 in a 80 by 80 lattice, and the efficiency of embedding the largest H-tree on lattice of size 40 by 40, or 80 by 80 is 32%, and the delay on the H-tree is about 3.4 [10]. Comparing these numbers with Table 2 and Table 3, we see that we can configure cells into a defective array without much penalty even when there are many defective cells in the array.

## Mesh

On the mesh of cells, every cells have four neighbors: left, right, up, down. The working cell on the defective array are configured into a mesh by setting its Connection Registers CR[0..3] to the directions of the neighbors connected as up, right, down, and left neighbor of the cell.

Manning [12] describes the algorithm for embedding a mesh on the defective square array, and Green [5] describes embedding a mesh using the channel between the cells. Both uses the knowledge of the global state of the defective array. Here a distributed algorithm where each cell knows only the state of the neighbors (working or defective) is described.

| size | 40X40 | | | 80X80 | | |
|---|---|---|---|---|---|---|

**Table 3.** Delays on the embedded trees

The Controller sends a message to the cell at a boundary of the massively fault-tolerant cellular array, where the message tells the cell to grow a horizontal line of the mesh. If it is successful, the Controller sends a message to the cell at the other boundary to grow a vertical line of the mesh. Growth of horizontal and vertical line alternates until no more line of the mesh can be grown on the array. The cells at the junction of a horizontal line and a vertical line becomes the nodes of the mesh. The cells at the nodes of the mesh are computation cells, and the cells connecting the nodes are connection cells. The computation cells are given the coordinates of the mesh.

Since the complexity of the mesh is four, and the degree of the defective square array is less than four, efficiency of the configuration may be low on square array. When a growing horizontal line comes across a defective cell, the line should veer around the cell, and this uses the cells which can be used for a vertical line. Veering around the defective cell on the square array while growing a horizontal line blocks the growth of a vertical line, and vice versa. Therefore, bending the line should be done sparingly. On the hexagonal and octal array, the growing horizontal line can use the connection without occupying the cell in the other direction. This increases the efficiency of configuring the cells into a mesh on hexagonal and octal array.

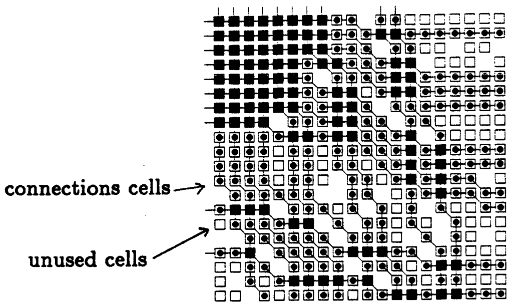

**Figure 12.** Configuration of cells into a mesh in the defective hexagonal array, p = 0.9

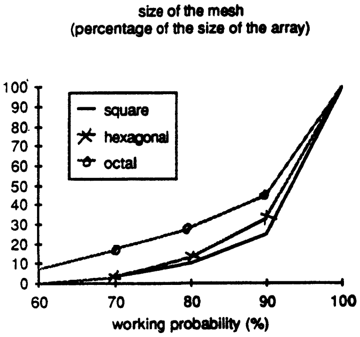

**Figure 13.** Efficiency of mesh configuration

| size | 40X40 | | | 80X80 | | | 120X120 | | |
|---|---|---|---|---|---|---|---|---|---|
| working probability | degree | | | degree | | | degree | | |
| | 4 | 6 | 8 | 4 | 6 | 8 | 4 | 6 | 8 |
| 70% | | 16 | 5.0 | | 40 | 5.3 | | 35 | 5.2 |
| 80% | 9.5 | 5.2 | 3.2 | 13 | 7.0 | 3.3 | 12 | 7.7 | 3.5 |
| 90% | 4.2 | 2.65 | 2.1 | 5.0 | 2.9 | 2.1 | 4.8 | 3.0 | 2.2 |
| 95% | 2.5 | 1.7 | 1.6 | 3.2 | 2.0 | 1.7 | 3.1 | 2.1 | 1.7 |
| 100% | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 |

**Table 4.** Delays on the embedded meshes

When the cell receive the messages, it tries to grow in the direction of the line. When the neighbor on the direction of the line is defective, it tries to grow on the direction specified on the message. If the cell cannot grow the line, it backtrack to its predecessor cell. Figure 12 shows the cells configured into a mesh.

Figure 13 shows the size of the mesh as the percentage of the array size, and Table 4 shows the delay of the configuration. As shown in the Figure 13 and Table 4, the efficiency of the configuration increases rapidly and the delay decreases rapidly with the increase of the number of the neighbors.

## Conclusion

As shown in this paper, self-configuration of cells into various computation graphs can be done efficiently when cells are adequately powerful. When we use the massively fault-tolerant cellular array for a particular application, we need to configure cells into a particular computation graph, and we can determine the defect rate of cells which allows acceptable efficiency of configuration from the data in this paper. We can change this acceptable defect rate by changing the interconnection patterns or the size of a cell to find the feasible implementation on available technology. Currently we are designing a wafer-scale signal processing chip using the massively fault-tolerant cellular array. The architecture is very homogeneous and simple, and shows the potential for high performance.

## Abstract

Several approaches to the design of fault-tolerant arrays of processors with a view towards wafer-scale integration, have been proposed in the past. Using these approaches it is possible to design linear arrays that have several desirable features of an effective fault-tolerant design, that is, they facilitate testability, are easily reconfigurable, have short inter-PE wire lengths and make one hundred percent utilization of non-faulty processors. In contrast, no single scheme or combination of previously proposed schemes result in effective fault-tolerant implementation of 2-D arrays.

In [19] we presented a computing structure that has all the attractive implementation features of a linear array and can multiply matrices with a better time performance than a linear array. In this paper we examine the inter-relationship among the number of processors, the storage within a processor, internal bandwidth and the time complexity of matrix multiplication on such a model and establish lower bounds on the time complexity and the number of processors required as a function of the storage within a processor and the internal bandwidth. We then present a generalized algorithm which matches these bounds for arbitrary storage within a processor and arbitrary bandwidth.

An interesting side effect of our result is that the area and time complexities and the asymptotic complexity of the number of proceesors used by the algorithm in [19] and all previously known linear-array algorithms can be obtained as special cases of our generalized algorithm. Additionally, the techniques and the results of this paper can be readily adapted to obtain such a family of optimal algorithms for several other 2-D systolic algorithms.

## 1. Introduction

The ever growing demand for high performance computing, coupled with advances in integrated circuit fabrication technology has led to considerable interest in the design of VLSI architectures that realize high-performance parallel algorithms directly in silicon at modest costs. One such direction pioneered by Kung and Leiserson [12] is the concept of *systolic arrays* as a VLSI computing structure to implement high-performance parallel algorithms.

A systolic array consists of a collection of processing elements (PE's), interconnected in regular nearest-neighbor geometrical structures like a one-dimensional (1-D) linear array, or two-dimensional (2-D) rectangular or hexagonal array. A data item that has been retrieved from the memory by a systolic array, passes through several PE's before returning to the memory. This feature of using a datum from memory many times over without having to store and retrieve intermediate results gives rise to high computational throughput. Simplicity and regularity of systolic arrays make them suitable for VLSI implementation at minimal design costs. Systolic arrays find natural applications in signal and image processing where large matrix computations need to be performed rapidly.

Still higher performance can be had by application of wafer-scale integration (WSI) to the implementation of systolic arrays. Rather than dice a silicon wafer into chips as is usually done, the idea behind WSI is to assemble an entire system on a single wafer. Such an increased level of integration avoids the costs and performance loss associated with individual packaging of chips. However, since fabrication flaws in a wafer-sized circuit are inevitable it is necessary for these designs to be *fault-tolerant* so that wafers with defective components can still be used. The homogeneity of the PE's that make up a systolic array and their regular interconnection make systolic arrays attractive candidates for the application of WSI. Thus, several approaches to the design of fault-tolerant arrays of processors, with a view towards WSI, have been proposed in the recent past [6,9,11,13,17,21]. The designs resulting from all of these varied techniques, however, either ignore or fall short of meeting some of the desirable features of an effective fault-tolerant design - that the design facilitate testability, be easily reconfigurable, have short inter-PE wire lengths and make good utilization of non-faulty PE's. We will briefly highlight two of these approaches [11,17] as they form the basis for the research presented in this paper.

In [17] Rosenberg proposed the *Diogenes* methodology for the design of fault-tolerant VLSI arrays. The essence of this methodology is *linearization* of processor networks which are mapped onto collinear layouts of processors configured into the desired structure by appropriate switch settings on buses running parallel to the PE's. It provides scan-in/scan-out capability to enhance testability and configuration is achieved using a few control lines per processor. The PE's are scanned serially and are hooked into the network as and when they are determined to be fault free. Hence use of the Diogenes technique results in one hundred percent utilization of the good PE's. The switches can be set dynamically through the control lines which are accessible to the outside world thereby providing dynamic fault tolerance capability. Furthermore, Diogenes designs are modular, that is, chips designed in this manner can be cascaded together by connecting their corresponding buses. This feature can render feasible the use of a chip having only a few fault-free PE's, thereby increasing the effective yield.

A second approach tailored to fault-tolerant design of *systolic* arrays, attempts to alleviate the problem of clock rate degradation caused by the fact that wires connecting logically adjacent fault-free PE's may span a large physical distance. The essence of this approach involved retiming [14] of the systolic algorithm. We say that a systolic design is a retimed version of another design if the former differs from the latter by having additional delays on some of the communication links. Kung and Lam [11] and Varman [21] gainfully employed retiming to run systolic algorithms correctly without any degradation in their throughput even in the presence of faulty PE's. Specifically, for a linear-array systolic algorithm that is comprised of unidirectional data streams, retiming requires that the additional delay encountered by the data elements in each stream when bypassing a faulty PE be identical. This ensures that data elements that met at a PE in the fault-free array will indeed meet even in the presence of faulty PE's.

By combining the Diogenes approach to restructuring processor arrays with the retiming schemes described in [11,21], effective fault-tolerant implementation of linear arrays meeting all of the desiderata enumerated earlier can be achieved, that is, the resulting designs are modular and can be easily tested and configured in the presence of faults. In addition, all the working cells can be utilized and more importantly signals need travel only short wire lengths in every clock cycle.

In contrast, no single scheme or combination of previously proposed schemes for fault-tolerant implementation of 2-D arrays simultaneously achieves all the desirable characteristics of a fault-tolerant linear array implementation. For instance, the Diogenes scheme results in long wire lengths between logically adjacent PE's (even in the absence of faulty PE's) and requires significantly larger area than a two-dimensional implementation. For matrix computations like multiplication of two n×n matrices, such a design makes use of $O(n^3)$ ‡ area (rather than the optimal $O(n^2)$ of a 2-D array implementation). Furthermore, if we assume linear propagation delay for signals (not an unrealistic assumption for the large circuits being considered in a wafer-scale environment [2,3]) then matrix multiplication requires $O(n^2)$ time (rather then the optimal $O(n)$ of a 2-D array implementation). On the other hand, incorporating retiming techniques for fault-tolerant implementation of 2-D arrays requires the use of numerous programmable delay registers and extra wiring channel capacity in the wafer in order to achieve high PE utilization [11]. This makes the technique cumbersome to use.

While a linear array is easy to implement and possesses excellent fault-tolerant properties, simulating 2-D systolic algorithms (like matrix multiplication) on it results in significant degradation in time performance. For instance, multiplication of two n×n matrices requires $O(n)$ time on a 2-D systolic array [12] whereas it requires $O(n^2)$ time on a linear array [1,8,10].

A question that naturally arises is whether there exists a computing structure that has all the attractive implementation and fault-tolerant features of a linear array and can simulate 2-D systolic algorithms with a better time performance that a linear array.

In [19] we gave an encouraging answer to this question by presenting a collinear VLSI array that retains all the desirable fault-tolerant characteristics of Diogenes designs but obviates the need for signals to travel more than a fixed physical distance in any clock cycle. On such an array we established a lower bound on time of $\Omega(n\sqrt{n})$ to multiply two n×n matrices. We also presented an optimal $O(n\sqrt{n})$ time matrix multiplication algorithm that used $O(n\sqrt{n})$ processors, $O(\sqrt{n})$ storage per processor and $O(\sqrt{n})$ internal bandwidth (that is, the number of data items that may be simultaneously transferred in unit time across any vertical line passing through the array). The $O(n^2)$ area and $O(n\sqrt{n})$ time required by our algorithm is significantly lower than the $O(n^3)$ area and $O(n^2)$ time requirement of a straightforward linearization of the 2-D systolic matrix multiplication algorithm on our array.

In this paper we examine the inter-relationship among processors, storage within a processor, internal bandwidth and time complexity of matrix multiplication on our model. We establish lower bounds on the time and processor complexity for matrix multiplication as a function of the storage within a processor and the internal bandwidth. We then present a generalized algorithm that matches these bounds for arbitrary storage within a processor and arbitrary bandwidth. An interesting side effect of our result is that the time and area complexities and the asymptotic complexity of the number of processors used by the algorithm in [19] and all previously described linear systolic array matrix multiplication algorithms in [1,4,8,10,15,16] can be obtained as *special* cases of our generalized algorithm.

To illustrate the key ideas in this paper we focus only on matrix multiplication. However the techniques and results of this paper can be readily adapted to obtain such a family of optimal algorithms for other 2-D systolic algorithmms like LU decomposition, QR factorization, solution of linear systems of equations, etc.

The rest of this paper is organized as follows. In the next section we lay the theoretical framework for the research reported in this paper. In section 3 we will elaborate on our computing structure and outline the design of matrix multiplication algorithms on this model. In section 4 we present some closing remarks. The details of our algorithm, its proof of correctness and issues regarding fault tolerance and modularity appears in [20].

## 2. Theoretical Framework

One of our major objectives is to retain the excellent fault-tolerant characteristics afforded by collinear implementations of processor networks but avoid the degradation in throughput (caused by a lower clock rate) that long inter-PE wires would impose. Making the clock rate independent of the inter-PE wire length in a collinear implementation may be achieved by introducing *buffers* in the wires at fixed physical separation (say between every pair of physically adjacent PE's) so that signals are clocked in and out of these buffers at every clock cycle. Fig. 2.1(a) is a collinear implementation of a 3×3 2-D array obtained using the Diogenes methodology. Fig. 2.1(b) is the same implementation with buffers (denoted by   in the figure) on the connecting wires.

While incorporating buffers in the interconnecting wires may appear to be a relatively minor change, it drastically changes the nature of computations on the architecture. Interconnecting wires in the non-buffered case are now actually *pipelines* through which *several* data items may *simultaneously* be in transit from a source PE to a destination PE. As discussed below, algorithms on such an architecture need to be carefully designed to exploit the potential afforded by having pipelined buses.

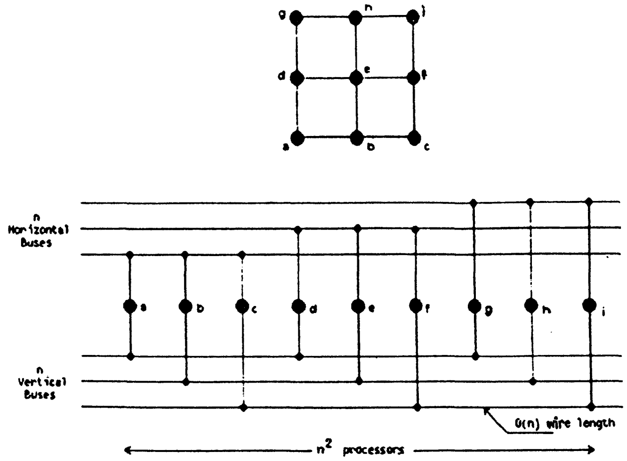

Fig. 2.1 (a): Linearization of 3×3 Mesh (without buffers)

‡ $f(n)=O(g(n))$ iff there exists constants c and $n_0$ such that $f(n) \leq c\, g(n)$ for $n \geq n_0$ and $f(n)=\Omega(g(n))$ iff $f(n) \geq c\, g(n)$ for $n \geq n_0$.

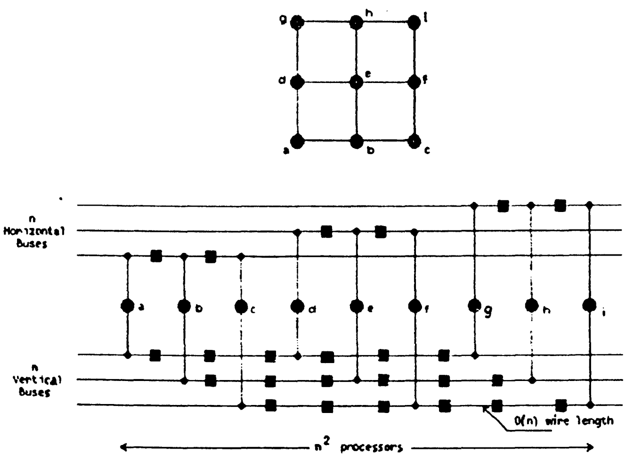

Fig. 2.1 (b): Linearization of 3×3 Mesh (with buffers)

First, consider a naive simulation of the well-known 2-D systolic algorithm for matrix multiplication [12] on our collinear pipelined implementation. It is easy to see that every communication step that transferred data elements between adjacent PE's along a column in the 2-D mesh would now require (n-1) clock cycles to move the element along the (n-1) buffers separating the corresponding PE's in the collinear implementation. Thus, the naive simulation would require $O(n^2)$ time rather than the O(n) required on a 2-D systolic array implementation. Even more interestingly, a theoretical result due to Gentleman [5] implies that as long as the PE's in the collinear implementation have only a constant (O(1)) amount of storage, then *any* matrix multiplication algorithm would require $O(n^2)$ time.

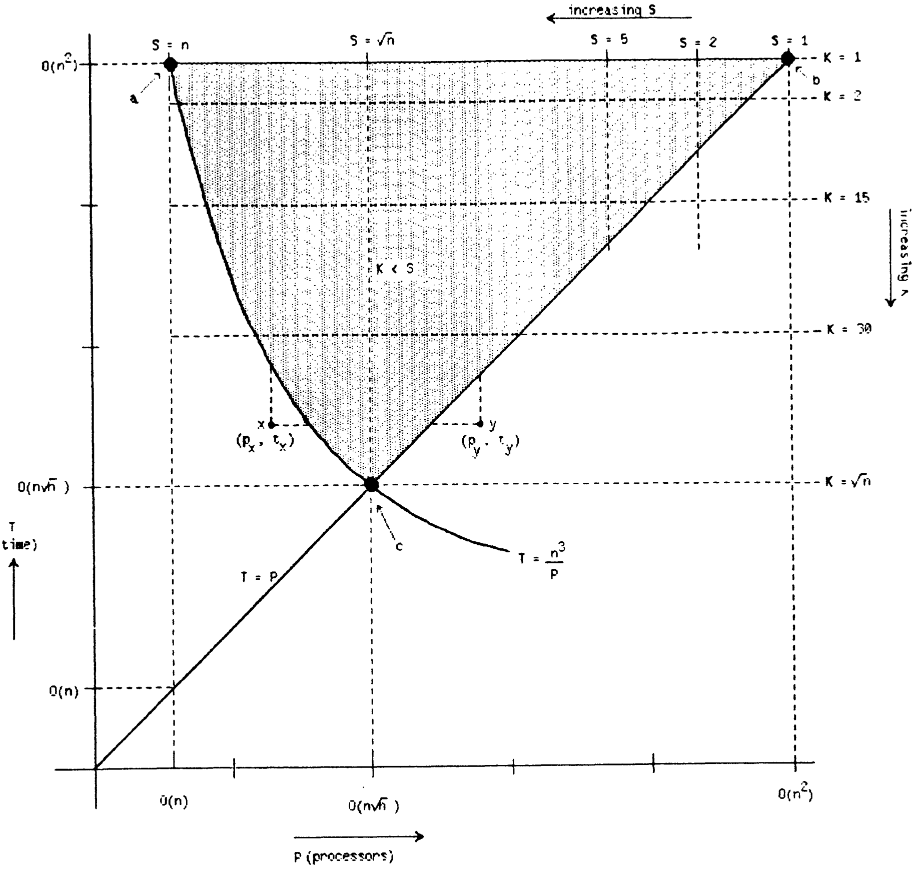
A consequence of the above result is that a minimum requirement for improving the time performance is to *increase* the *storage* within every PE. The intuitive reason for doing so is to *reduce* the *number* of PE's that take part in the computation and thereby decrease the maximum path length that any data item has to traverse during the computation. However, decreasing the number of PE's beyond a certain limit causes the computation to become *compute bound*, as we have too few PE's to perform the computation.

Thus, there exists an interesting tradeoff between the storage per PE and the execution time of the algorithm. In addition, as we shall show, the number of parallel wires in the collinear layout (the number of such wires is a measure of the number of data items that may be simultaneously transferred across any vertical line passing through the array, and will be denoted by the term *internal bandwidth*) also affects the time complexity of the algorithm in an interesting way. Thus we have a four-way tradeoff between the execution time, the storage per PE, the internal bandwidth and the number of PE's.

Our main contribution in this paper is to fully characterize the tradeoffs involved in such a collinear model. We present a generalized *family* of matrix multiplication algorithms on this model *parameterized* by the storage per PE (s) and internal bandwidth (k). All the algorithms in our family are *optimal* in that they make most efficient use of the given hardware resources and perform the computation in the minimum time possible.

The interplay between these resources (execution time, the storage per PE, the internal bandwidth and the number of PE's) can be summarized by the following graph (see Fig. 2.2).

Fig. 2.2



The curve *ac* denotes a lower bound on time of $\frac{n^3}{p}$ whereas the line *bc* denotes a lower bound of p which is the time it takes for an element to travel from one end of the collinear array to the other. Observe that the lower bound on processing time ($\frac{n^3}{p}$) matches the lower bound on the communication time (p) when p is $n\sqrt{n}$. For p either less or greater than this, one of the two times dominates. A rigorous proof of this $\Omega(n\sqrt{n})$ lower bound on time for multiplication of two $n \times n$ matrices appears in [19].

Note that to store $n^2$ elements in $n\sqrt{n}$ PE's we require $\sqrt{n}$ storage per PE. Moreover, $\sqrt{n}$ internal bandwidth suffices to accomplish transfer of the $n^2$ elements across any point in the array in $n\sqrt{n}$ time. Therefore both s and k are $\sqrt{n}$ at point *c*.

Feasible algorithms (that is, those that do not violate the time lower bound) are bounded within the region enclosed by the curve *ac* and the lines *bc* and *ab* for p in the range O(n) to O($n^2$) and T in the range O($n\sqrt{n}$) to O($n^2$) (the shaded region in the figure).

From information-flow arguments [18] it can be easily established that for any internal bandwidth k, the time required to multiply two $n \times n$ matrices must be at least $\frac{n^2}{k}$. The intuitive reason for this is that in any (approximately) equal-sized partition of the chip at least $n^2$ bits of information must flow between the two partitions and hence for any internal bandwidth k the lower bound follows. To store the $n^2$ elements we require at least $n^2$ storage (see [15,22] for a proof). Therefore, within the feasible region, the lower bounds on time and number of processors are $\Omega(\frac{n^2}{k})$ and $\Omega(\frac{n^2}{s})$ respectively.

Observe that any point x ($p_x$,$t_x$) in the region below *ac*, represents the situation where we have too few processors ($p_x$) to compute the $n^3$ scalar products in time $t_x < \frac{n^3}{p_x}$. Moving horizontally to the right (that is, keeping k fixed) would correspond to increasing the number of PE's and underutilizing the storage per PE. On the other hand, moving vertically up (that is, keeping s fixed and therefore the number of PE's fixed) we underutilize the inter-PE bandwidth (k) and also incur a penalty in time.

Observe also that any point y ($p_y$,$t_y$) in the region below line *bc*, corresponds to a situation where in time $t_y$ ($t_y < p_y$) a data item has to be distributed to $p_y$ PE's ($p_y = \frac{n^3}{s}$). Moving horizontally to the left corresponds to decreasing the maximum path length by reducing the number of PE's. This can only be achieved by increasing the storage per processor which may not always be possible for PE's embedded in a chip. We would therefore pay the time penalty of moving vertically to the top.

In this paper we will describe the design of a generalized *family* of systolic algorithms in the feasible region, parameterized by s and k that *simultaneously* meets both the time and processor lower bounds. Now the algorithms in [1,8,10] use O(n) PE's, O(n) storage per PE and require O($n^2$) time. These algorithms operate at point *a* in Fig. 2.2. When s is n our generalized algorithm will have the same processor, storage and time complexities. The modular algorithm in [15] requires O($n^2$) PE's, uses O(1) storage per PE and also requires O($n^2$) time. It operates at point *b* in Fig. 2.2. Our generalized algorithm will have identical processor, storage and time complexities when s is 1. Using a single bus (k=1) in our generalized algorithm results in the family of algorithms in [4,16] that operate along the line *ab* in Fig. 2.2. Lastly, the algorithm in [19] that operates at point *c* is obtained from our generalized algorithm when both s and k are $\sqrt{n}$.

## 3. Computing Model

Let A and B be two $n \times n$ input matrices and let C be the result matrix. Let s ($1 \le s \le n$) be the storage per PE and k ($1 \le k \le \sqrt{n}$) be the number of buses. (Observe in Fig. 2.2 that we never require more than $\sqrt{n}$ buses in the feasible region.) The cells used for multiplication are arranged on a straight line and communicate by multiple buses as shown in Fig. 3.1 below for the case n=4 and k=s=2.

The $n^2$ elements of matrix C are stored in the local memories of the PE's (s of them in each PE) and updated in-situ as elements of matrices A and B are made available to the PE's. There are four distinct types of buses which transport elements of matrix A (ABUS), elements of matrix B (BBUS), control signals (CNTRLBUS) and address signals (ADDRBUS) from the I/O port at the left end of the array to the different PE's. There are k buses of each type and each PE is hooked to *exactly one* ABUS, BBUS, CNTRLBUS and ADDRBUS. This makes our structure attractive for implementation purposes.

We can visualize all the cells in the layout as being subdivided into $k^2$ contiguous blocks where each block is a contiguous sequence of w cells ($w = (\frac{n}{k} - 1) \left\lceil \frac{n}{ks} \right\rceil + \frac{n}{k}$. See [20] for more details). Each ABUS is connected to kw (physically) consecutive PE's. The first ABUS is connected to PE's 1,2,..,w,w+1,..,2w,..,kw, the second one is connected to PE's kw+1, kw+2,..,2kw and so on. Each BBUS is connected to each of the cells in k different blocks where each block is separated by a run of (k-1)w PE's that are connected to the remaining k-1 BBUS's. Thus the first BBUS is connected to each of the PE's in the first block comprising of PE's 1,2,..,w and then to each of the PE's in the block consisting of PE's kw+1,kw+2,..,(k+1)w and so on. The second BBUS is connected to the block with PE's w+1,w+2,..,2w and then to the block with PE's (k+1)w+1,(k+1)w+2,..,(k+2)w and so on. The organizations of the CNTRLBUS and ADDRBUS are similar to the ABUS. Observe that the above interconnection transforms each of the $k^2$ blocks into a linear-array block. As an illustration, observe in Fig. 3.1 (w is 3 as n is 4 and s is 2) that $(\text{ABUS})_1$ is connected to the first six PE's whereas $(\text{ABUS})_2$ is connected to the remaining six PE's. $(\text{BBUS})_1$ is first connected to the block consisting of PE's 1, 2 and 3 then to the block with PE's 7, 8 and 9 whereas $(\text{BBUS})_2$ is connected first to the block with PE's 4, 5 and 6 followed by the block consisting of PE's 10, 11 and 12.

Finally, all the processors operate synchronously and are driven by a global clock.

Associated with each bus is a delay equal to the number of clock ticks required to move a data element traveling along the bus between consecutive PE's. The delay associated with the ABUS, CNTRLBUS is 1, as shown by the "unit-delay" buffers on these buses (  's in Fig. 3.1). whereas the delay encountered on the BBUS is 2 (  's in Fig. 3.1). Therefore, in our model no element has to traverse more than a fixed physical distance in one clock cycle and this distance is *independent* of the *size* of the array. In our model therefore, signal delay is proportional to the distance it has to propagate. Such a delay model appears appropriate for the large circuits produced by wafer-scale integration. See [3] for a justification of this delay model and [2] for a detailed discussion of the various delay models.

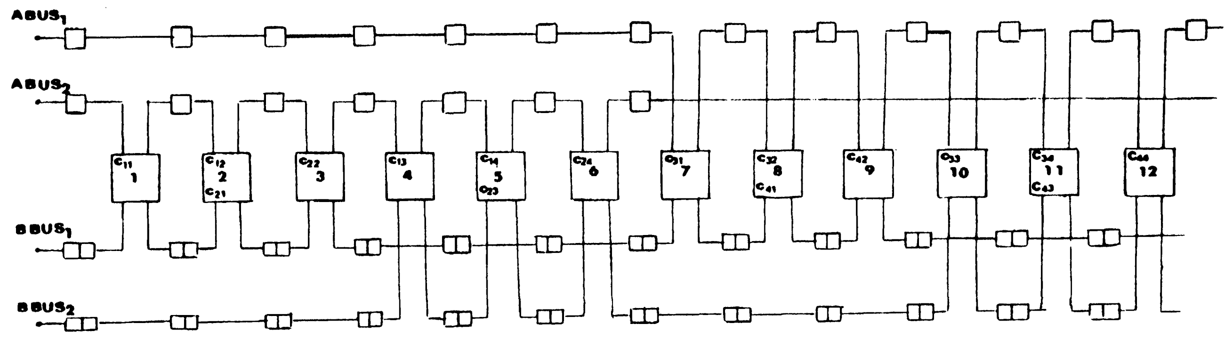


Fig. 3.1: Collinear Network of Processors (n=4)

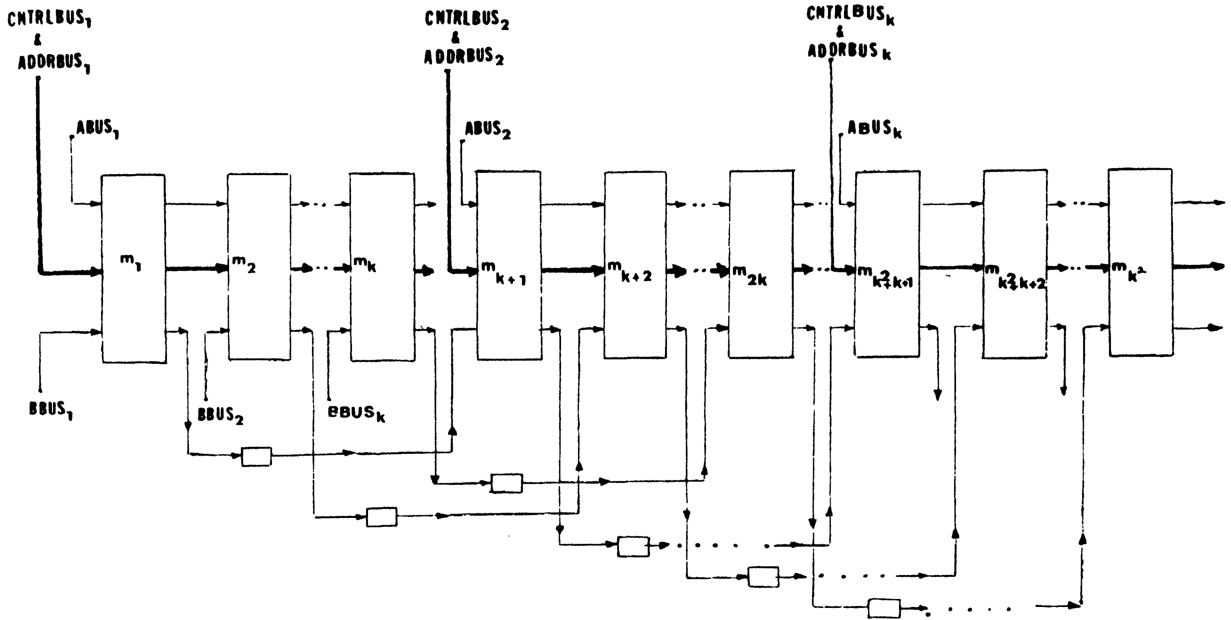

Fig. 3.2: Modular Arrangement

Fig. 3.2 is a logical arrangement of our computing structure. The linear array blocks are indexed $m_1, m_2, .., m_{k^2}$.

Note that we connect together the BBUS of blocks whose indices differ by k whereas the ABUS,CNTRLBUS and ADDRBUS of k adjacent blocks are connected. The difference in indices between the last processor in block $m_i$ and the first processor in block $m_{i+k}$ is (k-1)m+1. Recall that a data element that is travelling along the BBUS requires two ticks to move between consecutively indexed processors. Hence an element of matrix B that emerges from the last cell in $m_i$ reaches the first cell in block $m_{i+k}$ in 2((k-1)m+1) clock cycles. The on the BBUS between blocks models this delay. By distributing the delay along the BBUS (as shown in Fig. 3.1) the clock rate is made independent of the physical separation between the blocks.

## 3.1. Multiplication Algorithm

We will now outline our algorithm for multiplying two n×n matrices whose elements are pipelined through the buses in our computing structure. The elements of the result matrix C are stored in the local storage of PE's, one per word and updated in situ as elements of matrices A and B are made available to the PE's.

We first divide matrix C into $k^2$ submatrices each of size $\frac{n}{k} \times \frac{n}{k}$. Each of these submatrices are computed in a linear-array block of w cells. The first block of k submatrices are computed in the first k linear-array blocks, the second block in the next set of k linear-array blocks and so on.

If $s = \frac{n}{k}$ then we can compute the product of these submatrices using a linear array of $O(\frac{n}{k})$ PE's and $O(\frac{n}{k})$ storage per PE [1,8,10]. These algorithms store one of the input matrices (one row per PE) and pipeline the columns of the other matrix through the array. After all these columns pass through a PE, an entire row of the result matrix gets computed in that PE and there is sufficient storage within it to store the computed row. However the difficult and interesting case arises when $s < \frac{n}{k}$. This is because we have less storage within a PE to store an entire row of the input or result matrix. In contrast to the previous case (wherein a PE must use all the elements of the second input matrix passing through it in order to compute an entire row of the result matrix) a PE now will be required to use only certain of these elements in order to compute part of an entire row of the result matrix. We can handle both these cases by using the linear-array algorithm in [16] to compute the submatrices. Note that the $a_{ij}$'s and $b_{ij}$'s are required in different linear-array blocks. The final details of our algorithm involves carefully scheduling their arrival to the different blocks so that the correct product terms meet at the correct time in the appropriate PE and accomplish the entire computation in optimal $O(\frac{n^2}{k})$ time.

We estimate the time and processor complexity of our algorithm as follows (a detailed analysis appears in the appendix).

Recall that in the feasible region $\Omega(\frac{n^2}{k})$ and $\Omega(\frac{n^2}{s})$ are the lower bounds on time and processor complexity respectively.

We use $k^2w$ PE's and w is $O(\frac{n^2}{k^2 s})$ and hence the processor complexity is $O(\frac{n^2}{s})$.

For estimating the time complexity of our algorithm, first note that we need to compute $\frac{n^3}{k^3}$ scalar products of a submatrix in each linear-array block. This requires $O(\frac{n^2}{k^2})$ time which is $\leq O(\frac{n^2}{k})$. Secondly, an element from matrix B need travel a maximum path length of $O(\frac{n^2}{s})$. Now $k \leq s$ in the feasible region, and hence the time complexity is bounded by $O(\frac{n^2}{k})$.

Thus, for any s and any k, our algorithm achieves *optimal* time and *processor* bounds in the feasible region.

An interesting byproduct of our generalization is that the area and time complexities and the assymptotic complexity of the number of processors used by all known linear-array matrix multiplication algorithms [1,4,8,10,15,16] and the algorithm in [19] appear as special cases of our generalized algorithm. We show this as follows.

The algorithms in [1,8,10] use O(n) PE's, O(n) storage per PE and require $O(n^2)$ time. These algorithms operate at point *a* in Fig. 2.2. The algorithm resulting from our generalized algorithm when s is n will have the same processor, storage and time complexities. The modular algorithm in [15] requires $O(n^2)$ PE's, uses O(1) storage per PE and also requires $O(n^2)$ time. It operates at point *b* in Fig. 2.2. Our generalized algorithm will have identical assymtotic complexities for time, area and number of processors when s is 1. Using a single bus (k=1) in our generalized algorithm would result in the family of algorithms in [4,16] that operate along the line *ab* in Fig. 2.2.

Lastly, when s and k are both $\sqrt{n}$ (that is, they are *balanced* ), our generalized algorithm achieves the optimal time bound of $O(n\sqrt{n})$ using $\sqrt{n}$ buses, $\sqrt{n}$ storage per PE and $O(n\sqrt{n})$ PE's. All these complexities are identical to the algorithm in [19]. Some features of this algorithm are worth noting. Our balanced algorithm operates at point *c* in Fig. 2.2. Observe in the figure that the lower bound on communication time matches that of the processing time when n is $\sqrt{n}$ (point *c* in the figure). We compare this balanced algorithm with the naive simulation of a 2-D systolic matrix multiplication algorithm on the collinear structure in Fig. 2.1(b).

As mentioned earlier, the primary drawback with such a simulation is that n×n matrix multiplication on it requires $O(n^3)$ area, 2n buses and $O(n^2)$ time. Note that this is the case despite the *buffers* on the buses to pipeline several elements along them.

Fig. 2.1(a) is the collinear implementation obtained using the Diogenes design methodology. However, a major drawback with these designs is the long wire lengths between logically adjacent PE's (even in the absence of faulty PE's) resulting in significant degradation in throughput (due to a slower clock speed). Simulating two n×n matrices on this structure requires $O(n^3)$ area. Furthermore, if we assume that signals propagate a fixed physical distance in every cycle, then the time required for multiplication becomes $O(n^2)$.

In contrast, the time complexity of our balanced algorithm is only $O(n\sqrt{n})$. Furthermore, we require only $n\sqrt{n}$ processors (rather than the $n^2$ PE's required for simulation) and only $4\sqrt{n}$ (rather than the 2n required for simulation). The total area occupied by the $n\sqrt{n}$ processors is $O(n^2)$ (as each processor requires $\sqrt{n}$ storage). Also, each bus is $n\sqrt{n}$ long and hence the wiring area occupied by all the $\sqrt{n}$ buses is $O(n^2)$. Thus the total area required by our balanced algorithm is $O(n^2)$. In contrast, the simulated 2-D systolic algorithm requires $O(n^3)$ area. Thus our balanced algorithm succintly demonstrates that we can preserve the ease of testability and configurability that are characteristics of the linearization approach and also have better resource utilization and better time performance as well.

## 4. Conclusions

Several approaches to the design of fault-tolerant arrays of processors, with a view towards wafer-scale integration, have been proposed in the past. The designs resulting from all of these varied techniques, however, either ignore or fall short of meeting some of the desirable features of an effective fault-tolerant design, namely, that the design facilitate testability, be easily reconfigurable, have short inter-PE wire lengths and make good utilization of non-faulty PE's.

Some of these methodologies can be combined to produce effective fault-tolerant implementation of linear arrays meeting all of the desiderata stated earlier. In contrast, no single scheme or combination of previously proposed schemes for fault-tolerant implementation of 2-D arrays simultaneously achieves all the desirable characteristics of a fault-tolerant linear array implementation.

Diogenes designs proposed by Rosenberg are very attractive for fault-tolerant implementation of 2-D systolic algorithms. However, a major drawback with Diogenes designs is the long wire length between logically adjacent PE's (even in the absence of faulty PE's) resulting in significant degradation in throughput. Moreover, these designs require significantly large area for simulating 2-D systolic array algorithms. For matrix computations like multiplication of two n×n matrices, such a design makes use of $O(n^3)$ area. Furthermore, if we assume that signals propagate a fixed physical distance in every cycle then matrix multiplication requires $O(n^2)$ time.

In [19] we presented a collinear VLSI array that retains all the desirable fault-tolerant characteristics of Diogenes designs but obviates the need for signals to travel more than a fixed physical distance in any clock cycle. In our model, all signals travel a fixed physical distance in any clock cycle, *even* in the presence of faulty processors (that is, the clock rate is independent of both the number of faulty and non-faulty PE's). This feature of our model requires us to use retiming to ensure the correctness of our systolic algorithm despite the presence of faulty PE's. Their presence only contribute to an *additive* increase (equal to the number of bypassed faulty PE's) in the time complexity of our algorithm. We also described an algorithm to mutiply two n×n matrices in optimal $O(n\sqrt{n})$ time and $O(n^2)$ area.

In this paper we examined the inter-relationship among processors, storage within a processor, internal bandwidth and time complexity of matrix multiplication on our model. We established lower bounds on the time complexity and the number of processors required for matrix multiplication on our model as a function of the storage within a processor and the internal bandwidth. We than presented a generalized algorithm that matches these bounds for arbitrary storage within a processor and arbitrary bandwidth. An interesting side effect of our result is that the time and area complexities and the assymptotic complexity of the number of processors used by the algorithm in [19] and all previously described linear systolic array matrix multiplication algorithms in [1,4,8,10,15,16] can be obtained as *special* cases of our generalized algorithm.

To illustrate the key ideas in this paper we focussed only on one matrix computation (namely dense matrix multiplication) although our techniques can be easily extended to handle other important problems including LU decomposition, QR factorization and solution of linear systems of equations.

# FAIL SAFE DISTRIBUTED FAULT DIAGNOSIS OF MULTIPROCESSOR SYSTEMS*

Chung Yang Chiang and Chuan-lin Wu
Department of Electrical and Computer Engineering
The University of Texas at Austin
Austin,TX 78712

Abstract -- Techniques for distributively, reliably diagnosing multiprocessor systems are presented in this paper. Based on these techniques,trustworthy diagnostic results on the status,faulty or fault free,of every processor node will be revealed by fault free processors. An assumption which has been commonly made in most papers and might lead to totally incorrect results is eliminated for fail safe purpose. The assumption puts a limit on the number of existing faulty processors. Capabilites of the diagnosis system is analyzed in terms of trustability,diagnosability,coverage and mean diagnosability. Comparison to an existing diagnosis approach is also provided on diagnosing system using a multistage topology. The results single out the uniqueness of our approach on the fail safe diagnosis.

## 1. Introduction

A general guideline has been established to avoid introducing extra faults which can lead a fault tolerant system to earlier destruction whenever system recovery schemes, such as fault detection,diagnosis, isolation and reconfiguration,for restoring the system to operating mode are called for[1].

A lot of research works have been done to mold processor nodes together to form parallel processing systems. Yet,only a little effort has been exerted on how to reliably manage the system whenever faults occur. Fault detection and location are the first two steps to take to avoid further damages to the system. Basically there are two kinds of fault diagnosis methods. The first is the centralized one in which an external processor takes the responsibility of locating the faulty processors. The second is the distributed one in which every processor involves the execution of the diagnosis procedure. For a large and/or widely dispersed system,centralized diagnosis is not feasible due to the limitation of communication links. Besides,those diagnosis processors will form the hardcore of the system. For nonrepairable and/or autonomous systems,only distributed diagnosis is feasible.

Valid fault detection and location methods should imply one hundred percent reliability in carrying out the job. They should never come up with false diagnostic results. Otherwise,these methods would be as harmful as those faults which call for these methods since they could introduce more faults into the system. Previous papers in fault diagnosis tend to put a limit on the number of existing faults[2-8]. If more faults than the assumed limit occur,often times it is quite possible,depending on the reliability and size of the system,the system will simply yield false results. This is especially true for a large, distributed system in which only distributed fault diagnosis is feasible. There should be no room at all for uncertainty. A very small percentage of increase of uncertainty will result in dramatic decrease of system reliability as can be observed in [9]. This paper reports new techniques and concepts for reliably diagnosing multiprocessor system.

In section 2,we present a system graphs model and a fault model which forms the basis of a new fault diagnosis algorithm. Section 3 consists of the diagnosis algorithm and proof of the validity of this algorithm. Comparisons of coverage,trustability and mean diagnosability of systems with different diagnosability are presented in section 4. Section 5 concludes the work in this paper.

## 2. System Graphs and Fault Model

### 2.1 System Graphs

A system interconnection graph is an undirected graph showing the interconnections among processors of the system. Yet,test graph is a graph which shows the relationship between testing and tested processors. Interconnrction graph is the underlying graph of test graph. An example of these graphs is shown in Fig. 1. A directed test graph is depicted in Fig. 1.a in which the two processors linked by the arrowheaded link are associated with each other with the processor to which the arrowhead is incident defined as the tested processor and the other as the testing processor. Fig. 1.b is an undirected test graph in which every processor is both a testing and tested processor to its neighboring processors. In this particular case,the system test graph is the same as the interconnection graph.

A processor has two roles : it is a tester at one time,and a testee at another time. As a testing processor,it initiates its tested processors to commence self test and monitors the results from its tested processors. As a tested processor,it receives start signals from its testing processors to start self

test,reports its own status and reroutes received fault vectors from its testees to its testers.

## 2.2 Fault Model

The fault model is similar to most of the ones presented in previous papers[2-8] except one point,that is,no assumption on the number of allowable faults is ever made in order to avoid false diagnostic results and therefore possible system catastrophy.

The fault model is defined as follows :

(1) a faulty processor might modify the fault vectors sent to it by its testees.

(2)only permanent fault is considered. That is,once a processor is identified as faulty by any fault free processor,it will be regarded as faulty even though other processors might identify it as fault free.

(3)a fault free processor can become faulty during diagnosis period.

Link faults will be treated as proceesor faults since it is technically difficult to differentiate between link faults and processor faults. If that happens,the system simply loses those fault free processors which have association with the faulty links.

Since the diagnosis system is based on a distributed algorithm and no global clock has ever been provided as a system wide synchronization mechanism,it is impossible for processors to know the exact time of occurences of any link or processor faults. The only condition for the processors to differentiate link faults from processor faults is that they know exactly when faults have occurred. That implies a global,nonskewed clock should be implemented,which is impossible. The following paragraph explains in a circumstance on how link faults and processor faults can be differentiated by systems adopting distributed diagnosis algorithms.

For instance,we have 2 processors testing a common processor,the first tester identifies it as fault free and the second one identifies it as faulty due to the broken or stuck link between them. Following situations are possible :

(1)If the second tester identifies the link fault before the first one,then every processor will receive time-stamped messages from both the second tester indicating the tested processor as faulty and the first tester indicating it as fault free. Since only permanent fault is considered and fault condition was located first in terms of global clock,processors shall resolve this situation as a link fault. And the faulty link is the one that connects the second tester and the tested processor. In this case,the useful resource in this tested processor will not be dispensed. Only the faulty link will be isolated.

(2)Yet, if the first tester identifies the fault free processor first and the second one identifies the tested processor as faulty due to broken or stuck link between them after the first tester, then it is impossible to tell if it is a link fault or processor fault since the situation is the same as that of a fault free processor becoming faulty later before it is tested by the second testers. Unless the first tester,after receiving this conflicting message,can test this tested processor again and issue a later-time-stamped message indicating this supposedly faulty processor is still fault free.

# 3. Reliable Distributed Diagnosis Algorithm

## 3.1 Fail Safe Distributed Algorithm

The initiation and execution of the system fault diagnosis is assumed fully distributed. The following algorithm is for fault diagnosis only. Fault detection at individual processor is assumed. In this diagnosis system,we assume a certain number of processors can periodically initiate fault diagnosis cycles to locate faulty processors. The number of these watchdog-type processors should be greater than the expected degree of system fault tolerance in order to provide the necessary fault tolerance. Whenever the first processor initiates current cycle,every other processors which receive the initiation message,in addition to starting the diagnosis cycle,should also adjust its own internal clock to prepare for initiating next cycle. For the case in which faults did occur before the cycle is started,the effect of faults will be confined to only one cycle.

Definition 1 : Diagnosability -- A system is said to be t-fault self diagnosable if and only if each processor in the system can correctly identify all t faulty processors.

Diagnosability should not be taken as the sole gauge of the system diagnosis capability. The degree of confidence on the yielded results should be seriously taken into consideration in addition to diagnosability. Some might argue that we can always construct a system with diagnosability as high as possible. Yet no matter how complicated the system and therefore how high the diagnosability might be,it is always possible that the number of faults might surmount the diagnosability. On the other hand, for systems in which the diagnosability is low due to physically restricted structure of the system,the possibility of more fatal faults is even higher.

The algorithm is equally applicable to every processor in the system.The algorithm is written in C-like language.

Notations

(1) f[i] == fault vector maintained locally by p(i) (processor with logical id of i).

  (a) f[i][k] == kth element in f[i] representing the status of p(k) with the following possible values if k is not equal to i :

    0 : if p(k) is fault free.
    1 : if p(k) is faulty.
    x : status of p(k) is undetermined.

  (b) f[i][i] is the status of p(i) itself with only two possible values of 0 or 1.

(2) F[i] == fault vector sent by p(i) == f[i] ; F[i][k] == kth element in F[i].

Node p(j),j=0,1,....,n-1,after receiving diagnosis initiation messages,will perform following algorithm :

```
{
INITIALIZATION :
/*self test and initialization*/
broadcast diagnosis initiation message to
neighboring(both tested and testing) processors;
SELF_TEST :
if(self test passed)
    {
    f[j] = [$i_{n-1}$,..,$i_j$,..,$i_1$,$i_0$] = [x,x,..,0,..,x,x];
    send self test status to p(j)'s testers;
    }
else {
    f[i] = [x,x,..,1,..,x,x];
    send self test status to p(j)'s testers;
    break;
    }/*faulty processor makes self dormant if
      possible*/
while ((at least one element in f[j] undetermined) and
        (time not up yet))
    {
TEST : /*testing testees p(i)'s of p(j)*/
    for (every p(i) tested by p(j))
        switch (status of p(i)){
        case FAULT_FREE :
            f[j][i] = 0;
            break;
        case FAULTY:
        case NO_RESPONSE and TIMED_OUT :
            f[j][i] =1;
            break;
        case NO_RESPONSE and TIME_NOT_UP :
            break;
        } /*switch*/
BROADCAST : /*broadcast newly modified fault
vector to testers p(k)'s of p(j) if any*/
   while((any F[i] received from fault free p(i))) {
     if(F[i] results in changes of any element in f[j] from
       x to 1 or from 0 to 1)
       {
       initiate self test of p(i);
       if (p(i) is found fault free and F[i][i] ==0)
            update f[j] with F[i] from p(i);
       else    /*p(i) found faulty*/
            f[j][i]=1;
       }/*if*/
     broadcast newly changed element in f[j] to
     nonfaulty p(k)'s which test p(j);
     }/*while*/
   }/*while*/
if(at least one element in f[j] is undefined)
FAILED:
   for(nonfaulty p(k)'s which test p(j))
         broadcast failure message to p(k);
else{
   for(nonfaulty p(k)'s which test p(j))
         broadcast done message to p(k);
   while(at least one done message not yet received
   from fault free processors and time not up yet and
   no failure message received) ;
   if(timed out)
         go to INITIALIZATION;
   else
         if(failure message received)
           go to FAILED;
   }/*else*/
}/*main*/
```

The failure message indicates some of the fault free processors fail to generate decisive and unanimous result,although other fault free processors can locate all faulty processors.

### 3.2 Definition and Theorem

Definition 2 : Connectivity -- For an undirected(directed) test graph,the (vertex) connectivity $K_v$ is the minimun number of vertices whose removal from the graph results in a disconnected (weakly connected or disconnected)graph [10].

The test graph of Fig. 1.a is a directed graph with connectivity of 2. Yet ,the test graph of Fig. 1.b is an undirected graph with connectivity of 4.

When the number of faults is equal to the connectivity of the test graph,then the diagnosis system will fail us in some cases as the following paragraphs show. By failing us,we mean the diagnosis system found that current fault situation is undiagnosable due to lack of unanimous and decisive diagnostic result.

Assume the test graph of a multiprocessor system has connectivity of t,then the following cases are the situations in which the diagnosis system fails when the number of faults is not less than t.

case 1: Any processor with all its t testers being faulty. In this situation,the status of this particular processor will be unknown to other processors in the system.

case 2: Any processor with all its t testees being faulty. This particular processor will be totally blocked from the diagnostic information flowing around the system.

case 3 : There are some special cases with not less than t faults which also result in failed system.

As long as the number of faults is less than t,the diagnosis system always comes up with decisive and unanimous result.

From the above cases,we observe that the diagnosability of the system proposed in this paper is always 1 less than the connectivity. The main reason behind this decrease of diagnosability,as compared with that of the diagnosis systems proposed in other papers,is to achieve fail safety. Yet,it doesn't at all imply the system has an inferior capability of locating existing faults. On the contrary, it has a better capability.

The following theorem verifies that when the number of faults is less than the connectivity of the system,the system can always locate all faults by adopting the previous algorithm. And when the number of faults is eqaul to or greater than the system connectivity, the algorithm never comes up with false diagnostic results.

Theorem 1 - Using the above algorithm,a system with test graph T of $K_V$ equals t will either correctly locate all faulty processors or not incorrectly locate any faulty processors.

Proof : We will prove the validity of the algorithm in three cases.

(1)if the number of faults is less than t :

As the system has a test graph with $K_V$ equals t,therefore,it will still be connected(or strongly connected). There will be at least one path between every pair of vertices according to the definition of connected graphs. Therefore,for a directed test graph system,every fault free vertex can receive the diagnostic information from its fault free testees and broadcast new information to its nonfaulty testers. For a directed test graph,the set of testers and the set of testees of a vertex do not have any element in commom. Yet for an undirected test graph,the set of testers is the same as the set of testees for a vertex. There is still at least one path which consists of fault free vertices,and correct diagnostic information can be received and broadcast along this path.

(2)if the number of faults is greater than t :

According to the definition of connected graph,we encounter two situations :

(A)it is possible that the test graph is disconnected(or weakly connected),then there will be no path at all between some pairs of vertices. These vertices will fail to either collect status of other vertices or be known to other vertices of its status. Therefore,we can sort all fault free vertices into two categories : those which fail to collect status of every vertex and those which can collect status of every vertex. For those which fail,they will broadcast failure message to every other fault free vertex according to the algorithm. And since the other set consists of those which can collect status of every vertex,they will be able to collect this newly broadcast failure message. The result is no vertex in the system will ever go into a faulty state in which it thinks the system yields decisive and unanimous results. We conclude that no vertex will ever incorrectly locate faulty vertices.

(B)if the test graph is still connected(or strongly connected),then the situation is the same as that of (1).

(3)if the number of faults is equal to t :

This case is the same as (2) except the possibility of the test graph being connected is higher than that of (2). The only occassions that the test graph will be disconnected are : (a)when either all testers or all testees of a vertex are faulty,and (b)few special cases.

Q.E.D.

## 4.System Coverage,Diagnosability, Trustability and Mean Diagnosability

### 4.1 Analysis of Diagnosis Trustability

Definition 3 : Trustability of Diagnosis -- Trustability of fault diagnosis is the probability that the diagnosis system either yields correct or does not yield incorrect diagnostic results regardless the number of faults in the system.

Trustability is actually a reliability measure. A diagnosis system which guarantees locating up to k faults when the number of faults is not more than k will have diagnosis trustability of 1 when the number of faults is less than or equal to k. Yet,when the number of faults is greater than k,the trustability decreases as the number of faults increases. For example,in [2], the system will yield false results when the number of faults is greater than the assumed one. Take the 5-node completely connected graph system in Fig.1.a as an example. According to the structure of this system,diagnosis algorithm in [2] can diagnose up to 2 faults,yet,if the number of faults is greater than 2,the trustability of the diagnosis system will be the probability of any 3 or more existing faults in the system. According to the algorithm presented in this paper,the diagnosability is 1 instead of 2,which of course is 1 less than that of [2],yet the trustability of diagnosis is still 1 regardless the number of faults in the system. As we can see,the increase in diagnosis trustability is at the expense of diagnosability.

Analysis -- Trustability measures for both fail-safe and non-fail-safe diagnosis systems are analyzed below. We assume there is an exponential failure distribution for every processor in the system and the failure distributions are independent. The reliability function is : $R(t) = e^{-qt}$ . We will use R instead of R(t) just for simplicity. Equation for trustability is stated as follows :

$$T(t) = \sum_{i=0}^{n} p_i{*}C(n,i)R^{n-i}(1-R)^i \tag{1}$$

where C(n,i) is the number of combinations for choosing r faulty processors out of a total of n processors. The product term of C(n,i),R and (1-R) is the probability of exactly i faulty processors out of n processors. $p_i$ is the probability of correctly locating all i faulty processors or not incorrectly locating any faulty processor.

(1)Fail safe diagnosis system : A system with n processors can correctly locate up to k faults and doesn't incorrectly locate faults if the number of faults is greater than k. Then the trustability of diagnosis will be 1 as described below :

$$T_{fs}(t)= 1{*}R^n+1{*}C(n,1)R^{n-1}(1-R)^1+1{*}C(n,2)R^{n-2}(1-R)^2+...+1{*} C(n,k)R^{n-k}(1-R)^k + 1{*}C(n,k+1)R^{n-k-1}(1-R)^{k+1} + ... + 1{*}C(n,i)R^{n-i}(1-R)^i +... +1{*}(1-R)^n \tag{2}$$

which is the binomial expansion of $(R + (1-R))^n = 1$. The jth (j <= k) item is the probability of correctly locating all faults if there are j faults. The ith(i > k) item is the probability of not incorrectly locating any faults if there are i faults.

(2)Non-fail-safe diagnosis system : If the system can correctly locate only up to k faults,and can not guarantee the correctness of the results when the number of faults is greater than k,then the trustability will be :

$$T_{nfs}(t) = 1{*}R^n + 1{*}C(n,1)R^{n-1}(1-R)^1 + 1{*}C(n,2)R^{n-2} (1-R)^2+ ... +1{*}C(n,k)R^{n-k}(1-R)^k+p_{k+1}{*}C(n,k+1)R^{n-k-1} (1-R)^{k+1}+...+p_i{*}C(n,i)R^{n-i}(1-R)^i+... +p_n{*}(1-R)^n \tag{3}$$

where $p_i$'s are the probabilities that the diagnosis system yields correct diagnostic results if there are i faults(i > k) in the system. The probability that the system being led to incorrect state is 1 minus the trustability as follows :

$$\overline{T_{nfs}(t)} = (1-p_{k+1}){*}C(n,k+1)R^{n-k-1}(1-R)^{k+1} + ... + (1-p_n){*}(1-R)^n \tag{4}$$

### 4.2 Comparison of Trustability , Diagnosability , Coverage and Mean Diagnosability

We will compare the diagnosis system in [2] and the one proposed here. The system in [2] is the first one proposes a fully distributed diagnosis system. We call it R system and ours S system. The comparison is done on the diagnosis of a system employing multistage topology[11],which is also employed for functional language architectures[12]. An example topology is shown in Fig. 2.

(A) Trustability :

$$(1)\ \text{R system} = \sum_{i=0}^{2} 1 * C(n,i)R^{n-i}(1-R)^i + \sum_{i=3}^{n} 0 * C(n,i)R^{n-i}(1-R)^i$$

(2) S system = 1

$p_i$'s(i >=3) are 0's in R system simply because it assumes there are at most 2 existing faults in the system. If there are more than 2 faults,then,according to its diagnosis algorithm,every processor will conclude that it has already located all faulty processors whenever there are 2 1's in its fault vector even though there are still a few don't care terms. This is especially truly for those processors which fail to determine status of every processor,since they have no way of determining status of some processors. They can yield decisive results only by assuming 2 faults in the system. Trustability of S system is 1 because it determines to yield decisive and unanimous result,no guessing is ever involved.

Remember that part of trustability is just the probability of not incorrectly locating any faults. When the system can correctly locate all faults no matter how many existing faults in the system,it is equal to the probability of correctly locating the faults. Yet,when the system can locate the faults for some of the fault situations and falsely locates the faults in other fault situations,then the trustability is simply the portion in which the system can locate the faults.

(B) Diagnosability :

According to PMC model,we have :

(1) R system = 2 ; and

(2) S system = 1

Even though the diagnosability of the S system is 1,it does not imply that it can't locate 2-fault incidents at all. As the way in which diagnosability is defined,it simply means it can not locate all 2-fault incidents,although it is capable of locating most of the 2-fault incidents as we shall see in the next paragraph. Therefore,it should be coupled with coverage to give a better idea of the probability of correctly locating faults.

(C) Coverage :

Definition 4 : Coverage of Diagnosis -- The percentage of fault incidents in which diagnosis system can correctly locate all faulty processors.

Simulation Features -- Coverage measure for S system is acquired by simulation which is executed in the following manner :

(1)specify size of the system , i.e. , number of stages.

(2)specify number of faulty processing elements (PE's).

(3)for every possible combination of the number of faults , check if every fault free PE can receive fault vector broadcast by other fault free PE's.

If at least one PE is incapable of receiving broadcast fault vectors from at least one other fault free PE,then it is regarded as a failed diagnosis situation since it implies this particular PE has a fault vector with at least one element undertermined. Therefore,the whole system is incapable of coming up with a decisive and unanimous diagnostic results.

According to simulation,we have the following results :

(1) R system =

1 for all system size if # faults <= 2;
0 for all system size if # faults > 2.

(2) S system =

1.0000 for 3-stage system if # faults =1;
0.7879 for 3-stage system if # faults = 2;
0.4727 for 3-stage system if # faults = 3.

1.0000 for 4-stage system if # faults = 1;
0.9395 for 4-stage system if # faults = 2;
0.8218 for 4-stage system if # faults = 3.

The numbers shown above for 2-fault cases can be estimated quite easily as following example shows.

Example 1 -- For a 4-stage multistage interconnection network,there are three components which contribute to undiagnosable fault situations : (1)all testers of a particular PE are faulty,(2)all testees of a particular PE are faulty,and (3)special cases,as stated in the proof of Theorem 1.

For stage 0 PE's there are 2*8 such cases. As an example,in Fig. 2,assume PE(0,0) is the faulty PE addressed (0,0) with the first 0 representing its stage address and second 0 representing its address in that stage starting from top. If PE(0,1) is also faulty,then they will block the status of their two common testees in stage 1,PE(1,0)and PE(1,4),from being known to other PE's. Yet,if we assume PE(0,4) instead of PE(0,1) is faulty besides PE(0,0),then they will block their two common testers in stage 3,PE(3,0) and PE(3,1),from receiving diagnostic information. Therefore,for PE(0,0),there are 2 cases in which the diagnosis system fails. It is the same for other PE's in stage 0. Therefore,we have 2*8 cases in stage 0.

The numbers for stage 1 and 2 will still be the same. For stage 3,the number will be 1*8 only. We get 56 for cases covered by (1) and (2) situations stated at the begining of this example. Besides that,there are 4 special cases.

Therefore,there are 56+4 cases in which 2-fault situations make the diagnosis system fail. The total combinations for choosing 2 faulty PE's out of 4*8 PE's is 992. Thus,the coverage is (992-60)/992,which is 0.9395. The same estimation process can be applied to 2-fault cases for 3-stage system.

As the size of the system grows,the difference in coverage diminishes as can be observed in Fig. 3.a and 3.b. That implies S system can correctly locate almost the same number of faulty PE's when the size of system grows,as compared with those of R system,although diagnosability of S system is still 1.

As we pointed out earlier,when one considers the positive capability of a diagnosis system,he should take both coverage and diagnosability into account. We define the next measure accordingly.

Definition 5 : Mean Diagnosability -- The expected value of faults which can be correctly located regardless the number of faults in the system.

The mean diagnosability is as follows.

$$E[D] = \sum_{i=0}^{n} i * c_i \qquad (5)$$

where $c_i$ is the coverage of the diagnosis system provided there are only i faults.

(D) Mean Diagnosability :

$$\text{(1) R system} = 1 * 1 + 2 * 1 + \sum_{i=3}^{n} 3 * 0$$
$$= 3$$

$$\text{(2) S system} = 1 * 1 + 2 * 0.9395 + 3 * 0.8218 +$$
$$+ \sum_{i=4}^{n} 3 * c_i$$
$$= 5.3444 + \sum_{i=4}^{n} 3 * c_i$$

It is obvious that the mean diagnosability of S system is better than that of R system.

From the above comparisons,we acquire the following conclusions :

(1) Advantages of S system are :

(a) It either correctly locates all faulty processors or doesn't incorrectly locate any faulty processor,which is the basic requirement for a truly fault tolerant computing machine. This can be perceived from the trustability of S system. Implication of this capability is S system can afford to have a longer diagnosis period since it doesn't set an upper limit on the number of allowable faults. For R system,diagnosis period should be as short as possible in order to avoid extra faults occuring during diagnosis period.

(b) The actual number of fault incidents in which faults can be located by S system is far more better than that of R system. This is justified by coverage and mean diagnosability of S system.

(2) Disadvantage of S system is :

(a) Diagnosability is always 1 less than that of R system. Yet this is not an actual disadvantage as it is a false indicator of diagnosis system capability.

## 5. Conclusion

We have presented a technique which is suitable for fail safely, distributively,locating faults in multiprocessor systems. That the system is both competent and fail safe is justified by the measures defined in this paper in terms of mean diagnosability and trustability. As we perceived,the assumption which has been widely used in several research papers does not necessarily make diagnosis systems more competent nor reliable. On the other hand,it is always fail safe to make as few assumptions as possible. The simulation and comparison done on a multistage system proves that,by emphasizing fail safety,we improve not only reliability but also capability of the diagnosis system.

Tukwila, WA 98188

Abstract -- Recent vector supercomputers provide vector memory access to "randomly" indexed vectors, whereas early vector supercomputers required contiguously or regularly indexed vectors. This additional capability, known as "hardware gather/scatter", can be used to great effect in general sparse Gaussian elimination. In this note we present some examples that show the impact of this change in hardware on the choice of algorithms for sparse Gaussian elimination. Common folk wisdom holds that general sparse Gaussian elimination algorithms do not perform well on vector computers. Our numerical results demonstrate that hardware gather/scatter allows general sparse elimination algorithms to outperform algorithms based on a band, envelope, or block structure on such computers.

## Gaussian Elimination on Vector Computers

Early experience with sparse Gaussian elimination on vector computers /3/ showed none of the dramatic improvements in speed-up encountered in other linear algebra computations. This is due to the fact that Gaussian elimination with a sparse data structure requires access to irregularly spaced data. Early vector computers, such as the CRAY-1 and the CYBER 205 computers, allow vector transfers to and from memory only for contiguously or regularly spaced vectors. Most sparse Gaussian elimination algorithms spend the vast majority of the factorization execution time in a loop of the following type:

```
          INTEGER I, N, M
          INTEGER INDEX(M)
          REAL A, X(M), Y(N)
               .
               .
          DO 10 I = 1, M
             Y(INDEX(I))=A*X(I) + Y(INDEX(I))
  10      CONTINUE
```

The difficulty this loop presents for vector computers is the indexing or indirect addressing for the vector Y. This loop is often referred to as an sparse or indexed SAXPY. The efficiency of the implementation of this loop determines the performance of the algorithm. Because of the importance of this loop or kernel a subroutine called SAXPYI, which follows the spirit and the notation of the BLAS /6/, has been proposed as a facility in extensions of the BLAS /2/.

The use of the SAXPYI loop as presented above, in FORTRAN, would result in no use of the vector hardware of early supercomputers. The loop would be executed using scalar instructions only, producing no speedup at all over equivalent scalar computers. The indexed SAXPY loop can be rewritten to allow some use of of the vector hardware. Dembart and Neves /1/ analyzed seven different formulations of this loop on a CDC STAR 100, and determined that there were combinations of vector length and vector density for which each of the formulations was fastest. Similar analyses by these authors for the CYBER 203 and 205 showed equivalent results, althought the ratios changed. For reasonable combinations of vector length and vector density the most important of the six alternatives to the original scalar code was the same on all three machines. This alternative is first to gather all components on which operations are to be performed in a temporary dense vector, then to perform a dense SAXPY on this short vector, and finally to scatter the results back to the appropriate memory locations.

Although this looks far more complicated than the original loop, it permits the use of the vector arithmetic units for the SAXPY loop. The non-vectorizable memory transfers are isolated to separate loops that could be made more efficient by using assembly language subroutines (albeit in scalar mode). This formulation of the indexed SAXPY is known as a GATHER-SAXPY-SCATTER (GSS) implementation, for the operations performed in turn by the three loops.

On a CRAY-1 computer, the original indexed SAXPY loop written in FORTRAN executes at a maximum rate of about 4 megaflops, much less than the maximum rate of 155 megaflops this machine can achieve for other operations. Woo and Levesque /9/ analyzed the G-S-S formulation and showed that its maximum rate in assembly language was around 8 megaflops. Alternatively, a good assembly language implementation of the original loop using only scalar hardware, performs asymptotically at 13 megaflops (see /8/). This implementation is never slower than the G-S-S formulation, demonstrating that this is essentially a scalar computation for the CRAY-1.

In contrast, the standard implementation of banded or variable banded Gaussian elimination algorithms use dense dot products or dense SAXPY operations as their fundamental inner-loops. Such implementations can achieve vector speeds on vector computers. However, they usually do not approach the asymptotic speeds of these machines because the vector lengths are limited by the bandwidth, which should not become very large. The possibility of using the vector hardware for these schemes and the inherent performance limitation of the indexed SAXPY loop has led to the conventional folk wisdom that (variable) banded factorization schemes will usually outperform general sparse Gaussian elimination on vector computers.

The vector supercomputers being produced currently,

0190-3918/86/0000/0366 $01.00 © 1986 IEEE

in particular the CRAY X-MP/4 and the more recent models of the CRAY X-MP/2, are equipped with new facilities that permit memory access according to an index vector in hardware. That is, these machines permit the GATHER and SCATTER loops to be performed using vector memory transfers to and from a hardware vector register. This gather/scatter hardware leads to a much faster implementation of SAXPYI, using the G-S-S formulation. The assembly language coded implementation in VectorPak reaches 78 megaflops asymptotically. Some detailed SAXPYI timings are given in Table 1 below /8/:

**Table 1.** SAXPYI Speed on the CRAY X-MP/24 (1 CPU, rates given in megaflops).

| | M = 10 | M = infinity |
|---|---|---|
| (ignoring the hardware for gather/scatter) | | |
| CFT 1.13 | 5.0 | 5.7 |
| VectorPak | 6.3 | 14.5 |
| (using the hardware gather/scatter) | | |
| CFT 1.14 | 16.1 | 54.6 |
| VectorPak | 16.1 | 78.6 |

The older CRAY Fortran Compiler CFT 1.13 does not make use of the hardware for gather/scatter. A corresponding VectorPak implementation of SAXPYI has been developed for CRAY X-MP's without hardware gather/scatter. Both exhibit the scalar performance characteristic of the CRAY-1. In contrast the utilization of hardware gather/scatter either via CFT 1.14 or with VectorPak shows a dramatic improvement.

Numerical Results.

Our first series of numerical results demonstrates the speed-up which can be obtained using hardware/gather in a general sparse elimination algorithm on very large real life applications. We use a modified minimum degree (MD) algorithm by Liu /7/ to solve the following seven problems taken from the sparse matrix collection /4/. Below a short problem description and some ordering statistics are given. All problems with the exception of LRGPWR are finite element models of large three dimensional structures. All matrices are symmetric and positive definite.

**Table 2.** Problem Description.

| Problem | Description |
|---|---|
| STK3562 | Finite element model of Sports Arena<br>N=3562, $A_{nz}$=78174, $L_{nz}$=275360 |
| STK3948 | Finite element model of oil platform<br>N=3948, $A_{nz}$=56934, $L_{nz}$=647274 |
| STK4884 | Corps of Engineers model of dam<br>N=4884, $A_{nz}$=142747, $L^{nz=736294}$ |
| LRGPWR | Electric power network of U.S.<br>N=5300, $A_{nz}$=8271, $L_{nz}$=22764 |
| ST10974 | Elevated pressure vessel<br>N=10974, $A_{nz}$208838, $L_{nz}$=994885 |
| ST11948 | Nuclear power station<br>N=11948, $A_{nz}$=68571, $L_{nz}$=650777 |
| ST15439 | 76 story skyscraper<br>N=15439, $A_{nz}$=118401, $L_{nz}$=1401129 |

where,
N order of the matrix,
$A_{nz}$ nonzeros in lower triangle of the original matrix,
$L_{nz}$ nonzeros in the Cholesky factor of A,

The numbers in Table 2 show that with the exception of the power network problem LRGPWR all matrices considered have a substantial number of nonzeros per row. Thus we expect to see the theoretical speedups due to hardware gather/scatter realized on some practical applications.

All problems were solved using four different implementations of the key SAXPYI loop. The original source code was modified by inserting a few compiler directives to affect the vectorization of the key loops. Even though CFT1.14 can vectorize the access of random elements according to an index vector as in the SAXPYI-loop, a compiler directive must be inserted in the original code, in order to instruct the compiler to do so. The Fortran code with inserted compiler directives was then compiled twice under CFT1.14. Using a compiler option, code was generated both for a Cray X-MP with and without hardware gather/scatter.

Then the code was modified to call an optimized implementation of SAXPYI from VectorPak /8/. This modifed code was also compiled under CFT1.14, and then executed twice. First a VectorPak library for Cray X-MP's without gather/scatter was used, and then the corresponding library for machines with gather/scatter. Table 3 and 4 below present the execution times obtained for factorization and solution for the four implementations. All execution times are listed relative to the VectorPak with gather/scatter time, which is normalized to one. The actual execution time in seconds for the VectorPak with gather/scatter implementation is given in Table 5, together with the execution times for an envelope factorization based on the reverse Cuthill-McKee (RCM) algorithm from /5/.

Tables 3 and 4 show clearly the direct benefits of the hardware gather/scatter feature for general sparse elimination schemes. Using this feature factorization and solution are in some cases almost up to 8 times faster. Very sparse problems such as LRGPWR, however, do not benefit from this speedup, since the number of nonzeros per row is too small. Note that even the factored matrix LRGPWR has only about 9 nonzeros per row, too few to obtain the fast asymptotic rates in Table 1. On the other hand, the finite element problems do have a large number of nonzeros per row, and thus almost realize the speedup potential of the asymptotic rates given in Table 1.

The numbers for VectorPak demonstrate two facts. Obviously it pays more in terms of speedup to use a carefully assembly coded subroutine on a machine without hardware gather/scatter. And in spite of advances in the CRAY compilers, VectorPak still offers a 20-25% improvement in the factorization and a 30% improvement in the solution as compared to straight forward CFT1.14.

**Table 3.** Execution Times for Sparse Matrix Factorization.
(normalized so that VectorPak with g/s = 1.00)

| Problem | CFT1.14<br>no g/s | CFT1.14<br>with g/s | VectorPak<br>no g/s |
|---|---|---|---|
| STK3562 | 6.33 | 1.14 | 2.54 |
| STK3948 | 9.66 | 1.24 | 3.25 |
| STK4884 | 8.70 | 1.20 | 3.14 |
| LRGPWR | 1.25 | 0.93 | 1.17 |
| ST10974 | 7.24 | 1.16 | 2.80 |
| ST11948 | 8.75 | 1.22 | 3.12 |
| ST15439 | 8.78 | 1.25 | 3.15 |

**Table 4.** Execution Times for Sparse Matrix Solution.

| Problem | CFT1.14<br>no g/s | CFT1.14<br>with g/s | VectorPak<br>no g/s |
|---|---|---|---|
| STK3562 | 6.94 | 1.48 | 2.55 |
| STK3948 | 9.22 | 1.47 | 3.13 |
| STK4884 | 8.77 | 1.39 | 3.00 |
| LRGPWR | 1.96 | 1.57 | 1.11 |
| ST10974 | 7.45 | 1.48 | 2.68 |
| ST11948 | 5.94 | 1.50 | 2.23 |
| ST15439 | 7.54 | 1.49 | 2.68 |

**Table 5.** Execution Times (sec) for Factorization and Solution Routines.

| Problem | Factorization<br>RCM | <br>MD | Solution<br>RCM | <br>MD |
|---|---|---|---|---|
| STK3562 | 3.421 | 1.276 | 0.047 | 0.033 |
| STK3948 | 7.487 | 4.074 | 0.064 | 0.055 |
| STK4884 | 4.071 | 4.129 | 0.065 | 0.066 |
| LRGPWR | 3.642 | 0.102 | 0.061 | 0.028 |
| ST10974 | - | 4.891 | - | 0.108 |
| ST11948 | - | 3.871 | - | 0.094 |
| ST15439 | 17.440 | 7.791 | 0.213 | 0.152 |

The comparison in Table 5 shows that general sparse methods outperform envelope solvers on vector computers with hardware gather/scatter. Because of the natural vectorization of envelope methods and the essentially scalar performance of general sparse methods on earlier vector computers, general sparse methods were generally thought of non-competitive on vector computers. Table 5 disproves this assertion, in particular since some of the problems could not even be solved by RCM within the 4Mword available on the Cray X-MP/24 at Boeing Computer Services.

A final point worth making concerns a software issue. Sparse Gaussian elilimination software from /5/ had been modified with calls to computational kernels replacing some inner loops several years ago, when it was installed on the CRAY-1S. As soon as the CRAY X-MP arrived some of the above test examples were run again without any code modifications. By using computational kernels from a kernel library such as VectorPak the application programmer therefore can reap directly the benefits of hardware improvements, without concerning himself with the often subtle details of a new implementation, or without waiting for the compiler writer to catch up with the hardware architect. Thus the success in using hardware gather/scatter in the context of sparse Gaussian elimination also validates the concept of computational kernels as a tool for combining portability and optimality on advanced architectures.

## Abstract

In this paper, an algorithm for solving sparse sets of equations with an almost tri-diagonal structure on Single-Instruction-Multiple-Data Stream (SIMD) computers, like the ICL Distributed Array Processor (DAP) and the Goodyear Aerospace Massively Parallel Processor (MPP), is described. Central to this algorithm is the partitioning of the original sparse set of equations into a number of smaller tri-diagonal sets that can be solved in parallel using cyclic reduction. A DAP implementation of the algorithm, which demonstrates how the nearest neighbor connection network can be used to keep track of the couplings between unknowns, as these (the couplings) are modified by the solution procedure, is detailed. The paper concludes with a discussion of the algorithm's performance on an actual application.

## 1. Introduction

The numerical solution of one-dimensional differential equations often requires the inversion of matrices with a sparsity structure that we will refer to as almost tri-diagonal. Such problems can, for instance, be found in the field of nuclear reactor hydrodynamics and other branches of fluid dynamics. In this paper, we describe an algorithm for solving almost tri-diagonal problems on Single-Instruction-Multiple-Data Stream (SIMD) computers like the ICL Distributed Array Processor (DAP) and the Goodyear Aerospace Massively Parallel Processor (MPP).

These machines derive their high performance from the lockstep operation of a large number (4,096 and 16,384 in the case of the DAP and MPP, respectively) of simple, one-bit Processing Elements (PEs), rather than from a few, powerful processors as in the case of vector computers such as the CRAY-XMP and CYBER 205. Thus, algorithms cannot exploit the full processing power of the DAP and MPP unless they allow most, or all, of the PEs to be engaged in productive work[b] most, or all, of the time. Parallel cyclic reduction, which is a standard technique for solving single tri-diagonal sets of equations, satisfies this criterion. In our algorithm for inverting almost tri-diagonal problems, we take advantage of this by partitioning the original sparse matrix into a number of smaller matrices with tri-diagonal structures. As will be shown (see Section 2.2.2), these can all be inverted in parallel using cyclic reduction, provided the total number of equations in the almost tri-diagonal set does not exceed the number of PEs of the computer.

The full algorithm for solving almost tri-diagonal problems has been successfully implemented on the DAP. Following the description of the algorithm, details of this implementation are given. The paper concludes with a discussion of the algorithm's performance on an actual application.

## 2. An Algorithm for Solving Almost Tri-Diagonal Sets of Equations

Consider undirected graphs or networks of N nodes that satisfy the following requirements (see Figure 1):

(i) The majority of nodes [O(N)] have only two neighbors.

(ii) No nodes have more than three neighbors, and there are at most m such nodes ($0 \leq m << N$); these will be referred to as junctions.

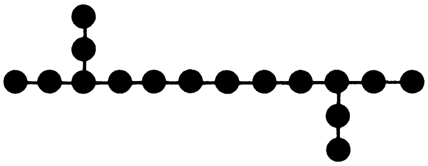

Figure 1. Sample Network

Networks like these are frequently used to numerically solve one-dimensional differential equations.

[a] This work was supported by a grant from the United Kingdom Atomic Energy Establishment, Winfrith.

[b] We here define productive work as an operation that contributes toward completing the task of an algorithm.

In that case, some quantity x is to be computed at each node. Typically, this involves solving a set of simultaneous, linear equations which, given conditions (i) and (ii), can be expressed by:

$$a_i x_r + b_i x_i + c_i x_\ell + e_i x_b = d_i \qquad (1)$$

where

$r, \ell, b, i = 1..N$

$$\begin{array}{l} r = i-1 \\ \\ \ell = i+1 \end{array} \quad ; \; j_k + 1 < i < j_{k'}-1 \qquad (2)$$

$j_k, j_{k'}$ = numbers of junctions; $k, k' = 1..m$

From (2) it follows that for each sub-graph or sub-network, $j_k+1 \le i \le j_{k'}-1$, (1) may be rewritten as three equations:

$$\begin{array}{lll} a_i x_{i-1} + b_i x_i + c_i x_{i+1} = d_i ; & j_k+1<i<j_{k'}-1 & \\ a_i x_{j_k} + b_i x_i + c_i x_{i+1} = d_i ; & i = j_k+1 & (3) \\ a_i x_{i-1} + b_i x_i + c_i x_{j_{k'}} = d_i ; & i = j_{k'}-1 & \end{array}$$

Furthermore, if $a_i x_{j_k}$ and $c_i x_{j_{k'}}$ are treated as right-hand-side terms, (3) can be compressed to a single equation:

$$a_i x_{i-1} + b_i x_i + c_i x_{i+1} = d_i + \alpha_i x_{j_k} + \beta_i x_{j_{k'}} \qquad (4)$$

where

$$\begin{array}{ll} a_i x_{i-1} = 0; & i = j_k+1 \\ c_i x_{i+1} = 0; & i = j_{k'}-1 \\ \alpha_i = 0; & j_k+1<i\le j_{k'}-1 \\ \alpha_i = -a_i; & i = j_k+1 \\ \beta_i = 0; & j_k+1\le i<j_{k'}-1 \\ \beta_i = -c_i; & i = j_{k'}-1 \end{array}$$

It can be seen that (4) is of tri-diagonal form although it has three right-hand-side terms. The m junctions separate the original network (graph) into S [$O(2^m)$] sub-networks. Hence, (1) can be partitioned into S tri-diagonal sets of equations like (4). These can be solved separately to yield $x_i (i \ne j_1 ... j_m)$ as a linear function of $x_{j_k}$ and $x_{j_{k'}}$ :[c]

$$x_i = p_i + q_i x_{j_k} + r_i x_{j_{k'}} \qquad (5)$$

where

$k, k' = 1..m$
$i = 1..N \; (i \ne j_1 ... j_m)$

To complete the solution of the original sparse set of equations, (1), the m equations for the junctions ($e_i \ne 0$; $i = j_1 ... j_m$) must now be used. By substituting the expressions for $x_r$, $x_\ell$, and $x_b$ obtained from (5) in these junction equations, a closed matrix problem (size mxm) is created, which can easily be solved to yield values for $x_i$, $i = j_1 ... j_m$. Back-substitution in (5) then gives the values for the remaining N-m unknowns.

An additional step is needed in the above algorithm when the network (graph) represents a closed loop. Unless the nodes can be numbered so that the loop closes back on itself ("wraps around") at a junction--this is, of course, impossible if a network does not contain junctions--(5) will have a slightly different form for the two sub-networks, s' and s", that close the loop:

$$x_i = p_i + q_i x_{s''_n} + r_i x_{j_{k'}} ; \qquad s'_1 \le i \le s'_n \qquad (6)$$

$$x_i = p_i + q_i x_{j_k} + r_i x_{s'_1} ; \qquad s''_1 \le i \le s''_n \qquad (7)$$

where

$s'_1$ = lowest numbered node of sub-network s'

$s''_1$ = lowest numbered node of sub-network s"

$s'_n$ = highest numbered node of sub-network s'

$s''_n$ = highest numbered node of sub-network s"

Before proceeding to substitute in the equations for the m junctions, the terms $q_i x_{s''_n}$ and $r_i x_{s'_1}$ must be eliminated. It will be seen that this is easily accomplished using the equations obtained by writing down (6) and (7) for $i=s'_1$ and $i=s''_n$, respectively.

A fundamental problem in implementing the algorithm described in this section on SIMD computers like the DAP and MPP is how to keep track of the $(x_{j_k}, x_{j_{k'}})$-pair to which each $x_i$ is coupled. The method for accomplishing this on the DAP is described in Section 2.3.3. A brief overview of this machine is now given.

[c] Obviously, the pair (k, k') is different for each sub-network.

### 2.1 Brief Overview of the DAP[d] and its High-Level Language (HOL)

The ICL DAP is an SIMD computer consisting of $64^2$ (4096) one-bit Processing Elements (PEs)--all under control of a Master Control Unit (MCU). Communication lines between PEs are provided by a nearest-neighbor connection network, and each PE is equipped with 16 kbits of memory for a total storage capacity of 8 Mbytes. All of this can be used as a memory module of the DAP's front-end, an ICL 2980 mainframe computer.

The DAP can operate in two different parallel processing modes. The most powerful of these performs sequential operations on bit slices from 4096 different memory words and is referred to as matrix mode. In the less powerful vector mode processing, the PEs are made to carry out operations on 64 words simultaneously with all bits of each word processed in parallel.

A special, non-portable HOL, called DAP FORTRAN, has been developed for the DAP. It differs from ordinary FORTRAN mainly in that it has facilities for expressing the hardware parallelism of the DAP. More specifically, DAP FORTRAN allows an operation to be specified for all elements of a vector or matrix simultaneously. There is, however, one proviso: the dimensions of a vector and matrix declared in DAP FORTRAN must match those of the PE array; thus, a vector can only have 64 elements and a matrix 4096, arranged as a two-dimensional $64^2$ array. A matrix can also be reduced to a one-dimensional structure by treating it as a "long" vector consisting of 4096 linearly arranged elements. Operations on data arrays with more than two dimensions must be broken up into sets of either vector or matrix operations depending on the array declarations.

To complement the parallel data structures, the indexing facilities of ordinary FORTRAN have been extended in DAP FORTRAN. Most notably, logical expressions, or masks, can be used to select data items from vectors and matrices.

### 2.2 DAP Implementation Details of the Algorithm for Solving Almost Tri-Diagonal Sets of Equations

2.2.1 Memory Mapping. For algorithms to efficiently exploit the processing power of the DAP, they must engage on the order of 4,096 PEs simultaneously in productive work. It is demonstrated in the following that the algorithm described in Section 2 can achieve this, provided the networks (graphs) are mapped onto the PE array so that all information associated with node i is stored in the local memory of PE i. This information consists of the coefficients for equation i and the numbers of the nodes to which this equation couples node i. Without the latter, neither the substitutions into the m junction equations nor the back-substitution step can be performed.

2.2.2 Extending the Use of Parallel Cyclic Reduction to Multiple Sets of Tri-Diagonal Equations. Parallel cyclic reduction is a standard technique for solving tri-diagonal equations on SIMD machines like the DAP and the MPP. Formally, for a single system of equations, $a_i x_{i-1} + b_i x_i + c_i x_{i+1} = k_i$, the technique is expressed by the following recursive formulae:

Left-Hand Side

$$a_i^{(\ell)} = -a_i^{(\ell-1)} a_{i-2^{(\ell-1)}}^{(\ell-1)} / b_{i-2^{(\ell-1)}}^{(\ell-1)} \qquad (8)$$

$$c_i^{(\ell)} = -c_i^{(\ell-1)} c_{i+2^{(\ell-1)}}^{(\ell-1)} / b_{i+2^{(\ell-1)}}^{(\ell-1)} \qquad (9)$$

$$b_i^{(\ell)} = b_i^{(\ell-1)} - a_i^{(\ell-1)} c_{i-2^{(\ell-1)}}^{(\ell-1)} / b_{i-2^{(\ell-1)}}^{(\ell-1)} - c_i^{(\ell-1)} a_{i+2^{(\ell-1)}}^{(\ell-1)} / b_{i+2^{(\ell-1)}}^{(\ell-1)} \qquad (10)$$

Right-Hand Side

$$k_i^{(\ell)} = k_i^{(\ell-1)} - a_i^{(\ell-1)} k_{i-2^{(\ell-1)}}^{(\ell-1)} / b_{i-2^{(\ell-1)}}^{(\ell-1)} - c_i^{(\ell-1)} k_{i+2^{(\ell-1)}}^{(\ell-1)} / b_{i+2^{(\ell-1)}}^{(\ell-1)} \qquad (11)$$

where

$\ell$ = step number

$a_i^{(\ell-1)} = 0;\ i \leq 2^{(\ell-1)}$

$c_i^{(\ell-1)} = 0;\ i \geq n-2^{(\ell-1)}$

After $\log_2 n$ steps, where n is the number of equations in a set, all coefficients $a_i$ and $c_i$ will have been eliminated, and the values of the unknowns are given by (11). It will now be shown how parallel cyclic reduction can be used to solve S sets of tri-diagonal equations like (4) simultaneously on the DAP.

[d] The description is confined to the installation at Queen Mary College (University of London), and the reader should be aware that there are DAP systems that differ from this one in a number of respects.

By applying (11) to the right-hand-side terms of equation (4), it follows that:

$$\alpha_i^{(\ell)} = \alpha_i^{(\ell-1)}; \qquad j_k \leq i < j_k + 2^{(\ell-1)} \tag{12}$$

$$\alpha_i^{(\ell)} = -a_i^{(\ell-1)} \alpha^{(\ell-1)}_{i-2^{(\ell-1)}} / b^{(\ell-1)}_{i-2^{(\ell-1)}}; \; j_{k'} \geq i \geq j_k + 2^{(\ell-1)}$$

$$\beta_i^{(\ell)} = \beta_i^{(\ell-1)}; \qquad j_{k'} - 2^{(\ell-1)} < j \leq j_{k'} \tag{13}$$

$$\beta_i^{(\ell)} = -c_i^{(\ell-1)} \beta^{(\ell-1)}_{i+2^{(\ell-1)}} / b^{(\ell-1)}_{i+2^{(\ell-1)}}; \; j_k \leq i \leq j_{k'} - 2^{(\ell-1)}$$

Comparing equations (12) and (13) with equations (8) and (9), respectively, we observe that:

(A) $a_i^{(\ell)} \neq 0$ for those values of i that $\alpha_i^{(\ell)} = 0$.

(B) The recursive formula for $\alpha_i^{(\ell)}$ when $j_{k'} \geq i \geq j_k + 2^{(\ell-1)}$ is identical to equation (8).

(C) $c_i^{(\ell)} \neq 0$ for those values of i that $\beta_i^{(\ell)} = 0$.

(D) The recursive formula for $\beta_i^{(\ell)}$ when $i_k \leq i \leq i_{k'} - 2^{(\ell-1)}$ is identical to equation (10).

(A) and (C) show that the coefficients $a_i^{(\ell)} \neq 0$ and $\alpha_i^{(\ell)} \neq 0$ and $c_i^{(\ell)} \neq 0$ and $\beta_i^{(\ell)} \neq 0$, respectively, can be merged into two vectors, each of length N. If these are declared as "long" vectors in DAP FORTRAN--in keeping with the previously specified memory mapping--it follows from (B) and (C) that their elements, and hence all S sets of equations, can be operated on in parallel on the DAP as long as $N \leq 4,096$. Furthermore, no extra arithmetic is required to compute $\alpha_i^{(\ell)}$ and $\beta_i^{(\ell)}$ compared with that which would be needed to solve a tri-diagonal problem with a single right-hand-side term.

2.3.3 Details of the DAP FORTRAN Code. Figure 2 is a DAP FORTRAN listing of the main subprogram in the implementation of our algorithm for solving almost tri-diagonal problems. SUBROUTINE NET_TRID_SOLVE first inverts S sets of equations of form (4) using parallel cyclic reduction as described in the preceding section. The vectors whose elements are $a_i^{(\ell)} \neq 0$ and $\alpha_i^{(\ell)} \neq 0$ and $c_i^{(\ell)} \neq 0$ and $\beta_i^{(\ell)} \neq 0$, respectively, correspond to LDC and UDC of Figure 2. To perform left-hand-side indexing operations on these vectors, three Boolean "long" vectors, or masks, MSK_JCT, RIGHT, and LEFT are used. Their effect is to disable writing into memory in those PEs whose logical positions in the PE array correspond to the positions of elements with value FALSE in the masks. For instance, the statement LDC(RIGHT) = -LDC... computes the coefficients $a_i^{(\ell)} \neq 0$ and $\alpha_i^{(\ell)} \neq 0$ with RIGHT inhibiting overwriting of the elements $\alpha_i^{(\ell-1)} \neq 0$: these are needed in the back-substitution step of the algorithm for solving sparse problems of form (1). The coefficients $\beta_i^{(\ell-1)} \neq 0$ are also needed in this step. Hence, in the statement UDC(LEFT) = -UDC..., which calculates $c_i^{(\ell)} \neq 0$ and $\beta_i^{(\ell)} \neq 0$, LEFT inhibits overwriting of these coefficients. Finally, MSK_JCT disables processing in those PEs that hold the coefficients of the m junction equations.[e] Thus, the parallelism achieved during the cyclic reduction of S sets of equations is (N-m)[O(N)]. After $n = O[\log_2 \max(j_{k'} - j_k + 1)]$ steps, all solutions of form (5) have been obtained, and the first stage of the algorithm is complete.

Now, the number of elements $\alpha_i$ and $\beta_i$ that have values different from zero doubles at each step in the cyclic reduction phase. Thus, at step $\ell$, $x_i$ is coupled to $x_{j_k}$ and $x_{j_{k'}}$ for $j_k + 1 \leq i < j_k + 2^{\ell}$ and $j_{k'} - 2^{\ell} < i \leq j_{k'} - 1$, respectively. If the values of $j_k$ and $j_{k'}$ are initially stored in the elements $(j_k+1)$ and $(j_{k'}-1)$, respectively, of two separate "long" vectors, rc and lc, then the elements of these vectors must be updated according to:

$$rc_i^{(\ell)} = j_k; \qquad j_k + 1 \leq i < j_k + 1 + 2^{\ell} \tag{14}$$

$$lc_i^{(\ell)} = j_{k'}; \qquad j_{k'} - 1 \geq i > j_{k'} - 1 - 2^{\ell} \tag{15}$$

where

k, k' = 1..m;
i = 1..N;

In Figure 2, RIGHT_JCT and LEFT_JCT correspond to rc and lc, respectively. The modification of the information stored in these "long" vectors, as specified by equations (14) and (15), is performed by using DAP FORTRAN built-in shift functions: SHRP propagates data from a PE to its "right" neighbor, and SHLP performs the same task in the "left" direction.

[e] The reader is reminded that these equations are set aside during the first stage of the algorithm described in Section 2.

Figure 2. DAP FORTRAN Listing

At the end of the cyclic reduction process, the coefficients $q_i$, $r_i$, and $p_i$ are held in the "long" vectors LDC, UDC, and C, respectively. In the case of a single tri-diagonal system of equations, $q_i$ and $r_i$ are all zero. Thus, C represents the solution of the system and no further processing need take place in NET_TRID_ SOLVE (see Figure 2).

Sub-programs SOLVE_2X2 and SUB_WRAP_TERMS perform the special eliminations that are required if a network represents a closed loop, while the substitutions from (5) into the m junction equations take place in SUBROUTINE JUNCTIONS. Both of these are sequential tasks, and no use of the DAP's parallelism can be made in performing them. It is thus vital to the efficiency of our algorithm for solving almost tri-diagonal problems that the number of junctions, m, in a network, as well as being very much smaller than the total number of nodes, N, also is small in absolute terms.

The subprogram that solves the closed mxm matrix problem for $x_{j_k}$ (k=1..m) is invoked by SUBROUTINE JUNCTIONS. On return from JUNCTIONS, the values of x are stored in the DAP FORTRAN vector SOL_JCT with element k being the value of $x_{j_k}$.

Finally, the back-substitutions for $x_{j_k}$ and $x_{j_{k'}}$ in (5) are performed by the DO 500 loop. At the start of each pass through this loop, the values of $j_k$ and $x_{j_k}$ are placed in J_CELL and X_VAL, respectively.

This is followed by the broadcasting of X_VAL to those PEs for which J_CELL is equal to $j_k$ or $j_{k'}$: the broadcasting is effected by the expressions J_CELL .EQ. RIGHT_JCT and J_CELL .EQ. LEFT_JCT. At the end of each pass through the DO 500 loop, the value of $x_{j_k}$ is placed in the $j_k^{th}$ element of C so that on return from NET_TRID_ SOLVE, the complete solution to a sparse matrix problem of form (1) is stored in this "long" vector.

## 3. Applications of the Algorithm for Solving Almost Tri-Diagonal Sets of Equations

The algorithm described here has been used to solve some fairly simple one-dimensional problems in nuclear reactor hydrodynamics on the DAP. In one case, a grid depicting a loop with two branches connected to it (see Figure 1) was used with the total number of nodes being 256. The different steps of the algorithm were timed, and the results, together with estimates for a 1000-node case, are summarized in Table 1. It will be seen that the scalar operations (SUBROUTINE SUB_WRAP_TERMS, JUNCTIONS, and SOLVE_2X2) consume less than 10 percent of the total processing time. This demonstrates that the algorithm uses the DAP's parallel processing power efficiently, provided the requirement m<<N is satisfied. Ideally, of course, N should be 4,096, since this allows the full parallelism of the DAP to be exploited.

Table 1. Breakdown of Processing Time Spent in Different Parts of Algorithm for Solving Sparse Linear Problems With an Almost Tri-Diagonal Structure

| | Number of Network Nodes | |
|---|---|---|
| Code Section | 256 | 1000* |
| SUBROUTINE NET_TRID_SOLVE | 118 ms | 141 ms |
| SUBROUTINE SUB_WRAP_TERMS | 11 ms | 11 ms |
| SUBROUTINE JUNCTIONS | 5 ms | 5 ms |
| SUBROUTINE SOLVE_2X2 | 1 ms | 1 ms |

ms = milliseconds

* Figures are estimates

## 4. Conclusions

An algorithm for solving almost tri-diagonal sets of equations on SIMD computers like the DAP and MPP has been described. The algorithm exploits the sparsity structure of this class of problems, thereby allowing parallel cyclic reduction to be used as the main step in the solution procedure. It has been demonstrated that this results in efficient use of the DAP's processing power in solving problems with an almost tri-diagonal structure, provided the number of equations is comparable to the parallelism of the machine (4,096).

# BLOCK-ORIENTED, LOCAL-MEMORY-BASED LINEAR EQUATION SOLUTION ON THE CRAY-2: UNIPROCESSOR ALGORITHMS

D. A. CALAHAN

Dept. of Electrical Engineering and Computer Science
University of Michigan
Ann Arbor, MI, 48109-1109

## ABSTRACT

Experience with the CRAY-2 on the effects of common memory speed and loading on performance indicate that local-memory-based algorithms have potentially a large advantage. The performance of a number of common- and local-memory algorithms are compared for the LU factorization of a dense system of equations on the CRAY-2. A two-level blocked algorithm is introduced to allow both pivoting and high asymptotic performance. Measurements show as much as a 6:1 speedup between blocked assembly-language versus (traditional) vectorized Gauss Fortran implementations; the contributions of both the algorithm and the language to this speedup are evaluated.

## Introduction

### CRAY-2 Architecture and Algorithm Implications

The CRAY-2 architecture (Figure 1) has several features relevant to this algorithm study.

(a) Common memory features.The massive common memory (CM) trades size for access time, so that a considerable delay is usually encountered in reading from CM. Also, only one data path connects common memory to each processor's functional units.

(b) Local memory. The above speed disadvantages are compensated by a local memory (LM), which serves as backup vector and scalar storage for the functional unit's register storage.

(c) Chaining. The CRAY-2 does not have hardware chaining; this must be achieved by software and/or algorithm means.

The implications of distributed memory (including hierarchies such as CM and LM) on linear algebra algorithm organization has been studied since the existence of paged memory systems [1][2][3][4]. In general, computations must be arranged so that the number of floating-point operations on data at the low memory levels is sufficient to warrant data transfers to these levels. This implies, for example, that a matrix-vector multiply - which involves only two operations for each matrix data element - may perform less efficiently than a matrix-matrix multiply.

### Review of Vector Linear Algebra Algorithms

The asymptotic execution rate (MFLOPS) of a factorization algorithm is equal that of the kernel that performs the add-multiplies associated with reducing rows and columns. Three substantially different such algorithms deserve consideration.

Gauss vector-scalar multiply. This requires that, in reducing the rth row , successive operations on preceding rows must be performed serially since a partial result from each row-operation is used as an operand in the next one (the reader is assumed familiar with this procedure). In rows with lengths longer than the vector functional unit length, this dependency can usually be avoided by assembly coding; it is then termed the GAXPY kernel. It has the advantage of yielding the largest average vector length of any of the following kernels and so is a serious consideration when the matrix size is not significantly larger than the maximum allowable vector length, and assembly coding is allowed. This procedure does not lend itself to partitioning when large matrices are involved, but is a potentially useful subalgorithm in such cases.

Matrix-vector multiply. Early experience with the CRAY-1 indicated that block-oriented algorithm organization had at least a pedagogical advantage for large problems[5][6]. Unfortunately, the necessary {vector - (matrix*vector)} kernel was not made a part of the CRAY scientific library and consequently the kernel was not syntactically distinguished from the rest of CAL-coded factorization algorithms. The organizational concept of basing factorization on matrix-vector multiply subroutines was developed in [7][8], where it was illustrated how unrolling Fortran loops could be used to achieve a high performance completely from a high-level language. This emphasized portability and maintainability. More recently, these kernels - known as second-level BLAS - have been proposed as the basis for other common linear algebra algorithms[9].

Matrix-matrix multiply. Although it has always been clear that factorization can be accomplished by a matrix-matrix multiply kernel, the CRAY-1 memory hierarchy was not sufficiently distinctive to achieve a significant advantage over the above two kernels[3]. The additional memory paths of the X-MP made this even less attractive, and partially reduced the advantage of the matrix-vector multiply above. The disadvantages of basing factorization on matrix multiplies are the necessity for other matrix-level kernels to perform reciprocations and substitutions and, most important, the difficulty of partial pivoting.

The memory distribution must be quite distinctive to warrant the programming effort of matrix*matrix-based factorization. This paper documents this case for the CRAY-2, while laying the groundwork for a multiprocessor implementation.

## Pivoting Algorithms

### M*V-based Algorithms

Given a set of equations*

$$\mathbf{A}X=B$$

where **A** is an nxn matrix and X and B are vectors, the factorized solution proceeds by forming lower and upper triangular factors **L** and **U**, viz

$$\mathbf{A} = \mathbf{LU} \tag{1}$$

and then solving for Y and X in substitution steps

$$\mathbf{L}\,Y = B, \qquad \mathbf{U}\,X = Y$$

The complexity of the factorization step of Eq. (1) is $O(n^3)$. The substitutions have complexity $O(n^2)$, with only one add-multiply for each **L** and **U** element; consequently no algorithmic speedup results from transferring **L** and **U** to local memory, so that these substituion steps will not be studied.

*Matrices are in bold, vectors are in upper case, and scalars are in lower case type.

0190-3918/86/0000/0375 $01.00 © 1986 IEEE

For algorithms based on a matrix-vector multiply (abbr. M*V-based), the columns of L and rows of U are indicated as in Figure 2. Here the diagonal element, the row to its right, and the column below it are denoted $a_{22}$, $A_{12}$, and $A_{21}$ respectively. Ignoring pivoting for the moment, the steps to perform the factorization are then

$$\left|\begin{matrix} a_{22} \\ A_{32} \end{matrix}\right| \longleftarrow \left|\begin{matrix} a_{22} \\ A_{32} \end{matrix}\right| - \left|\begin{matrix} A_{21} \\ A_{31} \end{matrix}\right| A_{12} \qquad (2)$$

$$A_{23} \longleftarrow A_{23} - A_{21} A_{13} \qquad (3)$$

$$a_{22} \longleftarrow 1/a_{22} \qquad (4)$$

$$A_{32} \longleftarrow a_{22} A_{32} \qquad (5)$$

The performance of the matrix*vector kernel of Eqs. (2) and (3) depends on the implementation; even Fortran codings have radically different performance (see Appendix).

## M*M-based Algorithms

### Multiply kernel (level 1)

Another matrix partition permits the factorization to be performed on submatrices (Figure 3). The equations equivalent to (2) - (3) are

$$\left|\begin{matrix} A_{22} \\ A_{32} \end{matrix}\right| \longleftarrow \left|\begin{matrix} A_{22} \\ A_{32} \end{matrix}\right| - \left|\begin{matrix} A_{21} \\ A_{31} \end{matrix}\right| A_{12} \qquad (6)$$

$$A_{23} \longleftarrow A_{23} - A_{21} A_{13} \qquad (7)$$

where $A_{22}$ is an $n_d x n_d$ matrix. This multiply kernel has an asymptotic execution rate of approximately 400 MFLOPS when written in assembly language (CAL) and executing from LM with $n_d = 64$. This includes time to transfer to/from CM from/to LM under a daytime memory load condition.

### Pivoting and block reduction (level 2)

On a vector machine such as the CRAY-2, partial column pivoting has two components: (1) the search for the maximum element of a column, and (2) exchange of two complete rows of the matrix. The latter is usually preferred over maintenance of an index pointer in order to avoid relatively slow indirect addressing. These two functions are denoted

$$a \longleftarrow \text{piv} \{ s, V \}$$

where $a$ is the element of maximum absolute value of scalar s and the elements of vector V.

In M*V-based factorization this search is routinely performed after Eq. (2) or (3) by the step

$$a_{22} \longleftarrow \text{piv} \{ a_{22}, A_{32} \} \qquad (3a)$$

However, in the M*M-based version, the granularity of the algorithm does not recognize individual matrix elements and columns. The problem then becomes to preserve the high performance of the matrix-matrix multiply by performing the majority of computations at the block-level, yet to occasionally expose individual columns to permit pivoting. The solution is the following 2-level algorithm (Figure 3).

In level 1, Equations (6) and (7) are first carried out as an $O((n/n_d)^3)$ process. The columns of the resulting $A_x = [ A_{22}^T \ A_{32}^T ]^T$ block-column matrix are at this point partially reduced, with all the accumulations from the columns of $A_{31}$ performed but without contributions from the internal columns of $A_x$. Level 2 begins by reducing $A_x$ using either a GAXPY kernel or the M*V method of Eqs. (2)-(5), viz (an underline represents components of this second reduction level)

$$\left|\begin{matrix} \underline{a}_{22} \\ \underline{A}_{32} \end{matrix}\right| \longleftarrow \left|\begin{matrix} \underline{a}_{22} \\ \underline{A}_{32} \end{matrix}\right| - \left|\begin{matrix} \underline{A}_{21} \\ \underline{A}_{31} \end{matrix}\right| \underline{A}_{12} \qquad (8)$$

$$\underline{A}_{23} \longleftarrow \underline{A}_{23} - \underline{A}_{21} \underline{A}_{13} \qquad (9)$$

$$\underline{a}_{22} \longleftarrow \text{piv} \{ \underline{a}_{22} , \underline{A}_{32} \} \qquad (10)$$

$$\underline{a}_{22} \longleftarrow 1/\underline{a}_{22} \qquad (11)$$

$$\underline{A}_{32} \longleftarrow \underline{a}_{22} \underline{A}_{32} \qquad (12)$$

The computations of Eq. (8-12) are performed from CM and will so be slowed by memory access delays. The execution rate of this step is approximately 125 MFLOPS, using a CAL-coded pivot search.

Eqs. (8)-(12) have the effect of performing the block factorization and substitution steps

$$A_{22} \longleftarrow L_{22} U_{22} \qquad (13)$$

$$A_{33} \longleftarrow A_{32} U_{22}^{-1} \qquad (14)$$

Level 2 is then completed by the block substitution

$$A_{32} \longleftarrow A_{32} L_{22}^{-1} \qquad (15)$$

This can be carried out in local memory at a speed somewhat less than 200 MFLOPS.

With $n_d$ fixed, the complexity of level 2 is readily shown to be $O(n^2)$, whereas the M*M kernel complexity remains $O((n/n_d)^3)$. For large n, the execution rate should therefore approach that of the multiply kernel or approximately 400 MFLOPS.

## Performance

Both the M*V- and the M*M-based pivoting algorithms were run on the MFECC CRAY-2 in November, 1985, using the CIVIC Fortran compiler and CRAY-2 assembly langusge (CAL). Figure 4 presents the results of a number of algorithms and implementations.

The poor performance of the conventional vectorized Fortran Gauss algorithm is due to the lack of chaining and the long, single path to CM. A significant advantage accrues from use of the M*V algorithm, with or without use of CAL. The superior performance of the M*M-based solution eventually becomes evident for $n \geq 1000$; indeed the latter is the best algorithm for all but the smallest n shown. However, it would likely not be worth the programming effort for matrices in the order of n = 100.

Although such large matrices can rarely be factored without pivoting, it is interesting to observe the degradation due to introduction of the 2-level algorithm. The CRAY-2 implementation the piv{ s, V } function of Eq.

(3a) requires a fixed overhead dependent only on the length of V and independent of the matrix element values. Consequently, it is possible to delineate between the pivoting speedown due to piv{ s, V } and that due to the 2-level nature of the algorithm. These are presented in Figure 5 for the M*M algorithm. For n $\geq$ 256, the larger degradation is the result of the piv { s, V } function. Since the latter cannot be avoided, the algorithmic speedown from the introduction of a second level does not appear significant.

### Parallel Implementations

In general, the partitioning of an algorithm into larger computational tasks favors a parallel implementation, since fewer task startups are involved. Thus, an M*M-based algorithm seems advisable, with $n_d$ large. However, in a CRAY-2 system dedicated to an equation solution (a somewhat unlikely event), equalizing the workload among the processors (load-leveling) also becomes an issue; this favors smaller tasks associated with M*V-based factorization or else a smaller $n_d$. These issues are currently under investigation.

## APPENDIX

Fortran statement complexity has a significant impact on the performance of linear algebra and other scientific codes. This is illustrated in Figure 6, where the M*V Fortran kernel is unrolled and the resulting performance plotted. Performance continues to increase significantly for unrollings as large as 32, in contrast to the X-MP, where a 4-way unrolling is considered satisfactory. This phenonenom is considered to be the result of above-mentioned architectural featires. A 16-way unrolling is used in the M*V kernels cited in Figure 4.

## ACKNOWLEDGEMENT

High-performance CAL kernels used in the equation solvers were developed by Geoffrey Carpenter, U. M. Fayyad, and Jimmy Hsiao with a CRAY-2 instruction-level timing simulator developed by K. B. Elliott, as part of a CRAY-2 scientific library sponsored in part by NASA Ames Research Center [11 ].

The research was sponsored by the Mathematical and Information Sciences Directorate of the Air Force Office of Scientific Research under Grant AF-AFOSR 84-0096. CRAY-2 time was provided by MFECC, Lawrence Livermore National Laboratory.

University Park, PA 16802

## ABSTRACT

Recent interests in the so called 5th generation machines and languages coupled with the inefficiency of conventional machines in handling large volumes of non-numeric data, have given a new dimension to the design and implementation of data base machines. The majority of these architectures are based on the relational model, because of its simplicity and the mathematical foundation on which this model is based. Among the primitive relational operations, literature has placed the greatest emphasis on join. This is because of its complexity and the practical applications of the join operation in combining relations with common domain(s). This paper introduces an associative parallel join algorithm and its hardware design. In addition, it addresses the VLSI time/space complexity of the proposed model, as well as its performance evaluation.

## 1. INTRODUCTION

Continuing interests in data base systems coupled with advances in technology have motivated special purpose architectures. These architectures are designed to remove the shortcomings of the conventional von-Neumann design in the efficient handling of large volumes of non-numeric operations. In addition, recent discussions about knowledge base machines [16], and logic data bases have opened a new door for further research in this area. Finally, the definition of 5th generation languages such as PROLOG [13] calls for the practical/efficient implementation of these languages which necessitates the design and implementation of data base architectures.

The architecture of these special purpose systems is based on constraints which are imposed by the data base environment, i.e., associating name space with the information space at the high level, and performing a sequence of simple and repetitive non-numeric operations on a massive amount of data at the low level. Data base machines have met these conditions by:

i) searching and selecting the data at or near secondary storage in an associative fashion, and

ii) hardware implementation of suitable parallel algorithms for non-numeric operations.

In contrast to conventional architectures, such a direction eliminates the existing address mapping resolution and reduces the data transportation and semantic gap. The underlying structure of the majority of these architectures are based on the relational model [4]. This is due to the following reasons:

i) The simplicity of the relational model,

ii) The strong mathematical foundation on which the relational model is based, and,

iii) The one-to-one mapping between the representation of data and primitive operations in logic programming and the relational model [4, 6].

In practice, the performance of a relational data base system has been associated with the join operation. Such an association is based on the practical applications of the join in the queries and the complexity of the operation. This complexity directly affects the time and space efficiency of the join operation. Different hardware/software algorithms have been defined and implemented to improve the efficiency of such operation. This paper addresses a hardware module for the join operation along with its performance evaluation. Section 2 overviews some of the proposed join algorithms. Section 3 introduces the overall organization and the flow of data and control in the proposed architecture. Section 4 discusses the VLSI time/space complexities of the proposed model, and finally, section 5 evaluates the performance of the model.

0190-3918/86/0000/0379 $01.00 © 1986 IEEE

## 2. BACKGROUND

Join has been defined as a binary operator which combines two relations over their common attribute(s). Formally, let r(R) and s(S) be two relations and let $A \varepsilon R$ and $B \varepsilon S$ be $\theta$ compatible, where, $\theta \varepsilon \{=, \neq, <, >, \leq, \geq\}$, then $r[A\theta B]s$ is defined as:

$\{t| t_r(A)\theta t_s(B)$ and $t(R)=t_r$ and $t(S) = t_s\}$.

In a uniprocessor environment, three classes of join algorithms have been studied, namely nested loops, sort-merge, and hashing, with respective execution times of $0(n^2)$, 0(nlgn) and O(n). However, in a thorough evaluation of these algorithms, parameters such as communication, simplicity, regularity, space efficiency... etc., should also be taken into consideration. In the data base architecture where a higher performance and throughput is cited, the discussion about join should center around a parallel version of these algorithms. Although there are some designs which have ignored such a discussion[2,19], there is no reason to accept that they would not be able to perform this function. The assumption is that either a front-end machine or a dedicated join module will do the job.

Literature has studied different algorithms for join in both uniprocessor and multiprocessor environments[3,21]. In the following discussion, some of these algorithms which are proposed for systems on the exhaustive search policy will be overviewed:

CAFS[1] utilizes a hashing scheme. It can perform the semi-join operation by marking an array of bits based on the tuples in r and then using this array to select proper tuples in s. However, the architecture has not addressed the implementation of the Θ-join. Based on the hardware capability of the design, such an operation is expensive since it requires several passes over the data file.

RAP[17] has studied two types of join namely implicit (e.g. semi-join) and physical (e.g. Θ-join); the latter can be carried out as a sequence of implicit joins. The algorithm is based on the concept of nested loops, with some degree of parallelism, which is determined according to the number of read/write heads and the hardware capability of each read/write head.

DIRECT[5] is capable of performing a block oriented version of nested loops with some degree of parallelism (e.g. number of processors). During each iteration, a block (page) of the outer relation (say (r)) will be joined with entire blocks of the inner relation(s) which are distributed among different processors. Within each processor a simple sort-merge algorithm will be utilized to join two blocks together.

DELTA[7] has defined a parallel version of the sort-merge algorithm in its design: 12 sorters in parallel sort the relations in sequence based on the join attribute, and then a single merger is utilized to merge the sorted relations.

The performance of these algorithms has been formulated and compared against each other. Bitton et. al.[3] have shown that in a uniprocessor environment, the sort-merge algorithm has a better performance than nested loops. However, in a multiprocessor environment such as DIRECT, the nested loops algorithm outperforms sort-merge. This is due to the higher degree of parallelism in the operation, and better processor utilization made by the nested loops algorithm.

Valduriez and Gardarin[21] have compared the performance of a block oriented version of nested loops, parallel sort-merge, and parallel hashing schemes against each other. They have shown that in general, if the number of accesses to the hashed file is low, hashing algorithms offer a better performance than the other two techniques. Moreover, for relations of the same size, the sort-merge algorithm has a better performance. Finally, if the ratio between the relation sizes is different from 1, nested loops algorithm is the superior method.

The evaluation process as above[3,21] partially represents the relative behavior of these algorithms. A thorough evaluation and comparison should address:

i) The merit of each approach based on the environment, and

ii) Equally important parameters such as, space and processor utilization, ease of implementation from hardware/software point of view, processor-memory intercommunication and finally, practical overhead and practical limitations.

## 3. PROPOSED ARCHITECTURE

Associative memory has been defined as: "a collection or assemblage of elements having data storage capabilities, and which are accessed simultaneously and in parallel on the basis of data content rather than by specific address or locations,"[14]. Content addressability of data implies that each basic cell of memory should have the hardware capability to perform read, write, and search operations. Such a capability eliminates name resolution problem[9] and reduces the bottle neck between memory and CPU.

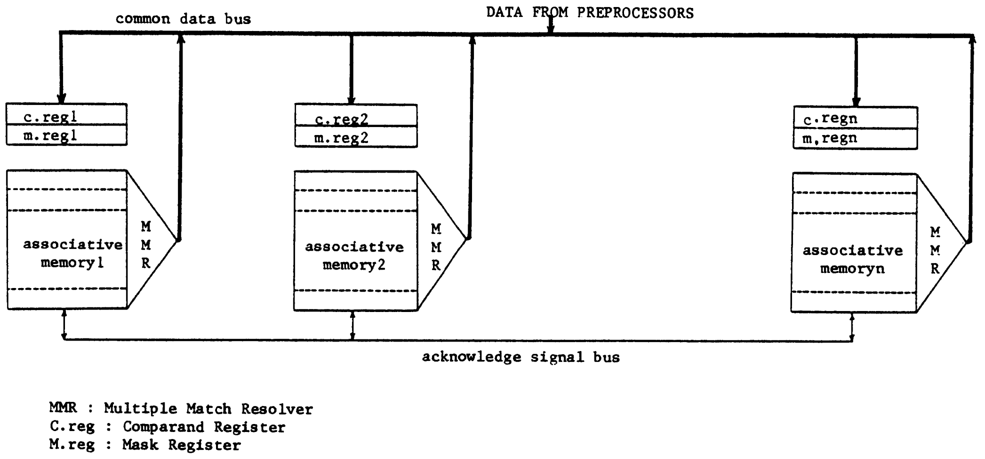

Figure 1 : Overall Organization of the Proposed Join Module.

Associative memory provides a suitable and fast medium for representation of the relational model and implementation of the basic relational operations. This stems from the fact that the representation of data in the associative memory is similar to the tabular representation of the data in the relational model. In addition, attributes in the relational data model are equally available to be searched, as in the associative memory where search can be performed on any defined field. Finally, there is a one to one mapping between the set operations and the associative operations.

The proposed join module is a collection of n identical and independent modules of associative memory (Figure 1). Associative memories can transfer data among each other under the control of a master controller, via a common data bus. In addition, they can pass control signals through a chain of acknowledge bus. These modules can be linked together to make a memory of size (k*w)*d ($1\leq k\leq n$, w is the word length and d is the depth) capable of holding d tuples of size k*w each, or they could be linked to form a memory of size w*(k*d) capable of holding k*d tuples of size w. This facility enables the system to adjust the available memorybased on the length of the tuples and the cardinality of the relation. The independence of the associative memories from each other enhances the modularity of the system and as such the fault tolerance of the system.

With respect to a query, domains in a relation (say r with relation scheme R) can be grouped into three classes:

i) those which are defined as a member of the search argument part (i.e., SA = $\{R_i | R_i \in R$ and $R_i \in$ search argument$\}$),

ii) those which are the member of the output set part (i.e., OS = $\{R_i | R_i \in R$ and $R_i \in$ output set$\}$), and

iii) those which are not the members of SA or OS (i.e., $\{R_i | R_i \in R$ and $R_i \notin (OS \cup SA)\}$).

Our assumption is that the relations are preprocessed before being routed to the join module, and then the selected tuples are passed to this module. In other words, a subset of the relation ($r_s$) with a relation scheme ($R_s$)will be explicitly stored in the join module:

$R_s \subseteq R$ and $\forall\, T_s \in r_s \Rightarrow T \in r$ such that

$T_s = T[OS]$ and $T[SA] \equiv$ search argument

This assumption is in accordance with the 90-10% rule.

The proposed join module performs a concurrent version of the nested- loops algorithm. Concurrency is achieved as a result of:

i) embedded parallelism in the associative operations, and

ii) the independence of associative memories from each other.

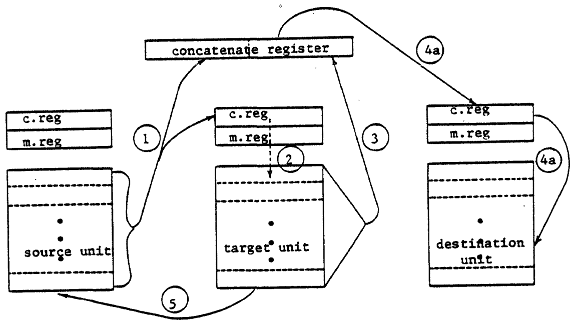
Therefore, we have parallelism within each associative memory and overlapping across the memories. For a join operation, three memory modules will be tightly coupled together (Figure 2). In our discussion we call them, source, target and destination modules respectively. Interestingly, one can utilize random access memory modules to house source and destination relations. However, for the sake of the uniformity and generality of the proposed join module, in the rest of this paper we assume three associative memory modules to house source, target and destination relations. Tuples from the source module (source-tuples) are routed to the concatenate-register and target module (1) one at a time. A source-tuple is searched against the contents of the target module (2). In case of a match, the selected tuples are routed to the concatenate-register in pipeline fashion (3). The result of concatenation is then sent to the destination module (4). When, the selected tuples in the target module are about to be exhausted, an acknowledge signal is sent to the source module informing the need for a new tuple (5).

The order of this algorithm with respect to the number of searches is O(n), as opposed to $O(n^2)$ in the uniprocessor systems. Moreover, because of the interaction between the source and target memory modules (acknowledge signal bus), operations in the source memory can be initiated and overlapped with operations in the target memory. From this discussion, one can conclude that the steps ① , ④ , and ⑤ are overlapped with step ③ (Figure 2). Algorithm 1 represents the sequence of operations according to the notations and the organization which have been adopted in this paper. The generality and adaptability of the associative operations increases the versatility of the proposed model in performing different variations of the join operations (e.g. natural join, semi-join) without additional hardware overhead.

The proposed model can be extended over a parallel execution of a sequence of interrelated joins. Such a concept is of special interest in a PROLOG type logic programming environment[13].

```
FOR ALL $t_r \in r$ DO;
    parallel search $t_r$ against s
    while there is a $t_r$ such that $t_r(A) \theta t_s(B)$
        $q = t_r || t_s$
    end;
end;
```

ALGORITHM 1: AN ASSOCIATIVE JOIN



① source tuple to concatenate-reg & target module

② associate search

③ target tuple to concatenate-reg

(4a) destination tuple to destination unit

(4b) store

⑤ acknowledge signal

## 4. VLSI TIME AND SPACE COMPLEXITIES OF THE PROPOSED MODEL

In the design and development of a topology for current technology, one should remember the practical constraints which are imposed by the VLSI technology. The idea is to reduce the execution time as well as the communication through the replication of a few basic blocks in time or space. A fully parallel associative memory bears these conditions and hence is suitable for VLSI implemention. This is not the intension of this article to discuss the organization of associative memory, the interested reader is referred to [14, 20, 22]. In this section we will calculate the VLSI time and space complexities of the proposed model according to the design rules discussed in [15]. Our associative module, should be able to perform read, write and different variations of search operations with resepct to the contents of the mask and word select registers. In our design each cell of the mask, comparand, and memory is a dynamic RAM cell refreshing itself during the second phase of a 2-phase clock system. Figure (3) depicts the stick diagram of the interaction between one bit of mask and comparand registers according to the following interpretation:

$$\begin{array}{lll} One1_j=1 & \text{iff} & M_j=1 \text{ and } Comp_j=1 \\ Z1_j=1 & \text{otherwise} & \end{array}$$

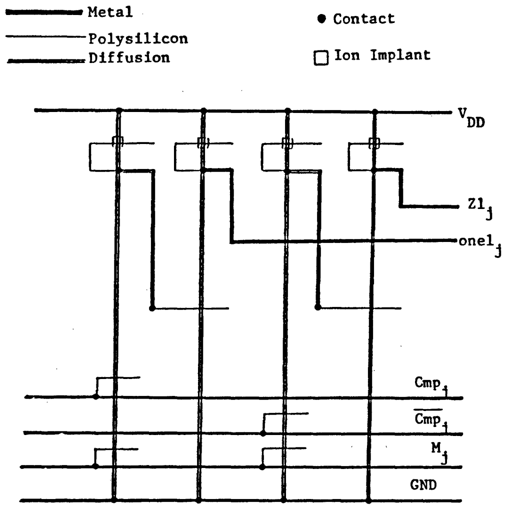

Figure 3: interconnection between mask and comparand registers.

the $Zl_j$ and $Onel_j$ are run in metal and shared by the $j^{th}$ bit of each memory word. The associated circuitry for read/write operations and selection of a selected word has been discussed in [23]. In order to simplify the memory cell and hence to reduce the size of the module: i) control signals (i.e., word select, search) are used at the word level rather than the bit level. In other words, the search is carried out for all the words, and then, the tag bit is set according to the control lines and the word select signal. ii) the searches on equality, in equality, less than equal, greater than equal are performed based on searches on less than and greater than.

Figure (4) represents one bit of the memory cell and the circuitry associated with it, where $C_{i,j}$ ($\overline{C}_{i,j}$) is the content of the $j^{th}$ bit of the $i^{th}$ word, $L_{i,j-1}$, $\overline{L}_{i,j-1}$, $G_{i,j-1}$, and $\overline{G}_{i,j-1}$ are less than and greater than signals generated by the left most bit (e.g. j-1) and finally $L_{i,j}$, $\overline{L}_{i,j}$, $G_{i,j}$, and $\overline{G}_{i,j}$ are the less than and greater than signals generated by the $j^{th}$ bit of word i. Figure 5 depicts the circuitry around the tag bit according to the above discussion, LT, GT, and EQ are the less than, greater than, and equality control lines respectively.

Assuming the $\Delta\tau$ be the average delay time of an inverter, then, the search time is calculated based on: i) 4 parallel delay for a 3-input NAND gate and an inversion, II) (n-1) $2\Delta\tau$ serial operation of (n-1) NOR gates and an inversion, and iii) $9\Delta\tau$ delay for setting the tag bit. Resulting in a total delay time of:

$13\Delta\tau + 2(n-1)\Delta\tau$ (n is the word length)

i) The geometry area of a cell is estimated at $200\lambda * 100\lambda$ including the area needed for routing the signals among the cells. Thus, an associative memory of m words, each n bits long requires an area of: $200n\lambda * 100m\lambda$ For m=512, n=256, $\Delta\tau=1$ ηsec. and $\lambda=1$ μm we will have a search time of less than 1000ηsec for an environment of $2^{17}$ bits (including the expected complexity due to the read/write circuitry around each cell). In addition, the geometry area for the above configuration is estimated to about 5 cm * 5cm.

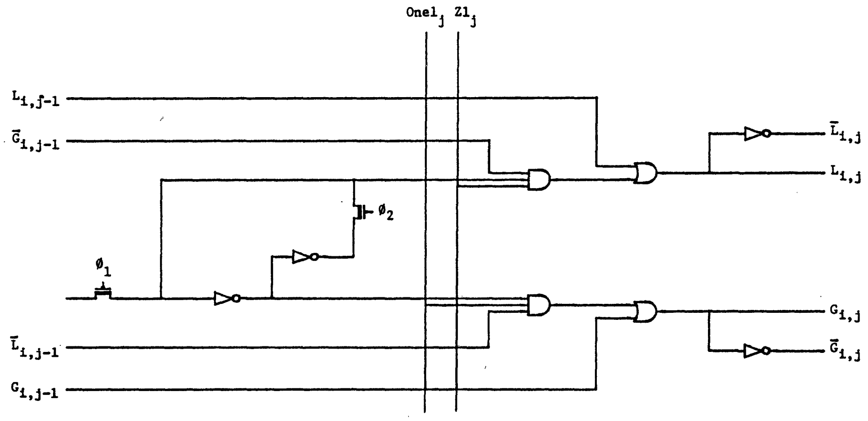

Figure 4: A Memory Cell.

## 5. PERFORMANCE EVALUATION OF THE PROPOSED MODEL

The objective of this seciton is two fold: First, the timing analysis of the proposed model is discussed and then its performance is calculated and compared against some of the available models in the literature.

### Execution time analysis

Our timing analysis is based on the sequence of operations discussed in Algorithm 1 and the following notations.

i) No ordering is imposed on the storage policy - i.e., unordered data file.

ii) According to 90-10% rule, the source and target relations are preprocessed before being transferred to the join module.

iii) Parallel preprocessors share a common cache memory with a hit ratio (H) of 85%. The organization of such intermediate memory between the secondary memory and array of preprocessors is similar to the model in [3,21].

iv) Size of associative memories (e.g. associative blocks) are different from the page sizes in secondary storage. This is due to the reconfigurability of the associative memories (section 3) and the technology.

v) n,m: Number of pages in the source and target relations respectively.

$C_r$: Time to read and pass one page from the cache memory to the preprocessors. It is defined as:

$$C_r=H(R_m)+(1-H)(R_m+R_c) \qquad (1)$$

where $R_m$ and $R_c$ are the page read time of secondary storage and cache memory respectively, and H is the hit ratio.

$C_{select}$: Time to select and project tuples in a page. This is proportional to the number of tuples in a page.

$$C_{select}=K*(T_{select} + T_{project}) \qquad (2)$$

$C_f$: Compaction factor defined by 90-10% rule [9].

P: Number of preprocessors.

$\delta$: The ratio between the associative memory block size and cache memory page size - i.e.,$\delta$=T/K where T and K are the number of words in an associative memory and cache page respectively.

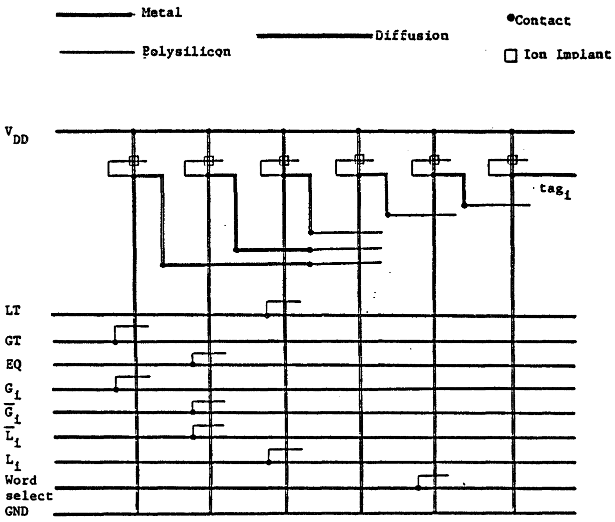

Figure 5: Circuitry around a tag bit.

$C_{PA}$: Time to fill out one associative memory by the preprocessors.

$C_{join}$: Time to join two associative memories together (equation 4).

$C_W$: Time to pass the contents of an associative memory to the front-end processor.

S: The join sensitivity factor. It is defined as the average number of tuples in the target relation which are joined with a tuple in the source relation. It should be noted that due to the preprocessing operation, the data in the associatve memories are more sensitive to the join operation. Therefore, the join sensitivity factor in our design should be higher than the one proposed in [3].

According to these parameters, the execution time of the operation is calculated as:

$$T_{NL} = (\frac{n+m}{P})\ (C_r + C_{select}) + \left\lceil\frac{n*C_f}{\delta}\right\rceil \Big(C_{PA} + \left\lceil\frac{m*C_f}{\delta}\right\rceil (C_{PA}) + C_{join} + S(C_W)\Big) \qquad (3)$$

In which:

$$C_{join} = C_{initial} + C_{read} + T\Big((C_{search}) + S(C_{read})\Big) + C_{ter}. \qquad (4)$$

where:

$C_{initial}$: represents the initial time which one has to spend before initialization of join operation (i.e., setting the mask registers).

$C_{read}$: is the time needed to read out a record from an associative memory module and pass it to the proper destination.

$C_{search}$: is the time needed to search the contents of the comparand register against the contents of the memory in associative fashion. This is a function of the word length and isindependent from the depth of the associative memory.

According to our implementation (Section 4), the search time is unique for equality and greater than/less than operations.

$C_{search}$: $C_{search} = aQ+b$ where Q is the word length and a,b are constant values which are defined by technology.

$C_{ter.}$: is the overhead time which is needed to terminate the operations (i.e., passing the last acknowledge signal to controller, etc.).

Performance Evaluation

Our evaluation and comparison are based on the time analysis of the basic operations as are dictated by the current technology. A detaileddiscussion for the time analysis of the basic operations is given in [24].

Table 1 depicts the execution time of the join module for different word sizes. In addition, Table 1 shows the estimated size of the source and target relations with respect to the 90-10% rule. As can be seen, the join operation between two relations of 256K and 2048K sizes regardless of the input/output operations is about 18 msec.

Table 2 shows the execution time of the proposed model against the models in [3, 21]. All the models in table 2 are based on the nested loops policy. The choice of the algorithm regardless of the uniformity among all algorithms is due to the fact that the nested loops algorithm in a parallel environment offers a better performance and resource utilization (Section 2), than the algorithms based on sort-merge and hashing.

## 6. CONCLUSION AND FURTHER DISCUSSION

An associative nested loops algorithm for join operation has been discussed. It has been shown that in a parallel environment a join operation based on the nested loops policy offers a better performance than algorithms based on the hashing or sort-merge policies. However, through the time analysis we have shown that the proposed algorithm has a better performance than the proposed models in [3, 21] by a factor of 7. In addition, the generality of the associative operations on one hand, and the one to one mapping between the relational operations and associative operations on the other hand can provide a general purpose module for relational operations. This increases the resource utilization of our model in comparison to other proposed models, which are utilized just by the join operation. Finally, our model is capable of handling a sequence of the interrelated join operations in parallel. A feature which is missing in all other proposed models.

TABLE 1: EXECUTION TIME OF THE PROPOSED JOIN MODEL.

| WORD SIZE (Byte) | EXECUTION TIME(msec.) | SOURCE RELATION (Byte) | TARGET RELATION (Byte) |
|---|---|---|---|
| 64 | 4.44 | 64K | 512k |
| 128 | 8.8 | 128K | 1024K |
| 256 | 17.54 | 256K | 2048K |

TABLE 2: EXECUTION TIME OF THE DIFFERENT JOIN MODELS.

| MODEL | EXECUTION TIME(msec.) |
|---|---|
| $T_{NL}$ (proposed model) | 926.93 |
| $T_{NL}$ (Bitton et.al.) | 6593. |
| $T_{NL}$ (Valduriez et.al.) | 6610.44 |

The regularity and, modularity of associative memory, and simplicity of each basic cell has provided a suitable ground for VLSI implementation of the proposed architecture. Our VLSI time and space analysis have shown that the proposed model is well within the range of the current technology.

In the past, due to the high cost of hardware, a wide range applications of associative processing were not feasible. It has been estimated that a basic associative cell is about 2-3 times more complex than a basic cell of random access memory. In addition, an associative module requires a special I/O connections for fast processing. However, because of its preprocessing capability the proposed model utilizes the same I/O connections as the models in [3, 6, 21]. Moreover, improvement in technology and hence cost reduction of the hardware modules, have made it feasible to increase the utilization of associative processing.

# A New VLSI System For Adaptive Recursive Filtering*

**Kam Hoi Cheng and Sartaj Sahni**
Computer Science Department
University of Minnesota
Minneapolis, MN 55455

## ABSTRACT

We develop an efficient bidirectional chain VLSI system for the adaptive recursive filtering problem. Our design is an improvement over previous designs. It matches the performance of a broadcast chain but does not use the broadcast capability.

**Keywords and Phrases**
VLSI architectures, systolic systems, adaptive recursive filtering

## 1. Introduction

VLSI architectures for a variety of problems have been proposed by several authors. A bibliography of over 150 research papers dealing with this subject appears in [KUNG83]. In this paper, we are concerned solely with the adaptive recursive filtering problem. The input to this problem is an $n \times w$ matrix $A$ of weighting coefficients and an $1 \times w$ vector $(x_{1-w}, ..., x_0)$. The output is a $1 \times n$ vector $(x_1, ..., x_n)$ where:

$$x_i = \sum_{j=1}^{w} a_{ij} \; x_{i+j-w-1} \qquad i = 1, 2, ..., n \qquad (1)$$

In evaluating a VLSI design, we assume that the VLSI system will be attached to the host processor using a bus. The evaluation of a VLSI design should take the following into account:

1. Processors --- how many processors are used in the VLSI system? This figure is denoted by $P$.
2. Bus bandwidth --- the maximum amount of data to be transmitted between the host and the VLSI system in any cycle. This figure is denoted by $B$.
3. Speed --- how much time does the VLSI system need to complete its task? This time may be decomposed into the times $T_C$ (time for computations) and $T_D$ (time for data transmissions both within the VLSI system and between the host and the VLSI system).

Let $C$ denote the time spent for computation by a single processor algorithm and $D$ denote the total amount of data that needs to be transmitted between the host and VLSI system. For the adaptive recursive filtering problem, $C = nw$ and $D = nw + n + w$.

The ratio

$$R_D = B * T_D / D$$

measures the effectiveness with which the bandwidth $B$ has been used. Clearly, $R_D \geq 1$ for every VLSI design.

The ratio

$$R_C = P * T_C / C$$

measures the effectiveness of processor utilization. Once again, we see that $R_C \geq 1$ for every VLSI design.

Finally, we may combine the two efficiency ratios $R_C$ and $R_D$ into the single ratio $R = R_C * R_D$. A design that makes effective use of the available bandwidth and processors will have $R$ close to 1.

The efficiency measure $R$ as defined here is the same as that used in [CHEN84a,b and 85] to evaluate VLSI designs for matrix multiplication and back substitution. This measure is also quite similar to that proposed in [HUAN82]. In fact, the two measures become identical when $T_C = T_D$.

In comparing different architectures for the same problem, one must be wary about over emphasizing the importance of $R_C$, $R_D$ and $R$. Clearly, by using $P = 1$ and $B = 1$, we get $R_C = R_D = R = 1$ but no speed up at all. So, we are really interested in minimizing $T_C$ and $T_D$ while keeping $R$ close to 1.

VLSI architectures for the adaptive recursive filtering problem have been proposed earlier in [KUNG78 and 84], [LEIS83], [HUAN82] and [ROBE84]. The design of [HUAN82] uses a broadcast chain and has $P = w$, $B = w + 2$, $T_C = n + w - 1$, $T_D = n + w$, $R_C \sim 1 + w/n \sim 1$, $R_D \sim 1 + 1/w + w/n \sim 1$ and $R \sim 1$. The design of [KUNG78] uses a bidirectional chain of processors. An improved version is described in [LEIS83]. For this, $P = \lceil w/2 \rceil$, $B = \lceil w/2 \rceil + 2$, $T_C = 2n + w - 2$, $T_D = 2(n + w - 1)$, $R_C \sim 1 + w/(2n) \sim 1$ $R_D \sim 1 + 3/w + w/n \sim 1$ and $R \sim 1$. The design of [KUNG84] uses a systolic ring architecture to solve the simple recurrence problem. It can be easily extended to solve the adaptive recursive filtering problem. This extension has $P = \lceil w/2 \rceil$, $B = \lceil w/2 \rceil + 1$, $T_C = 2(n - 1) + w$, $T_D = 2(n + w - 1) + 1$, $R_C \sim 1 + w/(2n) \sim 1$, $R_D \sim 1 + 1/w + w/n \sim 1$ and $R \sim 1$.

While all the above designs have an $R \sim 1$, the broadcast chain of [HUAN82] has a $T_C$ and $T_D$ that is about half that of the other designs. In this paper, we develop a bidirectional chain VLSI system that has the same (actually slightly smaller) $T_D$ and $T_C$ as the broadcast chain of [HUAN82]. For our design, $P = w$, $B = w + 1$, $T_C = n + \lceil w/2 \rceil$, $T_D = n + w + 1$, $R_C \sim 1 + w/(2n) \sim 1$, $R_D \sim 1 + w/n \sim 1$ and $R \sim 1$. Our design shows that a broadcast chain is not required to obtain this $T_C$ and $T_D$ performance.

## 2. $o(n)$ Throughput Bidirectional Chain

An $o(n)$ throughput bidirectional chain for the adaptive recursive filtering problem can be obtained by extending the systolic design of [ROBE84] for the nonadaptive recursive filtering problem. This extension requires us to recast (1) into the following form:

*This research was supported in part by the National Science Foundation under grant MCS-83-05567.

0190-3918/86/0000/0387 $01.00 © 1986 IEEE

$$\begin{aligned} x_i &= \sum_{j=1}^{w} a_{ij}\ x_{i+j-w-1} \\ &= \sum_{j=1}^{w-1} a_{ij}\ x_{i+j-w-1} + a_{iw} \sum_{j=1}^{w} a_{i-1,j}\ x_{i+j-w-2} \\ &= \sum_{j=1}^{w-1} a_{ij}\ x_{i+j-w-1} + a_{iw} \sum_{j=0}^{w-1} a_{i-1,j+1}\ x_{i+j-w-1} \\ &= \sum_{j=0}^{w-1} b_{ij}\ x_{i+j-w-1}, \qquad i \geq 1 \qquad (2) \end{aligned}$$

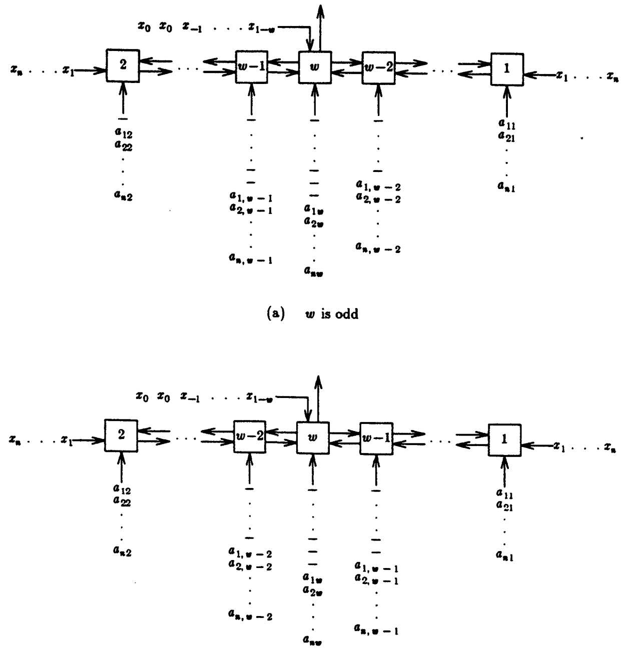
where

$$b_{i0} = a_{iw}\, a_{i-1,1},\ b_{ij} = a_{ij} + a_{iw}\, a_{i-1,j+1}, \qquad 1 \leq j \leq w-1 \qquad (3)$$

$$a_{01} = 1,\ a_{0j} = 0,\ 2 \leq j \leq w, \qquad x_{-w} = x_0 \qquad (4)$$

To calculate the $b_{ij}$'s of (3) dynamically, $w$ PEs in addition to the $w+1$ PEs used in [ROBE84] are needed. The performance figures of the resulting VLSI system are $P = 2w + 1$, $B = 2w + 3$, $T_C \sim n + \lceil w/2 \rceil$, $T_D \sim n + w$, $R_C \sim 2 + 1/w + w/n \sim 2$, $R_D \sim 2 + 1/w + w/n \sim 2$ and $R \sim 4$.

Improved performance can be obtained by using the bidirectional chain architecture of Figure 2.1. All the even numbered PEs are on the left, while all the odd numbered PEs are on the right. The output is generated from the middle PE, PE($w$). The PEs to the left of PE($w$) compute all terms involving even columns of $A$, while PEs on the right compute all terms involving odd columns of $A$. The case when $w$ is odd is shown in Figure 2.1(a). The case when $w$ is even is shown in Figure 2.1(b).



(a) $w$ is odd

(b) $w$ is even

Figure 2.1

The middle processor, PE($w$), has the five registers: $A$, $V$, $X$, $Y$ and $Z$. The remaining PEs have three registers ($A$, $X$ and $Y$) each. We use the notation $R(i)$ to denote register $R$, $R \in \{A, V, X, Y, Z\}$, of PE($i$). The $A$ register of each PE is used to hold an input value from the $A$ matrix. PE($i$) receives input from column $i$ of $A$ only, $1 \leq i \leq w$. The $X$ register of each PE holds an $x_i$ value while the $Y$ registers hold partial sums in the computation of an $x_i$. In each cycle, the $X(i)$s move one step away from the center PE, PE($w$), while the $Y(i)$s move one step towards this PE.

The working of the VLSI system is described formally in Algorithm 2.1. The first **for** loop sets up the initial configuration. The three steps in the **parallel do** are executed simultaneously. When this **for** loop terminates, PE($w$) contains $x_p$ for $p = \lceil (w-1)/2 \rceil - w = \lceil -(w+1)/2 \rceil$ in its $X$ register. The $X$ register of a PE that is $a$ units away from PE($w$) contains $x_{p-a}$. The second **for** loop contains two sets of concurrently executed statements. In the first set, i.e. first **parallel do**, essentially five concurrent activities are performed in each iteration of this loop:

(1) PE($w$) either inputs an $x_i$, $i \leq 0$ or outputs a newly computed $x_i$, $i > 0$.

(2) All $X$ values move one PE away from the middle PE.

(3) Each PE inputs an $A$ value. Note that we assume $a_{ij} = 0$ for $i \leq 0$.

(4) All $Y$ values move one PE towards the middle PE. However, the $Y$ value from PE($w-1$) is moved to the $Z$ register of PE($w$) rather than to its $Y$ register (this latter register receives the $Y$ value from PE($w-2$)). The boundary PEs (1 and 2) reset their $Y$ registers to zero.

(5) From the data patterns of Figure 2.1(a) and (b), we observe that if the $Y$ value in PE($w-1$) is a partial sum for $x_i$, then that in PE($w-2$) is a partial sum for $x_{i+1}$. Hence, $Y(w)$ and $Z(w)$ contain incompatible partial sums. The partial sum in $Y(w)$ is to be used in the next iteration. $V(w)$ is used to save the previous value of $Y(w)$. Consequently, $V(w)$ and $Z(w)$ contain partial sums for the same $x_i$.

In the second **parallel do** set of statements, either a new term is added to a partial sum $Y(i)$ or a new $x_i$ is computed. PE($w$) computes a new $x_i$ by computing $(V(w) + Z(w))$ and $A(w) * X(w)$ in parallel. The two results are then added (the operations may also be pipelined). Assuming that the time for an addition is no more than that for a multiply, the computation performed in PE($w$) takes the same time as that performed in the other PEs.

Figure 2.2 is a timing diagram for the case $w = 5$ where $j$ refers to the **for** loop index of Algorithm 2.1. For each PE, the contents of its $X$ and $Y$ registers following the execution of the **for** loop for that $j$ value are shown. The notation $[i, p]$ denotes $\sum_{\substack{j=1 \\ j\ odd}}^{p} a_{ij}\ x_{i+j-w-1}$ for PEs on the right of PE($w$) and $\sum_{\substack{j=1 \\ j\ even}}^{p} a_{ij}\ x_{i+j-w-1}$ for PEs on the left. $V(w)$ contains the sum of odd terms (as $w$ is odd), while $Z(w)$ contains the sum of even terms (as $w$ is odd).

The performance figures of this design are $P = w$, $B = w + 1$, $T_C = n + \lceil w/2 \rceil$, $T_D = n + w + 1$, $R_C \sim 1 + w/(2n) \sim 1$, $R_D \sim 1 + w/n \sim 1$ and $R \sim 1$.

```
for $j \leftarrow 1$ to $\lceil (w - 1)/2 \rceil$ do
  do in parallel
    $X(w) \leftarrow x_{j-w}$
    $X(w-1) \leftarrow X(w)$
    $X(i) \leftarrow X(i+2), \quad 1 \le i \le w-2$
  end
end
for $j \leftarrow \lceil (w + 1)/2 \rceil$ to $n + w$ do
  do in parallel
    case
      $j < w+1 : X(w) \leftarrow x_{j-w}$
      $j = w+1 : X(w) \leftarrow x_0$
      $j > w+1$ : output $X(w)$ { output $x_{j-w-1}$ }
    endcase
    $X(w-1) \leftarrow X(w)$
    $X(i) \leftarrow X(i+2), 1 \le i \le w-2$
    $A(w) \leftarrow a_{j-w,w}$
    $A(i) \leftarrow a_{j+\lfloor (w-i)/2 \rfloor + 1 - w, i}, 1 \le i \le w-1$
    $Y(1) \leftarrow Y(2) \leftarrow 0$
    $Y(i) \leftarrow Y(i-2), 3 \le i \le w$
    $V(w) \leftarrow Y(w)$
    $Z(w) \leftarrow Y(w-1)$
  end
  do in parallel
    $Y(i) \leftarrow Y(i) + A(i) * X(i) \; 1 \le i \le w-1$
    $X(w) \leftarrow (V(w)+Z(w))+A(w)*X(w) \quad j \ge w+1$
  end
end
output $X(w)$ { output $x_n$ }
```

## 3. Conclusions

We have developed a VLSI system for the adaptive recursive filtering problem that has $T_C$ and $T_D$ that is $o(n)$ and also has $R \sim 1$. Previously, this had been done only for the case of VLSI systems using the broadcast capability. Our design does not employ this capability. The performance characteristics for various VLSI systems for the adaptive recursive filtering problem are summarized in Table 3.1.

| Perf | Architecture | | | | |
|---|---|---|---|---|---|
| | Bidirectional | | | | Systolic |
| | Broadcast Chain | Chain | | | Ring |
| | [HUAN82] | [KUNG78] | [ROBE84] | Our | [KUNG84] |
| $P$ | $w$ | $\lceil w/2 \rceil$ | $2w$ | $w$ | $\lceil w/2 \rceil$ |
| $B$ | $w + 2$ | $\lceil w/2 \rceil + 2$ | $2w$ | $w + 1$ | $\lceil w/2 \rceil + 1$ |
| $T_C$ | $n + w$ | $2n + w$ | $n + \lceil w/2 \rceil$ | $n + \lceil w/2 \rceil$ | $2(n - 1) + w$ |
| $T_D$ | $n + w$ | $2(n + w - 1)$ | $n + w$ | $n + w$ | $2(n + w - 1)$ |
| $R_C$ | 1 | 1 | 2 | 1 | 1 |
| $R_D$ | 1 | 1 | 2 | 1 | 1 |
| $R$ | 1 | 1 | 4 | 1 | 1 |

$C = nw, D = nw + n + w$

Table 3.1

Further improvement in throughput (at the expense of design complexity) is possible. However, this cannot be obtained using recurrence (1) as in order to compute $x_i$, we need to know $x_{i-1}$. Hence $x_i$ can be computed, at best, one cycle after $x_{i-1}$ has been computed. However, we can bring both $T_C$ and $T_D$ down to $o(n/2)$ by computing two $x_i$s each cycle using recurrence (2) and formulae (3) and (4). The idea is the same as used in the back substitution problem in [CHEN84b]. The VLSI system that incorporates this uses more hardware and is quite a bit more complex. The method may be extended to get a $T_C$ and $T_D$ of $o(n/k)$ for any fixed $k$.

# RECBAR: A RECONFIGURABLE MASSIVELY PARALLEL PROCESSING ARCHITECTURE

*Vijay Balasubramanian and Prithviraj Banerjee*

Computer Systems Group
Coordinated Science Laboratory

Urbana, IL-61801

## ABSTRACT

This paper presents two massively parallel processing architectures suitable for solving a wide variety of divide-and-conquer type algorithms for problems such as the Discrete Fourier Transform, Production Systems, Design Automation and others. The first architecture, called the Chain-structured Butterfly ARchitecture (CBAR), consists of a two-dimensional array of $N = L.(log_2(L) + 1)$ processing elements (PE) organized as $L$ levels of $log_2(L) + 1$ stages, and which has the butterfly connection between PEs in consecutive stages with straight-through feedback between PEs in the last and first stages. This connection system has the desirable property of allowing thousands of PEs to be connected with $O(N)$ connection cost, $O(log_2(\frac{N}{log_2 N}))$ communication paths and a small number (=4) of I/O ports per PE. However, this architecture is not fault tolerant. We, therefore, propose a second architecture, called the REconfigurable Chain-structured Butterfly ARchitecture (RECBAR), which is a modified version of the CBAR. The RECBAR possesses all the desirable features of the CBAR, with the number of I/O ports per PE increased to six, and uses $O(\frac{log_2 N}{N})$ overhead in PEs and approximately 50% overhead in links to achieve single-level fault tolerance. Reliability improvements of the RECBAR over the CBAR are studied.

## 1. INTRODUCTION

Recent developments in technology have made it possible to interconnect a large number of processing elements in order to form an integrated system. Various network architectures have been proposed that are suitable for both multiprocessors and VLSI systems [1, 2]. In this paper, we present a massively parallel processing architecture suitable for solving a wide variety of divide-and-conquer type algorithms for problems in signal processing, production systems, design automation and others. This architecture, called the Chain-structured Butterfly ARchitecture (CBAR), has the desirable property of allowing thousands of PEs to be connected with $O(N)$ connection cost, $O(log(\frac{N}{log N}))^*$ communication paths and a small number (=4) of I/O ports per PE.

One attribute that is desirable in any complex parallel processing system but missing in the CBAR is fault-tolerance. Fault tolerant network architectures are emerging as an important area of study [3, 4, 5]. We, therefore, propose a second architecture, called the REconfigurable Chain-structured Butterfly ARchitecture (RECBAR), which is a modified version of the CBAR. The RECBAR possesses all the desirable features of the CBAR, with the number of I/O ports per PE increased to six, and uses $O(\frac{log N}{N})$ overhead in PEs and approximately 50% overhead in links to achieve fault tolerance.

## 2. CHAIN-STRUCTURED BUTTERFLY ARCHITECTURE

The chain-structured butterfly architecture (CBAR) is a novel parallel processing architecture which has processors in place of exchange switches in a regular butterfly interconnection network. In addition, the output ports of the processors in the last stage of the CBAR are fed back to the of the first stage. The network resembles the Loop Structured Switching Network proposed by Wong and Ito [6] except that there is no unshuffle while traversing the feedback path. The organization of a processing element (PE) is similar to that in the MAN-YO Architecture [7] ; each PE consists of the actual processor and a router cell, the latter managing packet transmission among different PEs. The router cell is basically a store and forward crossbar switch with three input and three output ports, one input- output pair being solely used for the processor, and the remaining two port pairs being network ports, used for connection among router cells.

### 2.1. Network Topology

The CBAR is a two-dimensional array of $N = L.(log\ (L) + 1)$ PEs arranged in $L$ levels and $S = log\ (L) + 1$ stages. The following description can be easily understood if the reader refers to Fig. 1, which shows the network for $N = 32$ and $L = 8$. The stages are labeled in a sequence from 0 to $log\ (L)$ with 0 for the leftmost stage and $log\ (L)$ for the rightmost stage. Similarly the PE levels are labeled in a sequence from 0 to $L - 1$. Each PE can be uniquely identified by the stage and level to which it belongs: $<i, j>$ represents a PE in the $i^{th}$ stage and $j^{th}$ level. The integers $i$ and $j$ can be represented by their binary equivalents with $s = log\ (S)$ and $l = log\ (L)$ bits, respectively. Hence the processor $<i, j>$ has a binary address $[q_{s-1} \cdots q_0, p_{l-1} \cdots p_0]$. An output link of a PE is referred to as the '0 link' if it connected to the upper output port, and a '1 link' if it is connected to the lower output port.

The topology describing rules of the network are defined as follows:
(1) For link 0: CBAR $<i, j> = <i + 1, j - 2^i .bit_i(j)>$,
(2) For link 1: CBAR $<i, j> = <i + 1, j + 2^i .[1 - bit_i(j)]>$,
for $0 \leqslant i \leqslant log\ (L) - 1, 0 \leqslant j \leqslant L - 1$,
where $bit_i(j)$ equals the bit with weight $2^i$ in the binary representation of $j$.
(3) For the feedback links, 0 and 1:
CBAR $<log\ (L), j> = <0, j>$, for $0 \leqslant j \leqslant L - 1$.

The labeling scheme and interconnection of the PEs can be verified in the example shown in Fig. 1.

[*] In this paper, we denote *log* to be the logarithm base 2.

### 2.2. Properties of the CBAR

This section states some useful results concerning the behavior of the CBAR for a single packet being routed from a source PE to a destination PE. We define a 'step' in packet routing as the transfer of a packet from a (network) input port buffer or the processor output port buffer of a PE router cell to a (network) input port buffer of the next PE router cell. This involves setting of the router cell to use either the 0 or the 1 link of the PE. The process of choosing the 0 or the 1 link of a PE in the $i^{th}$ stage can be viewed as modifying the $i^{th}$ bit of the address of the level in which the packet currently resides. For the remaining part of this section we consider a CBAR which has $L$ levels and a packet which is generated at the PE $<i, p_{l-1} \cdots p_1 p_0>$ and destined for the PE $<i', p'_{l-1} \cdots p'_1 p'_0>$, where $l = log\ (L)$, and $0 \leqslant i \leqslant l$.

Given two bit strings, $STR1$ and $STR2$, the maximum length common suffix of $STR1$ and $STR2$ will be denoted as $MLCS(STR1, STR2)$. Given a bit string $STR$, a cyclic shift left by k bits followed by a bit reversal will be denoted by $CSLR_k(STR)$. The length of a string $STR$ is denoted by $|STR|$. The Augmented Source Bit String ($ASBS$) and the Augmented Destination Bit String ($ADBS$) are defined as $(p_l p_{l-1} \ldots p_0)$ and $(p'_l p'_{l-1} \ldots p'_0)$, respectively, where $p_l$ and $p'_l$ are extra bits that are added to model the feedback connection of the CBAR network. The extra bits are equal to each other and can be assigned either 0 or 1.

It can be shown that the packet will be routed to the destination PE in exactly $k + [(i' - i - k)\ modulo\ (l + 1)]$ steps after its generation at the source PE, where $k = l + 1 - |MLCS\ (CSLR_{l-i+1}(ASBS), CSLR_{l-i+1}(ASBD))|$. It follows that in a CBAR with $L$ levels, a packet will be delivered to its destination within $2.log\ (L) + 1$ steps of routing regardless of where it is generated. This allows us to conclude that the CBAR network has $O\ (log\ (\frac{N}{log\ N}))$ communication between PEs.

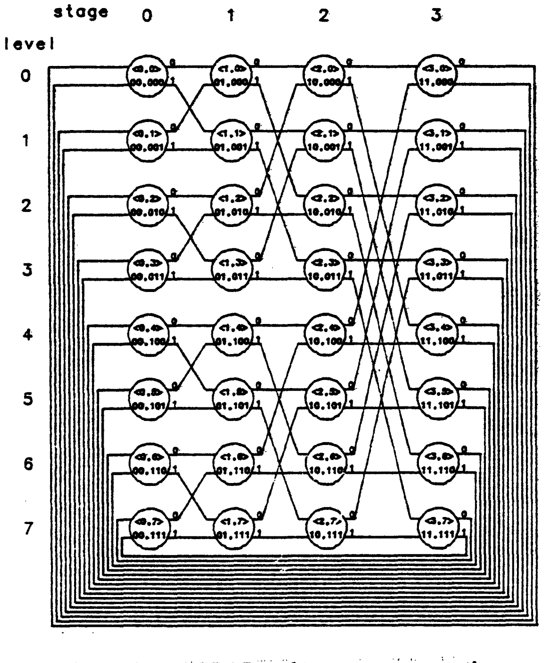

**Fig. 1.** *A 8×4 CBAR with name representation*

### 3. THE RECONFIGURABLE-CHAIN STRUCTURED BUTTERFLY ARCHITECTURE

We now propose a modified version of the CBAR which we call the reconfigurable chain-structured butterfly architecture (RECBAR).

### 3.1. Network Topology

The RECBAR can be formally described as follows. The network consists of $N = (L + 1).(log\ (L) + 1)$ PEs arranged in $L + 1$ levels and $log\ (L) + 1$ stages. The stages are numbered in a sequence from 0 to $log\ (L)$, with 0 for the leftmost stage and $log\ (L)$ for the rightmost stage. Similarly, the levels are labeled in a sequence from 0 to $L$. Each PE can be uniquely identified as $<i, j>$, where $i$ denotes the stage and $j$, the level to which the PE belongs. Each PE has three input and output ports except those in the first and last stages which have two input and three output ports, and three input and two output ports, respectively. An 'upper link' is attached to the upper output port of a PE, a 'middle link' to the middle output port and a'lower link' to the lower output port of the PE.

The topology describing rules of the network are as follows:

(1) For an upper link:
RECBAR $<i, j> = <i + 1, (j - 2^i)\ modulo\ (L + 1)>$,
(2) For a middle link: RECBAR $<i, j> = <i + 1, j>$,
(3) For a lower link:
RECBAR $<i, j> = <i + 1, (j + 2^i)\ modulo\ (L + 1)>$,
for $0 \leqslant i \leqslant log\ (L) - 1, 0 \leqslant j \leqslant L$.
(4) The feedback links:
RECBAR $<log\ (L), j> = <0, j>$, for $0 \leqslant j \leqslant L$

The reader may verify the PE interconnections in the example of Fig. 2. It should be noted at this point, that the RECBAR network resembles the Inverse Augmented Data Manipulator

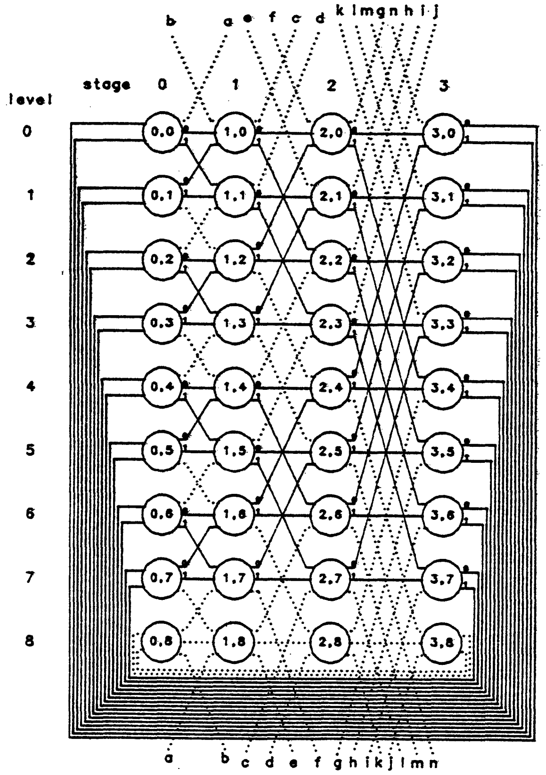

**Fig. 2.** *A 9×4 RECBAR with name representation*

Network proposed by McMillen and Siegel [8], with the following three differences. First, the exchange switches in the IADM are replaced by processing elements. Secondly, in the IADM there were $L$ levels, whereas we have $L+1$ levels in the RECBAR. Thirdly, we use only $L$ of the levels during operation, the extra level being included just for reconfiguration, whereas in the IADM, all the $L$ levels were used simultaneously and there were no ideas of reconfiguration.

### 3.2. The RECBAR operation under no fault

We will show that the RECBAR can emulate the CBAR under no fault conditions. The level of PEs labeled $L$ is not considered so that we have $L.(log\ (L)+1)$ PEs arranged in $L$ levels and $log\ (L)+1$ stages, as required by the CBAR. Now any PE $<i,j>$ $(i \neq log\ (L))$, in the CBAR is connected to PEs $<i+1, j>$, and $<i+1, j-2^i>$ *or* $<i+1, j+2^i>$ depending on the value of the $i^{th}$ bit of the binary word corresponding to $j$. In the RECBAR, we have the PE $<i,j>$ connected to PEs $<i+1, j>$, $<i+1, j-2^i>$ *and* $<i+1, j+2^i>$, the modulo operation coming into effect only if $j-2^i$ is negative or $j+2^i$ exceeds $L+1$, which would not be the case for the CBAR addressing scheme. The feedback links remain the same in both the networks. All one needs to do is to select the two proper output links out of the three available, in each PE (except for the last stage), and the RECBAR would operate as the CBAR.

The output link selection is based on the CBAR topology rules developed in Section 2.1. Address each PE $<i,j>$ $(i \neq log\ (L))$, by the binary representations of the stage and level to which it belongs. If the $i^{th}$ bit of the level address is a 0, choose the lower two output links, assigning a 0 to the middle link and a 1 to the lower link. If the $i^{th}$ bit is a 1, choose the upper two output links, assigning a 0 to the upper link and a 1 to the middle link. The significance of the 0 and the 1 links is the same as in the CBAR. Fig. 2. shows the RECBAR configured for operation under no fault. The continuous lines denote the links in use and the dotted lines denote the redundant links.

### 3.3. The RECBAR operation under a single fault

We will show that the RECBAR can emulate the CBAR in the presence of faults in a single PE level.

THEOREM 1: The RECBAR can be reconfigured to emulate the CBAR under failure of any single level.

PROOF: Suppose a level $r$ of PEs fails for some $0 \leqslant r \leqslant L-1$. We will show that it is possible to reconfigure the RECBAR such that the level $r$ is removed and the spare level $L$ brought instead. We will transform the addresses of the PEs by the following simple transformation: the PE whose old address was $<i,j>$ will be assigned the new address $(i, j-r-1)$, where the subtractions are performed *modulo* $(L+1)$. For example, the PE whose old address was $<i, r+1>$ is assigned the new address $(i,0)$ and the PE whose old address was $<i, r-1>$ is assigned the new address $(i, L-1)$, since $(r-1-r-1)$ *modulo* $(L+1)$ $=(-2)$ *modulo* $(L+1)=L-1$.

In order that the CBAR structure be realized, we need to have the following connections for the PEs in the new addressing scheme:

(1) $<i,j>$ to $<i+1, j>$,
(2) $<i,j>$ to $<i+1, j-2^i>$, if $bit_i(j)=1$,
(3) $<i,j>$ to $<i+1, j+2^i>$, if $bit_i(j)=0$,
(4) $<log\ (L), j>$ to $<0,j>$,
for $0 \leqslant i \leqslant log\ (L)-1$, $0 \leqslant j \leqslant L-1$.

This implies that the original network should have the following connections:

(1) $<i, (j+r+1)\ mod\ (L+1)>$
to $<i+1, (j+r+1)\ mod\ (L+1)>$,
(2) $<i, (j+r+1)\ mod\ (L+1)>$
to $<i+1, (j+r+1)\ mod\ (L+1) \pm 2^i>$.[*]
(3) $<log\ (L), (j+r+1)\ mod\ (L+1)>$
to $<0, (j+r+1)\ mod\ (L+1)>$,
for $0 \leqslant i \leqslant log\ (L)-1$, $0 \leqslant [(j+r+1)\ mod\ (L+1)] \leqslant L-1$.

From the definition of the RECBAR, these connections are present, where $j$ is replaced by $(j+r+1)\ mod\ (L+1)$. □

EXAMPLE 1: Consider a RECBAR with $L=8$. Let level 3 become faulty. We rename level 4 as 0, level 5 as 1,..., level 8 as 4, level 0 as 5,..., and level 2 as 7. Let us see whether we have proper connections for the PE <2,2> in the new addressing scheme. We need the connections <2,2> to <3,2> and <3,6>. These correspond to <2,6> to <3,6> and <3,1> in the original network, since $(j+r+1)\ mod\ (L+1)$ $=(j+4)\ mod\ 9$, which is equal to 6 for $j=2$ and is equal to 1 for $j=6$. We notice that these connections are present in the RECBAR of Fig. 2. Fig. 3 illustrates the reconfigured RECBAR for a fault in level 3.

The selection of the proper outputs ports in each PE is straightforward. Let level $r$ be the faulty level, for some $0 \leqslant r \leqslant L-1$. Compute $(j-r-1)\ mod\ (L+1)$ for each PE $<i,j>$ and represent the value obtained by its binary equivalent. Bit $i$ of this binary word then determines the ports to be selected, the selection process being similar to the one discussed in Section 3.2. The reader may verify the port selection on the example of Fig. 3.

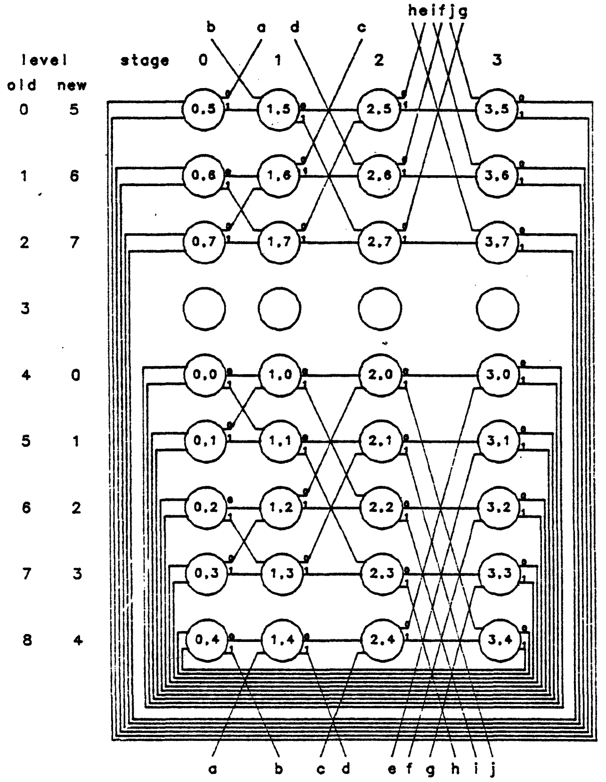

Fig. 3. *A reconfigured 9×4 RECBAR for a fault in level 3*

[*] The addition or subtraction of $2^i$ depends on $bit_i[(j+r+1)\ mod\ (L+1)]$.

### 3.4. Structure of the Router Cell

The router cell has three network input-output port pairs and one processor input-output port pair, as shown in Fig. 4. A 4×4 crossbar switch connects the input ports to the output ports. The output port set selection logic is shown in outline mode. It consists of two 1-to-2 demultiplexers controlled by a common port set selection line. The operation of the router cell is clear from the figure itself and need not be explained.

### 3.5. Overhead

Consider a CBAR with $L$ levels. It has $N = L.(log\ (L)+1)$ PEs and $2N$ links. The corresponding RECBAR has $N' = (L+1).(log\ (L)+1)$ PEs and $3N' - (L+1) = (L+1).(3.log\ (L)+2)$ links. The PE overhead ratio comes out to be equal to $\frac{1}{L}$ and the link overhead ratio comes out to be equal to $\frac{(L+3).log\ (L)+2}{2L.(log\ (L)+1)}$. In the limit as $L$ tends to a large value, the link overhead ratio becomes nearly 50%.

## 4. RELIABILITY ANALYSIS

We will now estimate the improvement in the reliability of the system topology. We assume that the failure rate of a PE is exponential with a failure rate of $\lambda_p$ and the failure rate of a link to be $\lambda_l$. In Fig. 5, we show the reliabilities of the CBAR and the RECBAR for $L = 8$, $\lambda_p = 0.1$ failures per unit time and $\lambda_l = 0.01$ failures per unit time. We assume that the failure rate of a link is much less than that of a PE because it is much less complex.

## 5. CONCLUSIONS

In this paper, we have presented a chain-structured butterfly architecture (CBAR) similar in organization to the architectures proposed by Wong and Ito [6] and Koike and Ohmori [7]. The CBAR has the desirable property of being able to connect an extremely large number of processors with $O(N)$ connection cost, $O\ (log\ (\frac{N}{log\ N}))$ communication paths, and a small number (=4) of I/O ports per PE. We have also discussed a reconfigurable version of the CBAR, the RECBAR, which can tolerate any number of failures of processing elements and links associated with a single level. This fault tolerance is achieved at a processor overhead ratio of $O(\frac{log\ N}{N})$ and a link overhead ratio of approximately 50%. The reliability analysis has shown that the RECBAR is much more reliable than the CBAR.

## Abstract

The performance of a parallel algorithm depends on the interconnection topology of the target parallel system. An interconnection network is called reconfigurable if its topology can be changed between different algorithm executions. Since communication patterns vary from one parallel algorithm to another, a reconfigurable network can effectively support algorithms with different communication requirements. This paper describes a reconfigurable optical network and explains how to generate network topologies which are optimized with respect to a given task. We describe an algorithm that takes as input a task graph and generates as output a topology that closely matches the given input graph. The best, worst and average case performance of the algorithm is analyzed and it is shown that on the average the optimum topology is generated.

## 1. Introduction

The performance of a parallel algorithm depends on how well its communication characteristics match the interconnection topology of the underlying parallel system. Since different algorithms exhibit different communication patterns, work in the area of general-purpose parallel system design centers on developing a network topology that is suitable for various communication requirements. A common approach is to statically connect processing elements in a regular pattern with certain properties such as small diameter, easy routing and expansion, low congestion, etc. General-purpose parallel systems with static interconnection networks however have several limitations due to their fixed nature. The first limitation is that a given algorithm, which may be viewed as a graph with nodes representing processes and edges representing potential communications, has to be mapped onto the parallel system. This mapping problem in general is computationally intractable even for parallel systems with homogeneous processing elements. The second limitation is that although one interconnection topology may be ideal for a set of algorithms, it may introduce unacceptable communication delays for other algorithms even with the best possible mapping. The third limitation is that developing parallel algorithms that closely match the interconnection topology of a target parallel system is a difficult task. A parallel system with a network whose interconnection topology can be configured to match the communication characteristics of an algorithm remedies these limitations.

An interconnection network is called *reconfigurable* if its topology can be altered between different algorithm executions or even between different phases of the same algorithm execution. Examples of architectures that can be configured into a limited number of interconnection patterns include the MPP [1] and the CHiP [2] architecture. In contrast to these networks which can only realize a limited number of topologies, this paper will investigate the use of a reconfigurable network which can realize any $r$-regular graph as a network topology. Such networks are referred as $r$-reconfigurable networks.

## 2. Reconfigurable Optical Network

Optics provides a way of implementing $r$-reconfigurable networks. We propose using an optical network that requires only $O(nr)$ components to implement a $r$-reconfigurable network for $n$ processors, where $n$ is ~ 100. The network consists of $nr$ optical transmitters (laser diodes), $nr$ deflectors (acousto-optic devices or mirrors) and $nr$ photo-sensitive receivers (photodiodes). The deflectors can be either mirrors mounted on servo motors or acousto-optic devices which deflect an incoming beam at an angle proportional to an applied frequency. To establish a communication channel between processors, the source processor directs a control signal to its deflector. The control signal's value determines the deflection angle of the incoming laser beam so that it impinges on the photodiode associated with the desired processor. The transmitting processor then modulates the laser beam with the information to be transmitted. The receiver detects this light beam, demodulates it, and processes the resultant data accordingly. Since laser beams do not interfere with each other,

0190-3918/86/0000/0394 $01.00 © 1986 IEEE

the network can realize any permutation. Other researchers have given alternate designs of optical reconfigurable networks [3].

In the design of our reconfigurable network, there is a tradeoff between the cost of the network and the time needed to reconfigure. For example, if mirrors are used as deflection elements, the network has a reconfiguration time of ~ 1 *msec*; whereas, if an acousto-optic deflector is used, the network has a reconfiguration time of ~ 1 *μsec*. The two networks differ in cost by at least an order of magnitude due to the cost of the acousto-optic deflector and related control electronics. In this paper, we consider the use of the network with the slower reconfiguration time. In particular, the time needed to make the transition from one configuration to another is long in comparison to the time between two communication events. Therefore, we assume that the topology changes only between different algorithm executions or between different phases of the same algorithm execution.

Given that the topology remains relatively static throughout the execution of an algorithm, the topology must be chosen so as to closely match the communication requirements of the algorithm. In the next section we describe an algorithm that takes as input a task graph and generates as output a topology that closely matches the given input graph. In section 4, we briefly analyze the best, worst and average case performance of the algorithm.

## 3. The Synthesis Problem

We now discuss the problem of generating an interconnection topology that matches closely the interconnection patterns of a given task graph. We define an optimum topology (and corresponding mapping) as one that maximizes the number of pairs of communicating tasks that fall on pairs of directly connected processors. The definition of the synthesis-mapping function can be stated as follows: Given a connected and undirected graph $T$, $|V(T)| = n$ such that each element of $V(T)$ is labeled $t_i$, $1 \le i \le n$, and a set $V(P)$ of $n$ nodes labeled $v_i$, $1 \le i \le n$, and a function $g: V(T) \rightarrow V(P)$, where $g(t_i) = v_i$, and an integer $r \ge 2$, then the problem is to find a function $c: V(P) \times V(P) \rightarrow \{0,1\}$ such that $P = \{V(P), E(P)\}$, where $E(P) = \{(u,v): c(u,v) = 1\}$, is a degree bounded connected graph with $degree(v_i) \le r$ for all $v_i \in V_{P,}$ $1 \le i \le n$, and *cardinality* =

$$|\{(u,v): (u,v) \in E(T) \; and \; (g(u), g(v)) \in E(P)\}|$$

is maximum.

$T$ is a task graph that models the algorithm to be executed on the system. The vertices in the graph correspond to individual tasks and an edge between two vertices signifies that communication occurs between these two tasks. No attempt has been made to quantize the amount or cost of communication between tasks. The processor system is also represented as a graph with vertices corresponding to processors and edges to communication links. The problem is to find the set of edges (communication links) to maximize the number of pairs of intercommunicating tasks that fall on pairs of directly connected processors. At the same time, because of the limited number of links each processor controls, the degree of each vertex must be bound. Also, the resultant topology must be connected since a message sent to a processor that is not directly connected to a source processor must be forwarded through intermediate processors. Graphs meeting these conditions will be referred to as degree constrained connected graphs (DCCG). The problem of finding such graphs will be referred to as the DCCG problem.

We have shown in [4] that the DCCG problem is NP-complete. Although the DCCG problem is NP-complete, the synthesis problem can be solved in polynomial time using graph matching methods if the condition that the resultant graph be connected is removed [5]. The outline of an algorithm [4] for finding sub-optimal DCCGs is as follows: First, use a matching technique to find a optimal disconnected topology (henceforth referred to as a maximal deficient $r$-factor or MDRF). Then, using heuristics, connect the disconnected components of the MDRF together. The connection of disconnected components may require that existing communication links interconnecting communicating tasks be broken. When links are broken, our algorithm ensures that further discontinuities are not introduced. The algorithm runs in the time complexity of $O(n^3)$.

## 4. Analysis of the Synthesis Algorithm

In the best case, our algorithm can generate topologies with a cardinality of $\lfloor nr/2 \rfloor$. In the worst case, we can bound the cardinality with respect to the optimum cardinality. To do this we note that the cardinality of the MDRF is at least as large as the cardinality of the optimum connected topology. Therefore, we can use the cardinality of the MDRF as a bound on the optimum cardinality. It is shown elsewhere [4] that use of our algorithm to connect the disconnected components of the MDRF reduces the cardinality by at most $\lfloor n/(r+1) \rfloor - 1$. Therefore, our algorithm always generates a connected topology that is within $\lfloor n/(r+1) \rfloor - 1$ of optimal. Furthermore, for any given $n$ and $r$, it is possible to construct a graph with a MDRF such that the connection of the MDRF by any connection algorithm results in a cardinality loss by the bound. That is, the performance of our connection algorithm equals that of an optimal algorithm in the worst case.

We use random graphs as processor graphs to analyze the average case. Random graphs are used since we want to determine the performance of our algorithm over a wide range of graphs. We define a random graph as a graph where the probability of an edge between two nodes is fixed. We say that almost every random graph has a given property if the probability of a random graph having that property approaches 1 as the number of nodes in the graph approaches infinity [6]. To apply well-known results from random graph theory in analyzing our algorithm for the average case, we assume that the topology synthesized by our algorithm can be modeled as a random $r$-regular graph. Since we are investigating the performance of our algorithm assuming a random graph input and since our algorithm generates a $r$-regular graph as output by deleting some of the edges of the input graph, this is a reasonable assumption to make.

To determine the average case performance, we need to determine the expected cardinality of a MDRF and also the expected reduction in cardinality due to the connection process. The cardinality of a MDRF has been characterized by Shamir and Upfal [7] who state that if almost every random graph $G$, with $nr$ even, has a minimal degree of $r$, then almost every graph $G$ has a MDRF with a cardinality of $nr/2$. Thus, for almost every random graph used as input with a minimal degree $\geq r$, a MDRF will be found with $nr/2$ edges.

Our algorithm diverges from optimality during the connection process. In particular, the algorithm does not connect the disconnected components so that the cardinality is reduced by a minimal amount. However, as we mentioned above, this reduction is $\leq \lfloor n/(r+1) \rfloor -1$. On the average, one would expect that the reduction would be smaller than $\lfloor n/(r+1) \rfloor -1$. Indeed, Wormwald [8] has shown that if $r \geq 3$ then almost every random $r$-regular graph is $r$-connected. Since almost every graph generated by the matching process is a $r$-regular graph, almost every graph generated by the graph factoring step of our algorithm will be $r$-connected and hence 1-connected. Therefore, almost every graph with minimal degree of $r \geq 3$ will have a cardinality of $\lfloor nr/2 \rfloor$ when mapped onto the topology generated by our algorithm.

To verify the average case prediction, we generated a range of random graphs with a varying number of nodes and edges. For each of the graphs we found a corresponding MDRF and then used our algorithm to connect the MDRF. It was observed that for almost all of the graphs the corresponding DCCG's had a cardinality of $\lfloor nr/2 \rfloor$. The only situation where the average case prediction failed occurred when the task graphs approached a completely connected graph. In this situation the matching algorithm that we were using to generate the MDRFs was producing MDRFs with relatively large numbers of disconnected components. This occurred since the algorithm used examines the edges adjacent to a node in sequential order in an effort to determine which ones to keep in the DCS. For example, let $r = 3$. The algorithm first examines node 1. It sees that there are edges (1,2),(1,3),(1,4) and adds them to the degree constrained subgraph (DCS). Similarly, it sees that there are edges (2,3), (2,4) and (3,4). Since it examines edges sequentially, it adds these edges to the DCS and thereby forms a component of nodes 1,2,3 and 4 to which no further edges can connect. This does not happen until the graph is almost completely connected since the probability of having all of the needed edges to form a component with consecutive nodes is low until the graph becomes almost completely connected. To avoid this problem the algorithm needs to be modified so that it examines the edges of each node in random as opposed to sequential order.

## 5. Summary

We have presented an optical reconfiguration network that requires only $O(nr)$ components. For this network to achieve better performance than that available from conventional static networks, the topology chosen must *match* that of the algorithm to be executed. We define what it means to *match* and mention an algorithm that takes as input an arbitrary task graph and generates as output a topology that closely matches the given input graph. We then analyze the best, worst and average case behavior of our algorithm. It is shown that on the average the algorithm almost always produces optimum topologies.

## Abstract

Throughput and latency in packet communication networks are determined to a large extent by throughput and latency in the first-in first-out (FIFO) queues used for packet buffering in these networks. We describe a design approach for self-timed FIFO queues with a novel organization which allows tradeoffs between area, throughput and latency in VLSI implementations. This flexibility is made possible by the use of asynchronous distributed control circuits. These circuits are synthesized directly from a graph model called Signal Transition Graphs, and are completely hazard-free. A number of nMOS test chips were fabricated and they worked at a 4 Mbytes/sec throughput rate.

## 1. Introduction

Multistage interconnection networks (MIN) are used to support communication among processing and storage modules in multiprocessor architectures [2]. To use a packet routing MIN, modules communicate by sending packets to each other. A packet consists of an address and data. The address is used to forward the packet along a path through the network from the sender to the destination module. Multistage interconnection networks are usually constructed out of $N \times N$ crossbar switches, where the number of ports $N$ is determined by performance requirements and packaging constraints. A switch forwards an input packet to an output port according to the destination address of the packet. Each switch may also provide buffering storage for packets whose forwarding paths are temporarily blocked by other network traffic. The buffering storage is usually managed by a first-in first-out discipline.

In this setting, the design of FIFO queues is an important consideration in the design of practical packet routing networks. We present an approach for designing FIFO queues in VLSI technology which allows tradeoffs between area, latency and throughput. At one end of the design spectrum, an area-efficient implementation with high throughput, but long latency, can be obtained. In this organization, the register stages are connected serially to allow data to ripple through; there is no global communication. At the other end of the spectrum is a queue with minimal latency, but somewhat lower throughput rate due to increased delay in the control operations and in the loading of global buses. On a VLSI chip, these buses are sets of wires carrying input and output data which are connected to the input and output of all register stages. An optimal design somewhere in the range of these extremes can be chosen depending on the application. A queue of $N$ stages can be partitioned such that only $M$ register stages load the buses; given that the permissible latency is $L$ stage delays, then $M = N/L$. Thus, this distributed organization also reduces the amount of global communication; this is particularly important for large queues, where the loading on control and data buses approaches the level existing in a typical memory array.

Our FIFO queue design makes use of distributed control structures and local communication. There are only a few types of modules in this design, with modules of each type replicated as necessary to construct complete FIFO queues. The distributed control structure allows the exploitation of concurrency. Concurrent read/write supports a higher throughput rate. The FIFO queue is also completely data driven, hence no potential read/write conflict exists and there is no need for any arbiter.

The distributed control organization of the FIFO lends itself naturally to a design using asynchronous, self-timed hardware circuits. Towards this end, a specification technique for asynchronous control structures based on a graph model called Signal Transition Graphs (STGs) have been proposed, and methods for direct and efficient synthesis of self-timed hardware circuits from such specifications have been developed. The STG model is especially appropriate for control modules which exhibit a high degree of asynchronous concurrency. A preliminary discussion of the STG model and its expressiveness and implementability are given in [5]. The use of STGs in the design and implementation of a self-timed $2 \times 2$ packet router is reported in [3].

The paper is organized as follows. Section 2 describes the functional behavior and alternate organizations of the FIFO queue. Section 3 introduces the STG model and discusses its use in the specification of self-timed circuits. In Section 4, STG specifications of the building block control modules for realizing the various FIFO queue organizations and their implementation are presented. Finally, Section 5 presents the results and some further discussions on the STG model.

## 2. Organization of the FIFO queue

This section discusses the one and two-dimensional organizations for the FIFO queue (Figs. 1a and b). The R-module is a control circuit designed to support pipelined operation of the register stages. A R-module has an input link from a previous stage, an output link to the next stage, and an output link to a register module in the same stage to control data loading into this register. A *link* is a pair of *ready/acknowledge* wires, depicted as an arc with the arrow pointing in the direction of the *ready* signal. When input data is available for loading into a register, a *ready* signal is sent to its R-module controller on the $I_r$ wire (Fig. 1a). The actual loading is performed when the R-module controller sends a *ready* signal to the register on the $L$ wire. Once data have been loaded into a register, an *acknowledge* signal is sent to its R-module on the $D$ wire. The R-module then returns an *acknowledge* signal on the $I_a$ wire of the input link and forwards a ready signal on the $O_r$ wire of its output link concurrently. The next data item will be loaded into its register only after the R-module has received an *acknowledge* signal on its $O_a$ wire and another *ready* signal on its $I_r$ wire. Thus, the operation of the R-module is pipelined. Data from one stage will be forwarded to the next unless the latter is full. The throughput rate of this queue is determined by the delays of the R-module and registers, whereas its latency is proportional to the number of stages in the queue.

A two-dimensional, or *ring* organization is shown in Fig. 1b. This queue consists of $M$ linear queues, each of $L$ stages, and two *token rings* for controlling input/output operation. The capacity of the queue is $M \times L$ and the latency is proportional to $L$. I-modules are connected together to form a *token ring* to control the writing of data into the queue. The ring is initialized such that only one I-module contains the token, marking the next available empty register stage. Since the *Write-request* signal, carried on wire $W_r$, is connected to all I-modules, the token should not be passed on to the next module in the ring if the *Write-request* signal is still active. This is an important timing restriction. The *Write-acknowledge* on wire $W_a$ is the output of an OR gate (shown as a heavy bar with a + sign) whose inputs are acknowledge wires from all I-modules. Similarly, reading from the FIFO is controlled by an *Output token ring*, formed by connecting O-modules together. Data written into the linear queues ripple to their output side, ready to be gated onto the output bus. The Output ring is initialized such that only one O-module contains the token. This module then controls the timing and signaling for gating of data to the output bus. The *Read-request* signal on wire $R_r$ is the output of an OR gate whose inputs are request wires from all O-modules. Another timing restriction exists for the Output token ring: since the *Read-acknowledge* signal, carried on wire $R_a$ is broadcast to all O-modules, the token should not be passed on to the next module while *Read-acknowledge* is still active.

0190-3918/86/0000/0397 $01.00 © 1986 IEEE

The Ring buffer which we fabricated is one with minimal latency ($L = 1$), with each of the linear queues containing exactly one stage. Registers in each stage have inputs connected to the input data bus, and outputs connected to the output data bus.

## 3. Signal Transition Graphs

In this section we introduce the STG model and its application to the specification of pipeline controllers. A more complete discussion of STG can be found in [6]. In short, STGs are a form of Petri nets restricted by a set of axioms, and their components (such as transitions and places) assigned attributes related to physical circuits. The result is a graph model which is much more amenable to analysis due to the reduced complexity, and still retains sufficient expressiveness for specifying most common behaviors of control circuits including concurrency, choices and conflicts.

A hardware circuit consists of an interconnection of *logic elements*, each having an output terminal and a number of input terminals. Every input terminal is connected either to an input terminal of the entire circuit, or to an output terminal of another logic element in the circuit. The set of all terminals of a circuit is called the set of *signals, M.* In order to describe the dynamics of a circuit, a set of *signal transitions* $T = M \times \{+, -\}$ is used to specify the rising and falling transitions of each signal in $M$. For each $i \in M$, its associated transitions are denoted by $i+$ and $i-$. It is often convenient to use the notations $t$ and $\bar{t}$ to denote pairs of transitions, such that if $t = i+$ then $\bar{t} = i-$ and vice versa.

For the purpose of this presentation, a STG is a directed graph represented as a triple $\langle T, \mathcal{R}, T_{E0} \rangle$ where $T$ is the set of signal transitions (defined over a signal set $M$), $T_{E0}$ the set of transitions which are enabled in the initial state of the circuit, and $\mathcal{R} \subseteq T \times T$ an *irreflexive, intransitive* relation over the set of transitions, called the *causal* relation. Graphically, $t_1 \mathcal{R} t_2$ is shown as an arc between two transitions: $t_1 \rightarrow t_2$. Let $\mathcal{R}^+ \subseteq T \times T$ denote the transitive closure of $\mathcal{R}$, $t_1 \mathcal{R}^+ t_2$ means that there exists a directed path from $t_1$ to $t_2$; this is shown graphically as $t_1 \rightarrow_p t_2$. The semantics of STG can be expressed in terms of *transition sequences* and their compositions; this has been carried out in [6] using trace theory [14]. Informally, $t_1 \mathcal{R} t_2$ means that the occurrence of transition $t_1$ causes that of transition $t_2$; this implies that if the circuit is in some state $s$ in which transition $t_1$ is enabled and eventually occurs, then the occurrence of $t_1$ brings the circuit to another state $s'$ say, in which $t_2$ is enabled and hence will eventually occur. This last statement hints that given an initial state of the circuit (in which transitions in $T_{E0}$ are enabled) and a STG expressing the causal relation between its signal transitions, one can generate a state transition graph from the STG. A circuit realization can then be obtained from the state graph. Furthermore, a constraint $t_1 \mathcal{R} t_2$ can be implemented as a logic element with $t_1$ as one of the inputs and $t_2$ as output. This important observation allows the decomposition of a STG specification into smaller subgraphs, each of which contains only transitions which are causally related. Thus, STG allows a very efficient and direct implementation based on this decomposition principle. This is a unique feature of STG compared to other approaches.

A multi-arc connects several tail transitions to one head transition, or one tail transition to several head transitions. We call these arc configurations *And Forks* and *Joins* (there are also *Or* constructs for specifying choices or conflicts in the complete STG model), and their diagrammatic notations are shown in Figure 2a. An And-fork is used to describe a situation in which the occurrence of a tail transition causes the occurrences of all of the head transitions. An And-join describes a situation in which all tail transitions in the relation have to occur to cause the occurrence of the head transition. These And constructs are used to describe concurrent operations in circuits.

**Liveness and Persistency.** A STG has a deadlock-free and hazard-free circuit realization only if it satisfies the properties of liveness and persistency. Since STGs are merely behavior specifications from which state graphs can be derived for implementation, these properties must ultimately be based on the latter type of graphs. However, there is a one-to-one correspondence between them, so that liveness and persistency will appear as *syntactic* constraints on STGs. We discuss briefly these properties and their STG syntactic ramifications.

The continual operation without deadlocking of control modules is a property called *liveness*. A STG is live iff its underlying state transition graph is strongly connected. The *necessary* condition for a STG to be live consists of (i) the STG is a strongly connected graph, and (ii) there is a *simple* cycle containing both $t$ and $\bar{t}$ for every $t \in T$. Since live STG are strongly connected, concurrency and ordering have to be characterized differently: two transitions can occur concurrently iff there is no simple cycle containing both of them in the STG; equivalently, the occurrence of two transitions are ordered iff there exists a simple cycle containing both of them.

Due to the similarity to a special class of Petri nets called *marked graphs* [7], it may appear that the form of STGs discussed here is always persistent. However this is not the case, as the underlying state graph may exhibit nonpersistency whenever two transitions are enabled in the same state and the occurrence of one removes the enabling condition of the other. A *persistency constraint* is an ordering constraint between two transitions used to eliminate nonpersistency, as illustrated in Fig. 2b. For a *live* STG, the condition $t\mathcal{R}^+\bar{t}$ always holds for every transition $t$. If $t\mathcal{R}u$ exists as shown and $u\mathcal{R}^+\bar{t}$ (depicted as an heavy arc in Fig. 2b) were not present, then transitions $\bar{t}$ and $u$ can occur concurrently. Suppose the course of action $t\mathcal{R}u$ is implemented by a hardware element with $t$ as one of its inputs and $u$ as its output. Concurrency between $\bar{t}$ and $u$ implies that while the hardware element is reacting to $t$ to cause $u$, $\bar{t}$ may be occurring simultaneously at the input of that hardware element. This is commonly known as a race condition in hardware circuits and can lead to malfunction. The approach to deal with this problem is to impose a persistency constraint on STG specifications, namely $u\mathcal{R}^+\bar{t}$, to eliminate this nonpersistent behavior. Hence, a STG specification is persistent if every transition $u$ caused by a transition $t$ precede $\bar{t}$, i.e. $\forall u \in T$, if $t\mathcal{R}u$ then $u\mathcal{R}^+\bar{t}$.

**Specification of Pipelined Circuits.** We can now develop a STG specification for pipelined control operations such that liveness and persistency are satisfied. Consider two cycles of transitions as shown in Fig. 2c. The left cycle (with $a$ and $\bar{a}$) represents the control sequence of the input portion of a pipelined circuit; the right one (with $b$ and $\bar{b}$) represents the control sequence of its output portion. The necessary condition for liveness is satisfied by each cycle if every transition in a cycle is paired with another in the same cycle. We want the two cycles to operate in parallel as much as possible, with the left one initiates control actions on the right one through arc $a\mathcal{R}b$. In order for the STG to be persistent, three additional arcs (in heavy line) are required. Because of the existence of arc $a\mathcal{R}b$, arc $b\mathcal{R}\bar{a}$ is required as a persistency constraint to prevent concurrent firing of $b$ and $\bar{a}$. The introduction of $b\mathcal{R}\bar{a}$ requires adding $\bar{a}\mathcal{R}\bar{b}$ to prevent concurrent firing of $\bar{a}$ and $\bar{b}$, and this in turns requires arc $\bar{b}\mathcal{R}a$. These four arcs allows the synchronization of two cycles of transitions in pipelined fashion such that the resulting STG is persistent. These constraints can be viewed from a different perspective by "unfolding" the cycles (Fig. 2d) into partial orders, in much the same fashion as occurrence nets [1]. In this type of nets, a node such as $a$ represents an *instance* of a transition $a$ in a cycle of operation. It can be seen that the persistency constraints appear as $a\mathcal{R}b\mathcal{R}\bar{a}\mathcal{R}\bar{b}\ldots$ and thus forces these transitions to occur in sequence. Otherwise, transitions belonging to other branches of the cycles can occur concurrently.

## 4. STG specification of control modules

In this section we apply the STG model to specify the I-module used in the FIFO organizations in Section 2. We will illustrate how to specify a STG such that it meets the liveness and persistency conditions set forth in Section 3. Once a STG satisfying these conditions is obtained, it can be translated directly into a circuit module using the synthesis steps discussed in [6]. We will give the hardware implementation obtained through this synthesis procedure for each STG specification, and discuss the procedure itself informally. The reader is referred to a complete version of the paper [4] for the discussion of O- and R-modules.

For all the control modules we will specify, event occurrences are signalled over control links, using the *reset signaling* handshake protocol [12]. Usually, an occurrence of an event is signalled by a positive transition on the ready wire of the control link; its acknowledgment is signalled by a positive transition on the acknowledge wire of the control link. The signals on these links are then reset through negative transitions before the occurrence of the next event can be signalled.

While liveness and persistency are considered to be fundamental properties of STG, there are other properties more related to the implementation of control circuits according to a certain design methodology. Two such constraints pertinent to the ensuing discussions called **R1** and **R2** are described.

**R1:** This constraint concerns the behavior in the initial state of a control circuit operating with the reset signaling protocol. Starting from the idle initial state, every control module used in the FIFO organizations alternates between an active phase consisting entirely of positive signal transitions, and a reset phase consisting entirely of negative signal transitions. In a circuit implementation, the signal state at each terminal is identified with a signal transition at that terminal: if the state of a signal $u$ is 1 (0), it implies that $u+$ ($u-$) has occurred. If the initial state of a circuit is all 0's then negative transition of the form $u-$ must have occurred in each of these signals in the immediate past. Thus, any positive transition in a STG, say $u+$ which is preceded only by negative transitions of the form $t-$ will always be activated in this initial state. When this is not desired, an artificial constraint from some other positive transition $r+$ to $u+$ must be added. Hence, it is required that *for every STG, the subgraph induced by the set of positive transitions is connected.*

**R2:** The second constraint results from the communication discipline imposed on a control circuit. Control circuits operating with the reset signaling protocol uses pairs of *ready/acknowledge* wires to communicate with the external world. A transition on the *acknowledge* wire can only occur in response to a transition on the *ready* wire and vice versa. For a pair of wires $\{I_r, I_a\}$ where $I_r$ is an input *ready* and $I_a$ an output *acknowledge*, this communication interface to the external world is specified in a STG by the pair of constraints $\{I_a- \mathcal{R} I_r+, I_a+ \mathcal{R} I_r-\}$. Similarly for a pair of wires $\{O_r, O_a\}$ where $O_r$ is an output *ready* and $O_a$ an input *acknowledge*, its corresponding set of constraints is $\{O_r+ \mathcal{R} O_a+, O_r- \mathcal{R} O_a-\}$. Thus, in a STG, *every transition of an input signal has exactly one transition which directly precedes it, and this transition must be that of an output signal.* Transitions of an input signals are underlined to distinguish it from transitions of "non-input" ones.

**STG Specification of the I-module**. An I-module controls the loading of input data into a linear queue (Fig. 1b). When its turn comes, a token is passed to the I-module from its immediate predecessor in the token ring, through a control link $P = \{P_r, P_a\}$. Upon receiving the token, the I-module responds to the next input request on its $W = \{W_r, W_a\}$ control link by sending a load request to the linear queue it controls through its $I = \{I_r, I_a\}$ control link. After loading a new data item into the linear queue, the I-module forwards the token it holds to the next I-module in the token ring through its $N = \{N_r, N_a\}$ link.

The STG description of I-module in Fig. 3 contains two main cycles, the left one coordinates the reception of the ring token with the reception of the next data item presented to the FIFO queue. The right one manages the forwarding of ring token to a successor I-module. The *-arc ($W_r- \mathcal{R} N_r+$) implements the timing constraint discussed earlier, such that $N_r$ does not go high (to pass a token to the next module) until after the input *Write-request* $W_r$ has gone low. These two cycles and the *-arc together provide the specification for proper event sequencing in the I-module. Other arcs are to be added to satisfied persistency and other constraints discussed above. First, arc $D_1$ ensures that all positive transitions form a connected subgraph according to constraint **R1**. Since $D_1$ is a constraint from transition $I_a+$ to $N_r+$, the pairs of transitions $\{I_a+, I_a-\}$ and $\{N_r+, N_r-\}$ could be used for implementing the persistency constraints. This set of arcs would include: $I_a+ \mathcal{R} N_r+$, $N_r+ \mathcal{R} I_a-$, $I_a- \mathcal{R} N_r-$, and $N_r- \mathcal{R} I_a+$. However, since $I_a+$ and $I_a-$ are transitions of an input signal, each can have no more than one incident arc according to constraint **R2**. To enforce these constraints, we change $N_r+ \mathcal{R} I_a-$ to $N_r+ \mathcal{R} I_r-$, and $N_r- \mathcal{R} I_a+$ to $N_r- \mathcal{R} I_r+$. These final constraints are shown as $D_1 - D_4$ in Fig. 3.

Liveness and persistency are satisfied by this STG. The synthesis procedure produces a state graph, from which the realization in Fig. 3 is obtained. The logic equation for $I_r$ is $I_r = W_r P_r \overline{N}_r + I_r(W_r + P_r + \overline{N}_r)$ and its implementation is a C-element with inputs $W_r, P_r$ and $\overline{N}_r$. The logic equation for $N_r$ is $N_r = \overline{N}_a \overline{W}_r I_a + N_r(\overline{N}_a + I_a)$ and its implementation is as shown in Fig. 3. The reader can readily verify that the circuit operates according to its STG specification.

## 5. Result and conclusion

A FIFO with 8 stages and 9-bit wide data path was designed, using a 4 micron nMOS technology. The chip size (including pads) is $3.15 \times 2.25 mm^2$. Six chips were received from MOSIS, they were tested and five were fully operational at a throughput rate of approximately 4 MBytes/sec. An nMOS circuit diagram for the chip is shown in Fig. 4, the lower portion is the control circuitry, with R-modules on top, I-ring in the middle and O-ring at the bottom. The control circuits take a relatively large amount of area in this chip. However, in a 2-dimensional organization with $L \geq 2$, the overhead due to I-modules and O-modules can be reduced significantly.

In this paper, Signal Transition Graphs have been used as a specification tool for asynchronous control modules. A STG specification can be viewed as an interpreted Petri net in which each transition is identified with a signal transition in a hardware circuit. In the synthesis approach proposed, a state transition graph is generated from a STG and then used to derive logic equations and hardware structures for the signals. A STG specification can thus also be viewed as a concise yet more abstract notation for specifying a class of state transition graphs.

In our specification and design examples, it has been shown how introducing additional constraints in a STG allows us to use level-sensitive hardware circuits instead of transition-sensitive hardware circuits in its implementation. These constraints are justified only informally. A more formal theory based on trace theory and state transition graphs are developed in [6].

The module descriptions used in this paper require only constructs for specifying sequencing and concurrency. There are other behaviors which exhibit conflict and data-dependent signal flow that would require additional STG constructs for their specification. These latter constructs are called OR-constructs, and the reader is referred to [5] for an introduction to their formulation and applications.

In [9] Martin described a design approach using constructs for non-deterministic programming to specify hardware modules whose behaviors exhibit only sequencing and arbitration requirements. This approach uses a subset of Dijkstra's guarded command language to specify each process; concurrent cooperating processes are described using notations similar to Hoare's CSP [10]. Heuristic procedures are used to "compile" a hardware implementation from a module specification into an interconnection of standard hardware templates such as And, Or, C-elements, etc.. During the compilation, the technique of reordering events in a sequence is made use to improve implementation efficiency. The complete STG model allows the specification of concurrency, sequencing and conflict in module behavior, and our implementation approach is aimed at automating the derivation of hardware structures from STG specifications. Recently there are works on the classification and synthesis of delay-insensitive circuits based on trace theory [13,14]. The relation of STG to trace theory is analogous to that of Petri nets model to its underlying sequence semantics. Thus, we believe that STG can serve as a high-level, more abstract specification than that of an approach directly based on trace theory.

There are also related works on verification of asynchronous hardware structures based on temporal logic [8]. Such techniques can be used fruitfully for correctness validation of self-timed circuits. The design of suitable translation techniques from high-level language to STG -in the same vein as those done by Martin and Rem [11]- is another area for further exploration.
